In general, the carriers have a temperature different from the lattice temperature after thermalization has been completed. In Fig. 8 it is assumed that the carriers have a higher temperature than the lattice. For this case, Fig. 8 schematically shows the cooling of carriers by the emission of phonons (i.e., energy transfer to the lattice). Cooling defines the time regime III. Typical time constants are in the picosecond and tens of picosecond range.

Finally, the optically excited semiconductor returns to thermodynamic equilibrium by the recombination of electron-hole pairs. Recombination is shown as time regime IV in Fig. 8. In a perfect semiconductor crystal, recombination proceeds via the emission of photons or Auger processes at high carrier densities. These recombination processes take place on time scales of tens of picoseconds and longer. These slow recombination processes as well as the relatively slow carrier cooling will not be discussed in more detail in this chapter. An excellent review can be found in Ref. 73.

Another ultrafast process is encountered if large densities of deep-level traps are incorporated in a semiconductor. Trapping of carriers into deep levels can proceed on subpicosecond time scales (not shown in Fig. 8). Since carrier trapping is important in many saturable absorber applications, it is discussed at the end of this section.

We note that the different time regimes temporally overlap. For example, a scattering process may destroy the coherence and contribute to thermalization. Nevertheless, it is very useful to distinguish between the different time regimes because they are a convenient means for the description of the complex semiconductor dynamics. The schematic picture of the different time regimes also demonstrates that two or more time constants are usually required to describe the temporal response of a semiconductor absorber. For example, we recall that thermalization typically takes place on the 100-fs time scale, while carrier trapping proceeds on times scales from a few hundreds of femtoseconds to picoseconds.

Experimental Techniques

In the following, we describe two very common experimental techniques for the study of ultrafast processes and nonlinearities. The discussion focuses on semiconductors. However, the experimental techniques have also been intensively used for the study of other condensed matter systems or molecules.

Transient Four-Wave Mixing Transient four-wave mixing (FWM) is an experimental technique for the study of the coherent regime. A schematic diagram of a transient FWM experiment is shown in Fig. 9. Two excitation pulses with wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ excite the sample. In most FWM experiments the two pulses have the same spectrum (degenerate FWM). We assume here that the case of degenerate FWM is realized. An optical delay line is used to introduce a time delay Δt between the pulses where positive Δt refers to pulse $\mathbf{k}_1$ arriving before pulse $\mathbf{k}_2$ at the sample.

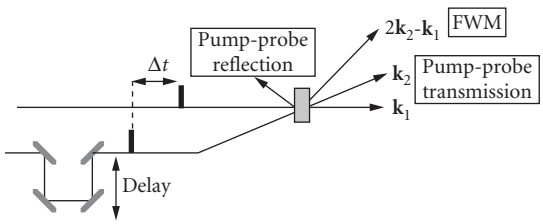

FIGURE 9 Schematic experimental setup for four-wave-mixing (FWM) and pump-probe spectroscopy.

Pulse $\mathbf{k}_1$ generates a coherent polarization in direction $\mathbf{k}_1$ in the sample. If the time delay Δt is smaller than the dephasing time of the coherent polarization, in a second step, this polarization interacts with the electric field of pulse $\mathbf{k}_2$ to set up an interference grating. In a third step, pulse $\mathbf{k}_2$ is self-diffracted from this grating and an electric field is emitted in the phase-matching direction $2\mathbf{k}_2$-$\mathbf{k}_1$. The diffracted field constitutes the FWM signal. A more detailed analysis shows that the FWM signal is due to a nonlinear polarization in direction $2\mathbf{k}_2$-$\mathbf{k}_1$.[73,78]

The FWM emission can be analyzed in different ways. First, the time integral over the FWM intensity can be measured versus the time delay. Such measurements usually provide information about the dephasing time since the strength of the FWM emission is determined by the coherent polarization in direction $\mathbf{k}_1$ that is left when pulse $\mathbf{k}_2$ is applied.[73,78] Spectral information is obtained if the FWM emission is analyzed with a spectrometer at fixed time delays. If more than one resonance is excited, the FWM spectrum shows the magnitude of the optical nonlinearity of the different resonances. Moreover, for homogeneously broadened transitions, the dephasing time can be obtained from the spectral width of the FWM emission. For a fixed time delay, the decay of the FWM signal can be measured in real time by optical gating with a reference pulse. Usually, sum frequency generation in a nonlinear crystal is used for this purpose. This is essentially a cross correlation measurement between the FWM signal pulse and the reference pulse, in which the time resolution is determined by the duration of the reference pulse. In such a correlation measurement, a slow photodetector can be used to detect the sum frequency signal. Real-time detection of FWM signals shows whether the excited optical transitions are homogeneously or inhomogeneously broadened. For homogeneous broadening, the FWM signal in direction $2\mathbf{k}_2$-$\mathbf{k}_1$ immediately sets in when pulse $\mathbf{k}_2$ is applied (for positive time delays). For inhomogeneous broadening, the FWM signal is emitted time-delayed with respect to pulse $\mathbf{k}_2$ as a so-called photon echo.[75] More details as well as a mathematical analysis of degenerate two-pulse FWM can be found in Refs. 73 and 78. Transient FWM with three pulses is treated in Ref. 79.

For excitation of interband transitions in semiconductors, occupation of valence and conduction band states contributes to the optical nonlinearity exploited in the FWM process. Occupation effects are a source of nonlinearity in many electronic systems, as shown by the analysis of simple two-level systems.[73,78] Other sources of nonlinearity will be briefly mentioned when we present some results of coherent semiconductor spectroscopy.

Pump-Probe Spectroscopy Pump-probe spectroscopy is the most widely used technique for the study of ultrafast optical nonlinearities. As shown in Fig. 9, the sample is excited by the pump pulse $\mathbf{k}_1$. The nonlinear changes of the transmission or reflectivity of the sample are detected by the time-delayed probe pulse $\mathbf{k}_2$. The time delay is defined as positive if the pump pulse precedes the probe. Often, the pump pulse train is amplitude-modulated and a lock-in amplifier is used for detection of the nonlinear transmission or reflectivity changes at the modulation frequency. It is important to note that the pump-probe experiment is a correlation experiment, in which a slow photodetector can be used.

With this technique, nonlinear reflectivity changes are measured in saturable absorbers which are integrated within a mirror structure, as mentioned in Sec. 18.4. In studies of microscopic processes, very often the nonlinear changes of the probe transmission are measured, which is referred to as *differential transmission* (DT) spectroscopy. In the simplest arrangement, the DT signal is spectrally integrated over the spectrum of the probe pulse. If the probe pulse has a large bandwidth, the DT signal at various photon energies can be obtained from measurements of the spectrum of the transmitted probe pulse in the presence and absence of the pump. The difference between those spectra represents the DT spectrum. Spectral information can also be obtained if a tunable narrowband probe pulse is scanned over a spectral window.

The differential transmission signal contains information on the coherent and the incoherent regime. In the coherent regime, the DT signal is determined by the nonlinear polarization in the direction of the probe pulse. The DT signal in the coherent regime is analyzed in more detail in Refs. 80, 81, 82, and 83.

Coherent effects can be neglected on time scales much longer than the dephasing time of the polarization. The DT signal is then determined by the population (i.e., the electron and hole distributions) generated by the pump pulse. In the incoherent regime, one can roughly distinguish between

two different sorts of effects that determine the DT signal of semiconductors: (1) occupation effects and (2) many-body Coulomb effects. Occupation effects are based on the fermionic nature of optical excitations and can be understood in the following way. A nonequilibrium carrier population in excited states reduces the optical transition rate into these states due to the reduced density of empty final states. This manifests itself by the reduction of the absorption at certain photon energies. Occupation effects are important in many electronic systems. Many-body effects are particularly important in semiconductors. They include the renormalization of the bandgap and screening of the Coulomb interaction. Details can be found in Refs. 84 through 87. Of course, the many-body effects are related to the occupation effects since they depend on the distribution of carriers.

If many-body effects can be neglected and if the optical matrix elements do not depend on the pump excitation, the nonlinear change $\Delta\alpha$ of the absorption constant α is directly proportional to the magnitude of the population (i.e., the electron and hole densities). In general, both refractive index changes and absorption changes $\Delta\alpha$ contribute to the differential transmission signal.[88] A considerable simplification is obtained if refractive index changes can be neglected and if the relation $\Delta\alpha d << 1$ holds (d sample thickness). Then the DT signal is proportional to $\Delta\alpha$, and the decay of the DT signal can be identified with the decay of the electron and hole densities. We note that in studies of carrier trapping, pump-probe data are very often analyzed under the just-described assumptions.

Results

In this subsection, examples are given that show how ultrafast spectroscopy has contributed to the understanding of ultrafast processes and nonlinearities in semiconductors. We will highlight those aspects that are particularly relevant for broadband saturable absorbers. The material is organized according to the different time regimes which have been identified at the beginning of Sec. 18.6.

Coherent Regime: Excitonic Excitations Studies of excitons in the coherent regime are an illustrative example for the issues addressed in coherent ultrafast spectroscopy of semiconductors. Therefore, we briefly discuss some aspects of coherent exciton dynamics even though excitonic excitations are less important for many ultrafast saturable absorber applications. This discussion will illustrate the main issues addressed in ultrafast semiconductor spectroscopy in the coherent regime: (1) dephasing times and underlying scattering mechanisms, (2) coupling and interference between optical excitations, and (3) the nature of the optical nonlinearity.

Four-wave mixing has been intensively used to study the dephasing of excitons and the underlying scattering mechanisms. Varying the excitation intensity, the effects of exciton-exciton and exciton-electron scattering on the dephasing of excitons have been investigated in bulk semiconductors[89] and quantum wells.[90] Varying the temperature, dephasing of excitons due to interaction with lattice vibrations (phonons) has been studied in Ref. 91. Summarizing these results, exciton dephasing times can be in the picosecond range at moderate exciton and free-carrier densities and Helium temperatures. Increasing the temperature decreases the dephasing time due to enhanced phonon scattering. Likewise, enhanced carrier or exciton densities cause faster dephasing. A detailed analysis of exciton dephasing in three- and two-dimensional semiconductors is presented in Ref. 92. We note that exciton dephasing can also give insight into the structural properties of a semiconductor, such as interface roughness in quantum wells and alloy disorder in mixed crystals.[93,94]

More recent four-wave mixing investigations of coherent exciton dynamics focus on quantum-mechanical coupling and interference between different exciton transitions. Beating phenomena between two exciton transitions have been observed in various systems[95–98] as well as beats involving the whole excitonic Rydberg series.[99] The study of beating phenomena allows for the extraction of level splittings and yields information on the quantum-mechanical coupling in multilevel systems (i.e., their internal structure[100,101]).

The nature of the optical nonlinearity in the coherent regime is another subject that has been intensively studied in four-wave-mixing experiments on excitons.[87,102–110] It has been shown that many-body Coulomb interaction substantially contributes to the coherent optical nonlinearity. With respect to the essence of this result we note that the polarization of a certain interband excitation

gives rise to an electric field which has to be added to the external laser field in order to determine the coherent dynamics of other excitations. A rigorous theoretical treatment can be found in Refs. 85 and 87.

Coherent Regime: Continuum Excitations Four-wave-mixing studies of continuum dephasing have been performed with broadband sub-10-fs pulses in three-dimensional bulk semiconductors[111] and quasi two-dimensional quantum wells.[112] These studies have shown that the decay of the coherent polarization of the semiconductor continuum is extremely fast. Decay times are only about 10 fs at high carrier densities, which are likely to be obtained in a saturable absorber in a laser cavity. The ultrafast dephasing is mainly due to carrier-carrier scattering with a density dependence that reflects the dimensionality of the semiconductor.[112] More recent work[113] shows that at reduced carrier densities interaction with the lattice also needs to be considered in continuum dephasing experiments. The interaction with the lattice has been identified as electron-LO-phonon scattering,[113] which has a time constant of about 200 fs.[114–116]

The internal structure of the continuum has been experimentally investigated in Ref. 117. The observation of a photon echo has demonstrated that the semiconductor continuum can be treated as an ensemble of uncoupled excitations at higher carrier densities.[117] Interaction between continuum and exciton transitions in coherent nonlinear optics has been studied both for degenerate[118–120] and nondegenerate excitons and continua.[121–124] This work has demonstrated the importance of many-body coupling effects between different interband transitions at lower carrier densities.

We note that it is not yet clear how coherence in a semiconductor saturable absorber affects the formation of broadband ultrashort pulses in a laser cavity. Some theoretical predictions can be found in Refs. 125 and 126. Experimental results about this issue are missing so far. Given the ultrafast dephasing times in semiconductors under the conditions in a laser cavity, coherence effects are most likely to be important for the generation of sub-10-fs pulses.

Thermalization Regime Here we will focus on the excitation of semiconductor continuum states. Studies of the thermalization of free electron and hole distributions are an instructive example for the usefulness of the differential transmission (DT) technique. In particular, measurements of differential transmission spectra have yielded considerable insight into the complex processes that determine the dynamics in the thermalization regime. For excitation well above the bandgap, nonthermal carrier distributions can be observed in bulk semiconductors, such as GaAs[127] and quantum wells.[128] These nonthermal distributions manifest themselves as positive signal in the DT spectrum with a shape that is approximately given by the spectrum of the pump pulse. Often, this signature in the DT spectrum is referred to as a *spectral hole*. The decay of the spectral hole and the thermalization of the carrier distributions lead to a substantial change of the shape of the DT spectrum. Thermalization occurs on the 100-fs time scale in undoped semiconductors and is determined by carrier-carrier scattering in many experiments. The exact thermalization time strongly depends on the carrier density, the excess photon energy with respect to the band edge, and the type of carrier.[73,127–129] Thermalization of optically excited carriers in the presence of cold electron or hole plasmas has also been investigated by the differential transmission technique.[73,130] These experiments have been performed in modulation-doped quantum wells[72] and show that thermalization can occur in less than 10 fs.

Besides carrier-carrier scattering, intervalley scattering is another process which can affect carrier dynamics in the thermalization regime. Semiconductors such as GaAs possess several conduction band minima at different points of the Brillouin zone. If electrons are created near the center of the Brillouin zone with large enough excess energy, they can scatter to the side valleys. This process has been investigated in DT experiments, and intervalley scattering times in the sub-100-fs range have been deduced.[131,132]

Spectrally resolved DT measurements have also revealed interesting many-body effects. A closer inspection of DT spectra has shown that the spectral hole is redshifted with respect to the pump spectrum.[133] Moreover, at the high-energy edge of the pump spectrum a negative DT signal is observed. These signatures have been interpreted in terms of Fermi edge singularities at the upper and lower edge of the nonthermal electron distribution generated by the pump pulse.[133,134] The

work on Fermi edge singularities is an instructive example for the interplay between occupation and many-body effects in differential transmission experiments in semiconductors.

Thermalization of carrier distributions and many-body effects also change the spectrally integrated DT signal or the impulse response of a semiconductor saturable absorber. In particular, thermalization contributes to the fast decay seen in the impulse response at early times (cp. Fig. 3). It is important to note that this fast decay is the result of the complex redistribution of nonlinear transmission or reflectivity changes in frequency space. As a consequence, no general concept has evolved so far for the engineering of this fast decay.

The fast decay of a spectrally integrated DT curve in the thermalization regime also depends on the temporal structure of the pump and probe pulses themselves.[135,136] This point has been recently demonstrated in experiments in which a so-called frequency chirp was imposed on 20-fs pulses. In a frequency-chirped laser pulse the frequency varies over the temporal profile of the pulse. Such chirped pulses have been used in DT experiments on continuum transitions in bulk semiconductors. The results show that the fast decay of spectrally integrated DT curves can be enhanced by an appropriate frequency chirp.[135,136] The manipulation of ultrafast nonlinearities by the chirp of the pulses can be viewed as an example of a much more general concept known as *coherent control*.[137] In coherent control experiments, the temporal shape or spectral content of ultrafast laser pulses are adjusted[138] to reach preset goals. The chirp control experiments in Refs. 135 and 136 demonstrate that the detailed temporal and spectral structure of the laser pulses should be included in the optimization of semiconductor saturable absorbers. That probably also means that the position of the SESAM within the laser cavity may play a role in sub-10-fs pulse generation.

Carrier Trapping Processes that remove electrons and holes from the bands of a semiconductor lead to a decay of the nonlinear transmission or to reflectivity changes resulting from the interband transitions. As discussed in Sec. 18.4, semiconductor saturable absorber applications in ultrashort pulse generation often require picosecond or subpicosecond absorber recovery times. The simplest way to obtain such short absorber recovery times would be to remove the optically excited carriers from the bands a few hundreds of femtoseconds after they have been created. Ultrafast depletion of the semiconductor band states is also important in all-optical switching devices[139,140] and optoelectronics.[141] However, intrinsic recombination processes are usually too slow to deplete the band states of a semiconductor on picosecond or subpicosecond time scales. Therefore, one generates defect states in the bandgap which give rise to fast carrier trapping, thereby depleting the bands. The trapping time is determined by the density and the type of the traps. Higher trap densities give rise to faster trapping.

Standard methods for the controlled incorporation of defect and trap states are ion implantation[142] and low-temperature (LT) molecular beam epitaxy.[143] In ion-implanted semiconductors, the trap density and the type of defect are determined by the implantation dose. The growth temperature controls the defect density in LT semiconductors, where larger defect densities are incorporated at lower temperatures.[144] GaAs is the best understood LT-grown III-V semiconductor. Low-temperature growth of GaAs is performed at temperatures of 200 to 300°C, as compared to about 600°C in standard molecular beam epitaxy. During LT growth of GaAs, excess arsenic is incorporated in the form of arsenic antisites (As on Ga lattice site: As_{Ga}) at densities as large as 10^{20} cm^{-3}.[144,145] In undoped LT GaAs, more than 90 percent of the antisites are neutral, while the rest is singly ionized due to presence of Ga vacancies (V_{Ga}) which are the native acceptors in the material (see Fig. 10*a*).[144,146] The ionized arsenic antisites have been identified as electron traps.[147] Annealing at higher temperatures (typically 600°C and higher) converts the arsenic antisite point defects into arsenic clusters, so-called As precipitates (see Fig. 10*b*).[148] A detailed review of the properties of LT GaAs can be found in Refs. 149 and 150.

The carrier trapping times in as-grown LT GaAs can be in the subpicosecond regime and show the expected decrease with decreasing growth temperature.[151,152] Subpicosecond recovery times of nonlinear transmission or reflectivity changes are also found in annealed LT GaAs, indicating that arsenic precipitates efficiently deplete the band states.[153,154] For more details about carrier trapping in LT semiconductors the reader is referred to Refs. 155 through 162.

Picosecond and subpicosecond carrier trapping times have also been found in semiconductors implanted with various ion species.[163–168] A decrease of the trapping time with increasing ion dose

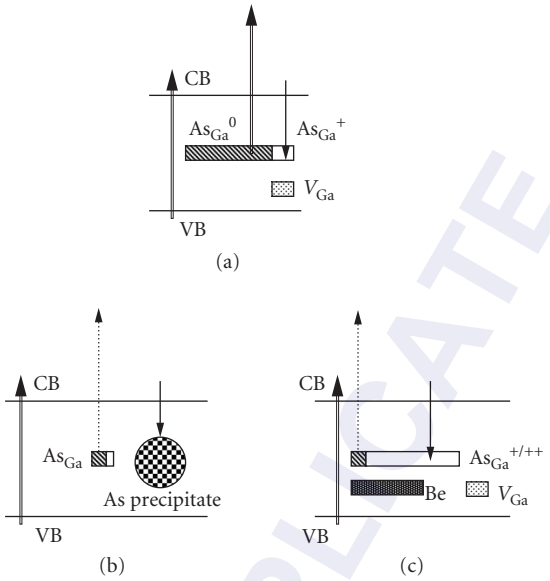

FIGURE 10 Electronic structure of undoped as-grown (*a*), undoped annealed (*b*), and Beryllium doped as-grown LT GaAs (*c*). The double arrows mark strong optical absorption transitions. Weak optical absorption transitions are indicated by dotted arrows. Trapping processes are shown by arrows that point downward.

was observed at lower doses.[163,164,167] At higher ion doses, the trapping time can increase with the dose.[168] The correlation of trapping times with structural properties of ion implanted semiconductors has given more insight into this unexpected dose dependence of the trapping time.[169] This work indicates that not only the defect density but also the type of defect depends on the ion dose.[169] Both the density and the type of defect affect carrier trapping, leading to longer trapping times if less effective traps are generated at higher ion doses.[169]

Besides an ultrafast carrier trapping and absorber recovery time, other important sat-urable absorber parameters are the modulation depth and the nonsaturable losses which remain even at the highest pump energy fluences (see Sec. 18.4). Optimized materials combine an ultrafast recovery time with high modulation and small nonsaturable losses. This material optimization issue has been addressed in recent publications.[154,168,170] In these studies, the nonlinearity of continuum transitions was investigated in different modifications of GaAs. The preparation of the semiconductor layers ensured that the modulation depth and the nonsaturable losses were determined by nonlinear absorption changes.

It has been shown that standard as-grown LT GaAs with an ultrafast carrier trapping time suffers from a small absorption modulation and high nonsaturable absorption losses.[154,170] Note that large nonsaturable absorption decreases the modulation depth and causes large nonsaturable losses when the semiconductor absorber is integrated within a mirror structure. The high nonsaturable absorption mainly results from the strong defect absorption from the neutral As antisites to the conduction band (see Fig. 10*a*) whose saturation fluence has been shown to be extremely high.[154] Therefore, the goals of material optimization are (1) to reduce the nonsaturable absorption by the reduction of the density of neutral As antisites and (2) to maintain a fast trapping and absorber recovery time.

We have demonstrated two different ways to reach those goals. Annealing of LT GaAs strongly reduces the density of neutral As antisites and the nonsaturable absorption.[154] The simultaneous reduction of the density of useful ionized As antisite electron traps does not substantially increase the

absorber recovery time due to the presence of the As precipitates (see Fig. 10*b*). Alternatively, doping with acceptors, such as Beryllium, can be used to reduce the density of neutral As antisites.[171] The simultaneous increase of the ionized As antisite density results in ultrafast carrier trapping and absorber recovery times (see Fig. 10*c*).[170] Annealed LT GaAs and Be doped LT GaAs combine ultrafast recovery times with high modulation depth and small nonsaturable losses. These materials are well suited for saturable absorber devices in laser physics and for all-optical switching applications.

Studies of the modulation depth ΔR, the nonsaturable losses ΔR_{ns}, and the recovery time τ_A in ion implanted GaAs have shown that ΔR decreases and ΔR_{ns} increases with decreasing recovery time.[168] Nevertheless, if the ion species, ion dose, and annealing conditions are properly chosen, combinations of ΔR, ΔR_{ns}, and τ_A can be obtained which are appropriate for saturable absorber applications. Ion-implanted GaAs is an alternative to annealed or Be doped LT GaAs as a material for saturable absorber devices.[168]

LASER-INDUCED DAMAGE TO OPTICAL MATERIALS

Marion J. Soileau

CREOL, The College of Optics and Photonics
University of Central Florida
Orlando, Florida

19.1 INTRODUCTION

For the general public the word "laser" brings to mind images of space ships zapping evil invaders, or perhaps earthbound military planners engineering speed-of-light weapons for destroying incoming ICBMs. However, the reality is that the things most often "zapped" or damaged by lasers are the various optical components used to make or direct laser beams.

This chapter deals with laser-induced damage (LID) in optical materials. LID refers to permanent damage produced by melting, ablation, cracking, plasma formation (spark), and so on in or on an optical material as a result of exposure to laser radiation. The LID threshold refers to the fluence or irradiance which causes such damage. In early literature on this topic LID thresholds were defined to be the average between the highest fluence or irradiance levels for which no damage was observed and the lowest levels for which damage was observed. Most recent literature defines the LID threshold as the fluence or irradiance level for which probability for damage goes to zero (a much more useful definition for use in designing laser systems). For more defect-free samples these two definitions give approximately the same values for LID thresholds.

The problem of LID is as old as the first pulsed laser. The reason for this is that the power density, or fluence, is most often largest inside the laser resonator itself. The problem can, in principle, be avoided by lowering the power density or fluence inside the laser system by appropriate expansion of the beam. However, such expansions can greatly increase the cost, weight, and volume of laser systems. In many cases, larger size components are simply not available.

The net result is that systems are constrained by cost, weight, and volume to be as compact as possible. In practical terms, this means that the LID thresholds of critical components form the limit of laser output power, or energy, for many pulsed laser systems.

Thus, the critical nature of LID has led to many efforts to understand the mechanisms of LID and to improve the damage resistance of optical components. As will be shown later, the LID processes are often highly nonlinear as well as complex. The range of operating wavelengths of lasers (infrared to the ultraviolet), pulse widths (continuous output to tens of femtoseconds), and variable repetition rates further complicate the situation.

There is vast literature on the subject of LID. A good start for data on LID of optical materials can be found in the proceedings of the annual Conference on Laser-Induced Optical Materials, also known as Boulder Damage Symposium, held in Boulder, Colorado, since 1969.[1] These proceedings

are available from the SPIE in hardcopy, online, or a set of CD-ROMs. The CDs and online versions are searchable by topics, key words, and authorship. The proceedings' of the 2008 meeting contain review articles on LID to surfaces and mirrors,[2] materials and measurements,[3] thin films,[4] and fundamental mechanisms,[5] for the previous 40 years of research on these topics. Much of the material in this chapter on fundamental mechanism is taken from Ref. 5.

19.2 PRACTICAL ESTIMATES

With few exceptions LID practical limits are determined at the surfaces and interfaces of optical materials. The reason for this is that these are the locations with the most defects and impurities. LID at such locations can occur at fluences that are orders of magnitude smaller than that in the bulk of materials, and below that expected from measurements of average absorption of light, or required for failure through operation of some fundamental mechanisms such as multiphoton absorption.

Given the large parameter space of laser operations many authors have tried to develop scaling rules for LID to aid the design of laser systems.[6] These models try to incorporate parametric dependence in various mechanisms but the parameter space can be huge. For example, in one of the earlier papers on LID[7] E.L. Bliss noted that LID depends on laser frequency, pulse duration, beam diameter, temperature, beam focusing, and the details of the materials growth and preparation. Even after more than 40 years of study, the parametric dependence of the various mechanisms of LID are not understood well enough to allow accurate scaling models that can ensure adequate design of laser systems.

However, there is a "rule of thumb," which gives a good starting point in estimating limits imposed by LID:[5]

$$E_d = (10\ \text{J/cm}^2)(t_p/1\ \text{ns})^{1/2} \tag{1}$$

where E_d = damage threshold fluence, J/cm^2
t_p = laser pulse width, ns

Equation (1) gives an *approximation* of the threshold fluence to within plus or minus an order of magnitude for optical materials (transparent dielectrics) over the wavelength range from the UV to the infrared. This is admittedly a gross over simplification. The proper use of this equation is simply to get an idea as to whether or not one should be concerned about the possibility of LID. Laser systems designs that anticipate fluences on the high side of this equation will likely be dominated by LID considerations. For fluences below this range, one can reasonably assume that LID will not be a major factor limiting system performance.

Note that Eq. (1) has little theoretical basis except for the case where damage is caused by a thin absorbing film on a surface or interface. For that case, damage fluence should be scaled as the square root of the pulse width due to one-dimensional heat dissipation into the surface.

If one must know the damage threshold to better than the approximation in Eq. (1), then one should make a careful measurement of the threshold for conditions (t_p, wavelength, etc.) similar to those expected in use.

19.3 SURFACE DAMAGE

A good optical surface can be polished and cleaned to have optical absorption of order 10^{-4} of the incident radiation,[8] which by itself should not result in optical damage. However, surfaces are subject to contamination and will have some amount of subsurface defects and imbedded impurities[9] (such as polishing particles). While minor surface contamination and point defects may not substantially contribute to the average linear absorption of light by a surface such factors can, and usually do, dominate LID of optical surfaces. Examination of surface damage sites indicates a morphology consistent with defect-initiated damage.

Surface damage thresholds can be raised by

- Using grinding and polishing techniques that produce minimum subsurface damage[10]
- Postpolishing etching or annealing[11]
- Proper surface cleaning[12]

A note of caution: Care must be used in cleaning optical surfaces as to not scratch the surface and not leave behind residue from the cleaning process. It is best not to get surfaces dirty! Holding a laser component on its edge by an ungloved hand will result in the diffusion of body oils across the surface sufficient to cause LID at low fluences. The references cited above are just a sampling. The Boulder proceedings[1] contain over 100 papers that relate to this one topic.

Standard optical polishing techniques can lead to substantial subsurface damage and contamination that in turn leads to LID. Typical procedures for preparing optical surfaces consist of a series of polishing or grinding steps with each subsequent step using finer grinding or polishing agents. A process sometimes referred to as "controlled grinding"[8] can raise LID thresholds. In such processes, each step first removes damaged layer (approximately 3 times the size of the previous grinding or polishing grit), then proceeds with the next step in surface finishing.

An effective method of surface annealing is pre-irradiation of surfaces with fluence levels below the single shot LID threshold of a surface. Two methods are used: the so-called N on 1 method, where multiple subthreshold irradiations are undertaken,[13] and the S on 1 process,[14] in which the surface is irradiated at levels substantially below the single-shot damage threshold and then ramped up to the expected operational level. Substantial increases in LID fluences have been observed by using these techniques.

Entrance versus Exit Surface Damage

Consider an optical component illuminated by laser radiation at normal incidence. An interesting damage phenomenon is that for a given power or fluence incident upon an optical component, the exit (or rear) surface will damage before the entrance (or front) surface. This is at first counterintuitive, since Fresnel reflection loss at the entrance surfaces results in less energy reaching the rear surface.

The puzzling fact that the exit surface damages first provided an important clue as to the more fundamental aspects of LID. Several exotic explanations were proposed, but the explanation from linear optics is simply that the electric field associated with the laser is larger at the exit surface than at the entrance (even though the beam is partially depleted by Fresnel reflection at the front surface).[15]

This is understood by considering that the reflected wave at the entrance surface is 180° out of phase with the incident field (Fresnel reflection for propagating from a low-index medium to a high-index medium). At the exit surface, propagation is from the high-index medium (say, glass) to the low (say, air). In that case, the reflected field is in phase with the incident field. Therefore, the exit surface damages first simply because the electric field is higher at the rear surface. The fluence and irradiance are proportional to the electric field squared thus for even linear damage mechanisms, for example, simple absorption, the LID thresholds (expressed in terms of incident energy or power) for the exit surface will be lower than that of the entrance surface.

This field dependence of LID has played an important role in the design of thin film coatings ("move" the E-field away from coating interfaces), understanding the effects of cracks, voids, and other surface defects, and in formulation of various models for fundamental mechanisms of LID.

LID in Optical Coatings

Section 19.3 emphasizes the dominance of surface damage in most damage-limited laser systems. In fact, most optical surfaces in high-performance laser systems are coated with thin films (usually multiple layers) to control or manage reflectivity. Examples include high-reflection mirrors, antireflection coatings on transmitting optics, partial reflecting beam splitters, and wavelength selectivity elements.

LID to thin films is the most likely factor limiting the performance of high-power laser systems. (See Ref. 4 and references contained therein.) Multilayer (ML) coatings are affected by the defects, contamination, and subsurface damage of the surfaces upon which they are applied. In addition, each coating interface contributes an additional surface to the system and thus additional opportunities for surface defects to effect damage. Among other thin-film problems affecting LID are: adhesion; differential expansion; defects in the films themselves; porosity, which allows diffusion of defects; and enhancement of E-fields within the thin film stack.

A few general statements and guidelines to minimize thin-film damage are

1. Proper surface preparation and surface cleaning is essential to maximize LID thresholds in thin films.
2. The problem is more severe for transmitting thin films. Among the issues is the simple fact that the film-substrate interface cannot be avoided and this is a common initiator of LID. In general, antireflection (AR) coatings exhibit lower thresholds than high-reflection (HR) coatings.
3. Stress in thin films can reduce LID thresholds so that coating materials choices and deposition conditions should be selected to minimize internal stress in the thin-film stack.
4. In general, lower index coatings will have higher damage thresholds than higher index films. However, multilayer systems must have both high- and low-index components and the smaller the index difference, the more layers are needed to achieve the same desired reflectivity or antireflectivity.
5. Amorphous coatings have less problems with impurity diffusion than do single or multicrystalline materials and so are better choices when available.
6. Inherent in thin-film design is arranging thicknesses and indices so that multiple reflections either enhance the E-field or reduce the E-field. One important design consideration is to ensure that regions of enhanced E-field are moved away from surfaces and interfaces. The simple addition of a half-wave layer can move the high-field region away from coatings interfaces.[16]
7. Modern thin-film design codes allow easy design of extremely complex multilayer systems for managing reflection and transmission of multiple laser systems and wavelengths. However, designers should be mindful that larger multilayer stacks and more complex designs are likely to significantly lower the LID thresholds of these optical elements and thus limit system performance. The general design rule is "keep it simple!"

Multishot LID

LID for sites experiencing multiple irradiations are different than those of sites irradiated once. Several multishot effects have been observed. Irradiation below the single-shot damage threshold can produce LID thresholds substantially larger than the single-shot values for surfaces, thin films, and even in the bulk of a material. This is sometimes referred to as laser conditioning or laser annealing. The N on 1[13] and S on 1[14] previously discussed are examples of this phenomena.

N on 1 or S on 1 conditioning are typically used in very large, high-power laser systems such as those used in laser fusion experiments. Such systems are typically dominated by LID limits so extra efforts in laser conditioning are essential for reliably achieving maximum output power. In some cases the LID threshold seems to be reduced by repetitive pulses. In such cases, small damage sites, which initially go undetected, grow in size until the damage reaches catastrophic portions. There has been much work done on this critical question. In some cases, damaged sites can be effectively annealed by multiple shots below the damage threshold, thus extending the useful life of a component.

19.4 PACKAGE-INDUCED DAMAGE

The cliché "cleanliness is next to godliness" is usually associated with LID. Care must be taken to avoid dust or other particulates on optical surfaces and samples should be handled with gloved hands to avoid diffusion of body oils onto surfaces. Exposure to water and other solvents can

substantially lower LID thresholds, and indeed many procedures meant to clean surfaces can leave behind residue that can substantially reduce the LID threshold.

The problem of contamination of optics has led to construction of laser systems, in which the laser cavity is backfilled with clean, inert gas (such as nitrogen). This approach is particularly attractive for laser systems that are expected to operate for extended periods without possibility of access or repair, for example, a laser rangefinder in orbit around Mars to map the planet's surface.

A nonintuitive consequence of such packaging is a substantial reduction in system's lifetime due to LID, even for systems conservatively designed with fluence levels safely below the expected LID thresholds. What is observed in repetitively pulsed laser systems is that any residual hydrocarbons inside the sealed system can be dissociated due to complex interactions with the packaging gas (which acts like a buffer), the residual hydrocarbons, and the laser pulses. The "freed" carbon in the system can then be deposited, with the assistance of the laser light, on the various optical surfaces. The carbon is deposited on the surfaces in the beam path. LID will be initiated at such sites if these carbon deposits become sufficiently dense.[17]

The problem of package-induced LID can be avoided by back filling the laser system with oxygen (or just air.) In this case any free carbon from laser-assisted decomposition of hydrocarbons forms carbon dioxide gas, which is transparent for lasers operated from the UV to the infrared. Since any free carbon is combined with oxygen, laser-assisted carbon deposition is avoided.

19.5 NONLINEAR OPTICAL EFFECTS

Since the time of James Clark Maxwell, it has been known that light is an electromagnetic wave. However, for "natural," incoherent light there are no easily observed effects of the E-field (other than that of the "carrier" of the light energy in the Poynting vector). The field strength in some cases results in substantial nonlinear optical (NLO) effects, some of which can cause LID. Examples include electrostriction (density changes due to an impressed electric field) and E-field-dependent electronic polarizability of optical materials.[18] These effects result in an increase in the index of refraction in regions of high fields. This in turn produces lensing within a material, which further increases the E-field, resulting in further increases in self-lensing until the threshold for damage is reached. This process, called self-focusing and is reviewed in the classic paper by Marburger.[18]

An important feature of self-focusing is that one can calculate a critical *power* at which it takes place. This is the beam power at which nonlinear refractive effects (self-focusing) overcome linear refractive effects (diffraction) leading to beam collapse. For a beam focused into the bulk of the sample this collapse can result in LID.[19]

Among the many effects of self-focusing is to confuse efforts to identify fundamental mechanisms of LID and the dependence of LID thresholds on various parameters, for example, pulse width, spot size, and wavelength dependence. Since self-focusing depends on the state of polarization of the light, linear or circular, a simple test for its contribution to LID in isotropic media is to measure the polarization dependence of the damage threshold.[20,21] If a polarization dependence is found the measured threshold is due to self-focusing and not the mechanism of LID.

19.6 AVOIDANCE OF DAMAGE

Given the NLO effects that influence damage, it is essential to avoid situation where field enhancement occurs. A simple example is diffraction associated with an aperture or edge. This diffraction produces regions of enhanced (coherent sum of fields) electric fields. This enhancement of fields can also cause regions of self-focusing along the beam, which in turn cause damage.

Such effects are minimized through the use of single-mode beams, avoidance of linear diffraction by apertures or other hard edges, and special filters to remove high spatial frequencies within the beam. These techniques are particularly useful in oscillator-amplifier systems. The amplifier(s)

will further enhance the interference patterns produced by diffraction, and thus increase the likelihood of self-focusing causing damage.

19.7 FUNDAMENTAL MECHANISMS

A subset of LID is laser-induced breakdown (LIB). LIB is the damage observed with pulsed lasers for highly transparent materials. Early observations of LIB include the following:

1. Abrupt truncation of the beam transmitted through the sample, that is, threshold like behavior. (See e.g., the work of Anthes and Bass[22] that showed that when damage occurs in a highly transparent material it goes from transparent to highly absorbing within less than 2 ps.)[22]
2. Bright, hot plasma accompanying damage.
3. Damage occurs at the peak of the pulse when at the threshold irradiance.
4. LIB in transparent dielectrics is the most complicated since it depends on materials, properties (most of which are not properly understood), laser parameters (wavelength and pulse width), beam spatial modes, and focusing conditions.

These observations plus the lack of any reasonable alternative for energy coupling in otherwise transparent materials with bandgaps 5 to 20 times the photon energy of the laser that produced damage led early investigators to conclude that LID was due to electron avalanche breakdown.

As early as in 1965 Yasojima showed[23] that

1. Laser damage in NaCl at 10.6 μm showed LIB, that is, avalanche like behavior.
2. LIB could be substantially reduced by "seeding" the damage with a flash of blue light, thus producing "starter" electrons for the LIB.
3. The author speculated that this avalanche was seeded by nonlinear processes.

This was a remarkable bit of work and went unnoticed in work reported in Western and Soviet literature on this subject.

Based upon his seeding experiments, Yasojima speculated that LIB was initiated by either multiphoton absorption or tunneling to produce free carrier that could be rapidly accelerated by the several megavolt E-fields associated with focused pulsed laser beams.

In the 43 years, since Yasojima's work, most work done by others has produced further evidence supporting the ideas of this unrecognized scholar!

Great progress in understanding multiphonon absorption—new materials, new methods, and design considerations—has been made over the past 40 years.[1] Among the many important fundamental results reported are multiphonon limits of linear absorption, very good models for LID to metals, the role of stress in high-power CW applications and the effects of absorption on beam quality. Many of these advances were made possible by progress in precision measurement of small levels of absorption, surface roughness, and scattering.

Linear absorption by defects, inclusions, and contamination remains practical concern, but the fundamentals of damage due to defects are reasonably well understood. LIB, the catastrophic, threshold like process in highly transparent materials has been the subject of much controversy and is where understanding still lags. The quest for understanding fundamental limits runs head on with the many varied and complex nonlinear processes involved. However, there is general agreement that for damage to occur there must be absorption of laser radiation by the material.

Beyond that there is little agreement, or perhaps more properly stated, no detailed understanding as to how a material goes from highly transparent to totally absorbing within just a few picoseconds.[22] The discussion of LIB mechanism is a discussion of the process(s) by which this sort of "change of phase" occurs.

One reason to seek understanding of fundamental mechanisms is to be able to do reasonable scaling with respect to various parameters such as pulse width, wavelength, beam properties, and

materials' properties. Another reason to seek this understanding is that if the fundamental mechanisms of failure are understood, ways to improve materials could be found.

Self-focusing complicates efforts to understand LIB. Self-focusing is not in itself a mechanism for LIB. Rather, it is a mechanism for concentrating the beam so that local intensities reach critical values at which other nonlinear processes occur.

Among the major advances in improving LID limits was understanding of how to pick and sometimes design materials to minimize the nonlinear refractive index, n_2, that governs self-focusing in a medium. Probably the most practical advance was the understanding that this problem could be managed by careful control of the mode of laser oscillators and properly accounting for self-focusing in the propagation of beams in large oscillator-amplifier systems. The key is to avoid and remove high spatial frequencies. In practical terms, this means oversizing the optics so that the beam is not clipped and using spatial filters to remove any high spatial frequencies that may occur during beam propagation. As a result, self-focusing in gain media in large laser systems such as those used in laser fusion experiments can be effectively managed. However, the problem often reappears as laser makers try to maximize energy output from gain media of limited size by multimode operation, a problem made worse by trying to compact multimode systems in limited space. This prevents the loss of high spatial frequencies and in turn results in catastrophic damage due to small-scale self-focusing.

The influence of self-focusing in damage experiments is a bit more problematic and has been a major issue in understanding the parametric dependence of LIB in transparent solids. Examples include the fact that the critical power for self-focusing scales as the square of the wavelength and as the inverse of the pulse width. Multiple mechanisms exist for self-focusing and these can scale as the spot size and pulse width together (electrostriction) and self-focusing can exhibit large dispersion. Thus self-focusing can be confused with the wavelength, pulse width, and spot size dependences of LIB.

The problem is trying to describe such a nonlinear process in enough detail such that materials may be improved, and predictions of the dependence on pulse width, wavelength, and spot size may be made with confidence. This situation was made more complex by the simple fact that no precursor to LIB has been found and experiments are hard to replicate since the sample(s) studied are consumed in the experiment and new samples often produced different results.

Early work concluded[24] that LIB was an intrinsic property of materials. This claim was based on the following factors:

- The observations of breakdown-like behavior previously mentioned
- The observed frequency dependence (really very little frequency dependence) of LIB in NaCl from 0.35 to 10.6 μm

This work assumed that the breakdown irradiance was an intrinsic property of a material, thus any sample-to-sample variations measured by others were due to poor quality samples and any spot-size dependence was purely due to self-focusing.

Other work produced different results[25–28] such as

- There are just not enough free carriers present in good insulators (highly transparent materials) to initiate damage for very small spot sizes, that is, it takes at least a few free electrons to be present to initiate the avalanche.
- Better materials with higher thresholds than the so-called "intrinsic" thresholds became available, some with a factor of 20 higher threshold than the previously reported "intrinsic" results.
- Subsequent frequency dependence measurements showed a decrease in threshold at 0.5 μm, inconsistent with a pure avalanche model.
- Evidence was produced that indicated that not all spot-size dependence was due to self-focusing. Feldman's[21] work on the polarization dependence of self-focusing was used to rule out self-focusing in some spot-size dependence measurements.

Where does this leave us? Figure 1 is an illustration of the problem. Here the spot size is constant and the pulse width and wavelength dependence is given for NaCl and SiO_2. Note that in this case

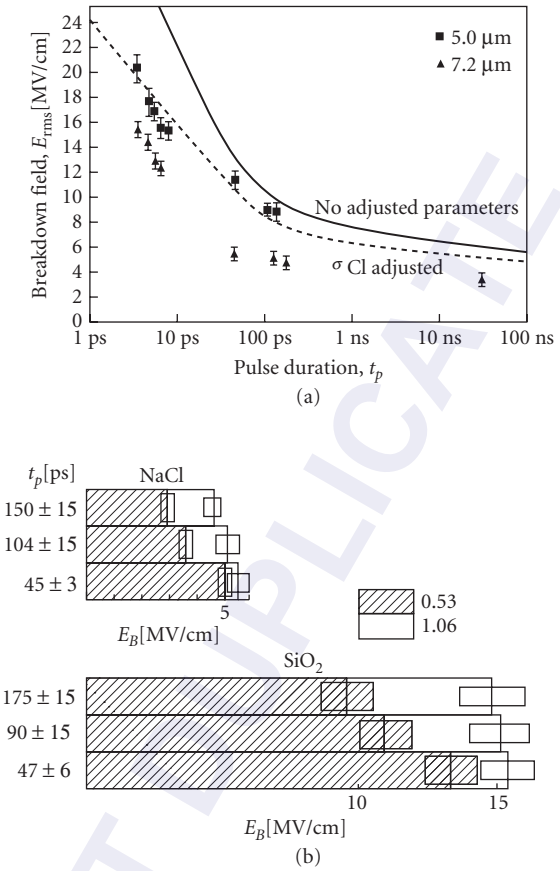

FIGURE 1 (*a*) The RMS breakdown field data for NaC1 (78-NC-6) at 1.06 μm are plotted as a function of pulse duration, t_0. The solid line and dotted line were obtained from the theory developed by Sparks *et al.*[30] for NaCl at room temperature. The dotted line uses a different value for the absorption cross section for C1 ions in the theory than the solid line. (*b*) Wavelength dependence of the breakdown field EB for NaCl and SiO_2 for a variety of laser pulse widths. All the above data was taken on the same sample of NaCl and the same sample of SiO_2. The 1.06 μm thresholds are taken from Ref. 2 and are interpolated from measurements made at spot size 6.1 and 10.3 μm. (*From Ref. 29.*)

the spot size was the same at both wavelengths, and lack of self-focusing was confirmed from measurement of lack of polarization dependence in the LIB thresholds.

The decrease in LIB field with pulse width in Fig. 1 is consistent with an avalanche process for these pulses in the picosecond regime. However, the wavelength dependence is not consistent with a purely avalanche model, and not strong enough to suggest a multiphoton model for LIB.

The pulse width dependence shown in Fig. 1 is consistent with the avalanche ionization model. Note that this model is very much dependent on the very nonlinear ionization rates, which in fact

are estimated from DC measurements! These results are *not inconsistent* with a model that assumes an avalanche initiated by multiphoton or by tunneling.

After more than 40 years of "*not inconsistent*" is the best one can do. We do not have quantitative information about avalanche ionization dependence of laser fields in solids. We have no accurate parameters for n photon absorption (nPA) (for $n > 3$) or tunneling models and we do not have definitive information that confirms that all the critical parameters have been considered.

19.8 PROGRESS IN MEASUREMENTS OF CRITICAL NLO PARAMETERS

A difficulty in the past has been lack of accurate measurements of NLO parameters. A great breakthrough was the invention of the so-called Z-scan[31,32] technique for measuring the sign and magnitude of the nonlinear of refractive index as a function of wavelength and pulse width. This technique also allows one to measure the nPA coefficients and free carrier cross section. Shown in Fig. 2[31,32] is the Z-scan technique for measuring nonlinear refraction (with sign as well as magnitude) and nonlinear absorption.

Note, in Fig. 3 the difference in signal for negative nonlinear refraction compared to positive nonlinear refraction. The sign of nonlinear refraction changes from 1 to 0.5 μm! By fully opening the aperture in front of the detector one can measure nonlinear absorption as is shown in Fig. 4.

The bottom curve shows the results of increasing the irradiance by about a factor of 5, and the fit is excellent, with no additional adjustment of parameters, indicating that the essential physics [linear and nonlinear absorption, positive and negative nonlinear refraction, and two photon absorption (2PA) and excited state absorption] is accounted for in this measurement. ZnSe is a 2PA material at 0.5 μm and a 4PA material at 1 μm. The nonlinearity shown is for picosecond pulses and is due to electronic effects. For nanosecond pulses electrostriction can also play a role for small spot sizes. An in-depth understanding of fundamental mechanisms LIB awaits such detailed, reproducible, nondestructive measurements of processes leading to damage.

What about many or n photon absorption (nPA)? Can this process be the mechanism leading to LIB? Figure 5[32] shows results for 2, 3, and 4PA materials at 1 μm for 49 ps pulses. The net result is that for 2 or 3PA the generated carriers prevent damage by defocusing the beam. Self-defocusing

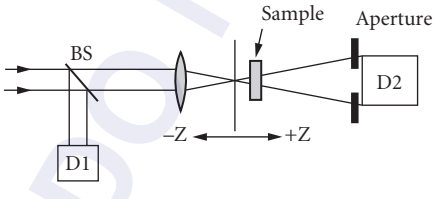

FIGURE 2 Note that the sample is scanned through the beam focus. The ratio of the readings of D1 and D2 is measured. The fit to the plot of this ratio versus Z (position relative to the focus) gives the nonlinear index of refraction. If the aperture D2 is fully open and captures all the transmitted beam then the nonlinear absorption is measured. (*From Ref. 31.*)

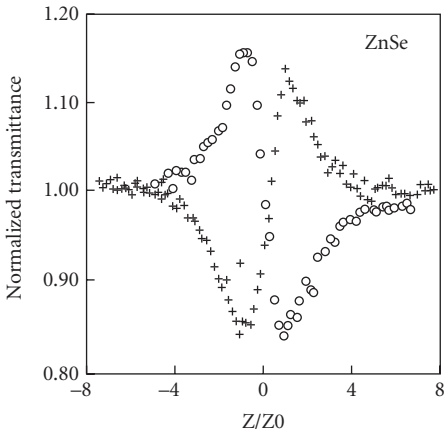

FIGURE 3 Measurement of n_2 (circles) at 1.06 and 0.53 μm (crosses) showing the sign change for ZnSe (positive n_2 and negative n_2, respectively). (*From Ref. 32.*)

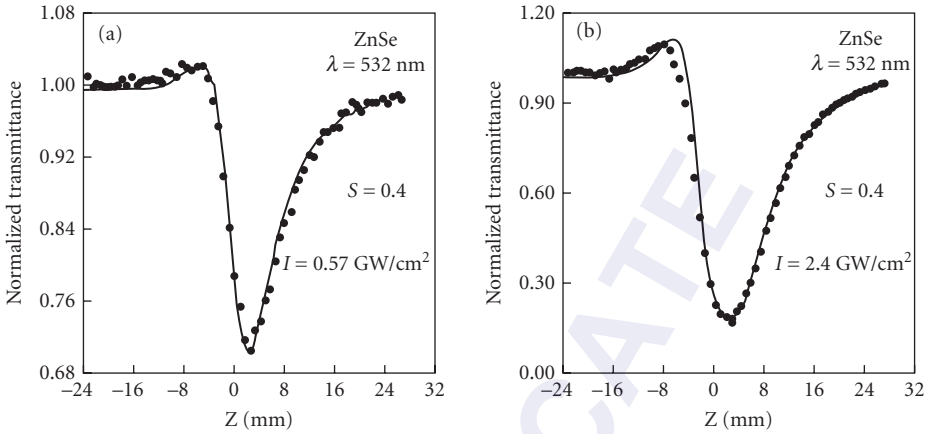

FIGURE 4 This figure shows the power of the Z-scan technique to help understand relevant nonlinear interactions, including two photon absorption, excited state absorption (free carrier absorption), and nonlinear refraction for ZnSe at 0.53 μm and 30 ps pulses. (*From Ref. 31.*)

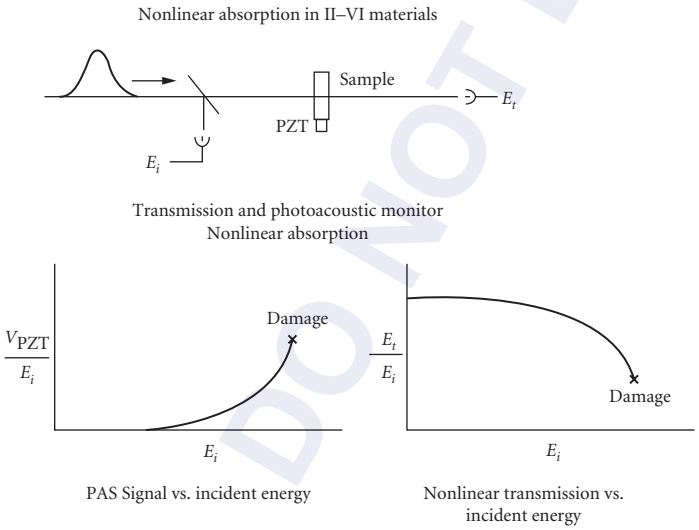
of the 2 to 3PA-generated carriers prevents bulk and rear surface damage. What happens when the process is 4PA? The carrier generation rate by 4PA is not sufficient to cause defocusing and thus allows the irradiance at the exit surface to increase to the LID threshold. Recent measurements using femtosecond pulses and interfermetric techniques for measuring carrier generation at focus, and so on offer hope of helping understand LIB in highly transparent materials.[33] One must be able to

Nonlinear spectroscopy



Material	Dominant absorption	Damage threshold (GW/CM^2)
CdTe	2 photon + free carrier	2.0 (front surface)
ZnTe	2 photon	0.46 (front surface)
Cds	3 photon + free carrier	19.0 (front surface)
CVD ZnSe	3 photon + free carrier	12.0 (front surface)
CVD ZnS	4 photon	15.1 (exit surface)
Cleartran (ZnS)	4 photon	18.1 (exit surface)

Summary of nonlinear absorption and damage threshold measurements in the II–VI materials. Data shown are for 40 ps pulses at 1.06 μm.

FIGURE 5 These data demonstrate different responses for *n*PA. The dynamics of 2 and 3PA are such that the rate of generation of free carriers is such that self-defocusing dominates propagation, preventing damage in the bulk of the material or the rear surface. For bandgaps beyond 3PA the LID of the rear surface occurs prior to field strengths that would cause significant 4PA. (*From Ref. 32.*)

measure the dynamical parameters with sufficient accuracy and time resolution to sort out different nonlinear parameters critical to the damage process. Only then will a more complete description and rigorous models for LID be possible.

20.1 INTRODUCTION

This chapter begins with some of the general ideas about laser cooling. One of the characteristics of optical control of atomic motion is that the speed of atoms can be considerably reduced. Since the spread of velocities of a sample of atoms is directly related to its temperature, the field has been dubbed *laser cooling*, and this name has persisted throughout the years.

In Sec. 20.2 we introduce the general idea of optical forces and how they can act on atoms. We show how such forces can be velocity dependent, and thus nonconservative, which makes it possible to use optical forces for cooling. The section concludes with the discussion of a few special temperatures. Section 20.3 presents a quantum mechanical description of the origin of the force resulting from the atomic response to both stimulated and spontaneous emission processes. This is quite different from the familiar quantum mechanical calculations using state vectors to describe the state of the system, since spontaneous emission causes the state of the system to evolve from a pure state into a mixed state. Since spontaneous emission is an essential ingredient for the dissipative nature of the optical forces, the density matrix is introduced to describe it. The evolution of the density matrix is given by the optical Bloch equations (OBE), and the optical force is calculated from them. It is through the OBE that the dissipative aspects of laser cooling are introduced to the otherwise conservative quantum mechanics. The velocity dependence is treated as an extension of the force on an atom at rest.

In Sec. 20.4 the first modern laser cooling experiments are described. Atoms in beams were slowed down from thermal velocity to a few m/s, and the dominant problem was the change in Doppler shift arising from such a large change in velocity. Some typical values of parameters are discussed and tabulated. Section 20.5 introduces true cooling by optical forces to the μK regime. Such experiments require at least two laser beams, and are called *optical molasses* because the resulting viscous force can slow atoms to extremely slow velocities, and hence compress the width of the velocity distribution. The limits of such laser cooling are discussed, as well as the extension from experiments in 1D to 3D. Here the velocity dependence of the force is built into the description via the Doppler shift instead of being added in as an extension of the treatment. In 1988 some experiments reported temperatures below the limit calculated for optical molasses, and Sec. 20.6 presents the new description of laser cooling that emerged from this surprise. For the first time, the force

resulting from spontaneous emission in combination with the multiple level structure of real atoms were embodied in the discussion. Here the new limits of laser cooling are presented.

The discussion up to this point has been on atomic velocities, and thus can be described in terms of a velocity space. Laser cooling thus collects atoms near the origin of velocity space. It is also possible to collect atoms into a small region of ordinary configuration space, and such trapping is discussed in Sec. 20.7. Neutral atom traps can employ magnetic fields, optical fields, and both working together. However, such traps are always very shallow, and so only atoms that have been cooled to the few mK domain can be captured. The combination of laser cooling and atom trapping has produced astounding new tools for atomic physicists, and Sec. 20.8 describes some of the applications and uses of these wonderful new capabilities.

20.2 GENERAL PROPERTIES CONCERNING LASER COOLING

These experiments almost always involve atomic absorption of nearly resonant light. The energy of the light $\hbar\omega$ raises the internal energy of the atom, and the angular momentum $\hbar$ changes the internal angular momentum ℓ of the electron, as described by the well-known selection rule $\Delta\ell=\pm1$. By contrast, the linear momentum of the light $p=E/c=h/\lambda(\vec{p}=\hbar\vec{k})$ cannot be absorbed by internal atomic degrees of freedom, and therefore must change the motion of the atoms in the laboratory frame. The force resulting from this momentum exchange between the light field and the atoms can be used in many ways to control atomic motion, and is the subject of this chapter.

Absorption of light populates the atomic excited state, and the return to the ground state can be either by spontaneous or by stimulated emission. The nature of the optical force that arises from these two different processes is quite different, and will be described separately. Such atomic transitions (i.e., the motion of the atomic electrons) must be described quantum mechanically in the well-known form of the Schrödinger equation. By contrast, the center-of-mass motion of the atoms can usually be described classically, but there are many cases where even this is not possible so it must also involve quantum mechanics.

In the simplest possible case, the absorption of well-directed light from a laser beam, the momentum exchange between the light field and the atoms results in a force

$$\vec{F}=d\vec{p}/dt=\hbar\vec{k}\gamma_p \tag{1}$$

where γ_p is the excitation rate of the atoms. The absorption leaves the atoms in their excited state, and if the light intensity is low enough so that they are much more likely to return to the ground state by spontaneous emission than by stimulated emission, the resulting fluorescent light carries off momentum $\hbar k$ in a random direction. The momentum exchange from the fluorescence averages zero, so the net total force is given by Eq. (1).

The scattering rate γ_p depends on the laser detuning from atomic resonance $\delta=\omega_\ell-\omega_a$, where ω_ℓ is the laser frequency and ω_a is the atomic resonance frequency. This detuning is measured in the atomic reference frame, and it is necessary that the Doppler-shifted laser frequency in the moving atoms' reference frame be used to calculate the absorption and scattering rate. Then γ_p is given by the Lorentzian

$$\gamma_p=\frac{s_0\gamma/2}{1+s_0+[2(\delta+\omega_D)/\gamma]^2} \tag{2}$$

where $\gamma\equiv1/\tau$ is the angular frequency corresponding to the decay rate of the excited state. Here $s_0=I/I_s$ is the ratio of the light intensity I to the saturation intensity $I_s\equiv\pi hc/3\lambda^3\tau$, which is a few mW/cm^2 for typical atomic transitions (λ is the optical wavelength). The Doppler shift seen by the moving atoms is $\omega_D=-\vec{k}\cdot\vec{v}$ (note that $\vec{k}$ opposite to $\vec{v}$ produces a positive Doppler shift). The force is thus velocity-dependent, and the experimenter's task is to exploit this dependence to the desired goal, for example, optical friction for laser cooling.

The spontaneous emission events produce unpredictable changes in atomic momenta so the discussion of atomic motion must also include a "random walk" component. This can be described as a diffusion of the atomic momenta in momentum space, similar to Brownian motion in real space. The evolution of the momentum in such circumstances is described by the Fokker-Planck equation, and it can be used for a more formal treatment of the laser cooling process. Solutions of the Fokker-Planck equation in limiting cases can ultimately be used to relate the velocity distribution of the atoms with their temperature.

The idea of "temperature" in laser cooling requires some careful discussion and disclaimers. In thermodynamics, temperature is carefully defined as a parameter of the state of a closed system in thermal equilibrium with its surroundings. This, of course, requires that there be thermal contact (i.e., heat exchange) with the environment. In laser cooling this is clearly not the case because a sample of atoms is always absorbing and scattering light. Furthermore, there is essentially no heat exchange (the light cannot be considered as heat even though it is indeed a form of energy). Thus the system may very well be in a steady-state situation, but certainly not in thermal equilibrium, so that the assignment of a thermodynamic "temperature" is completely inappropriate.

Nevertheless, it is convenient to use the label of temperature to describe an atomic sample whose average kinetic energy $\langle E_k \rangle$ in one dimension has been reduced by the laser light, and this is written simply as $k_B T/2 = \langle E_k \rangle$, where k_B is Boltzmann's constant. It must be remembered that this temperature assignment is absolutely inadequate for atomic samples that do not have a Maxwell-Boltzmann velocity distribution, whether or not they are in thermal equilibrium: there are infinitely many velocity distributions that have the same value of $\langle E_k \rangle$ but are so different from one another that characterizing them by the same "temperature" is a severe error.

With these ideas in mind, it is useful to define a few rather special values of temperatures associated with laser cooling. The highest of these temperatures corresponds to the energy associated with atoms whose speed and concomitant Doppler shift puts them just at the boundary of absorption of light. This velocity is $v_c \equiv \gamma/k \sim$ few m/s, and the corresponding temperature is $k_B T_c \equiv M\gamma^2/k^2$, and is typically several mK. (Here M is the atomic mass.)

The next characteristic temperature corresponds to the energy associated with the natural width of atomic transitions, and is called the *Doppler temperature*. It is given by $k_B T_D \equiv \hbar\gamma/2$. Because it corresponds to the limit of certain laser cooling processes, it is often called the *Doppler limit*, and is typically several hundred μK. Associated with this temperature is the one-dimensional velocity $v_D = \sqrt{k_B T_D/M} \sim 30\,\text{cm/s}$.

The last of these three characteristic temperatures corresponds to the energy associated with a single photon recoil. In the absorption or emission process of a single photon, the atoms obtain a recoil velocity $v_r \equiv \hbar k/M$. The corresponding energy change can be related to a temperature, the *recoil limit*, defined as $k_B T_r \equiv \hbar^2 k^2/M$, and is generally regarded as the lower limit for optical cooling processes (although there are a few clever schemes that cool below it). It is typically a few μK, and corresponds to speeds of $v_r \sim 1$ cm/s.

These three temperatures are related to one another through a single dimensionless parameter $\varepsilon \equiv \omega_r/\gamma$ that is ubiquitous in describing laser cooling. It is the ratio of the recoil frequency $\omega_r \equiv \hbar k^2/2M$ to the natural width γ, and as such embodies most of the important information that characterize laser cooling on a particular atomic transition. Typically $\varepsilon \sim 10^{-3} - 10^{-2}$, and clearly $T_r = 4\varepsilon T_D = 4\varepsilon^2 T_c$.

In laser cooling and related aspects of optical control of atomic motion, the forces arise because of the exchange of momentum between the atoms and the laser field. Since the energy and momentum exchange is necessarily in discrete quanta rather than continuous, the interaction is characterized by finite momentum *kicks*. This is often described in terms of *steps* in a fictitious space whose axes are momentum rather than position. These steps in momentum space are of size $\hbar k$ and thus are generally small compared to the magnitude of the atomic momenta at thermal velocities $\bar{v}$. This is easily seen by comparing $\hbar k$ with $M\bar{v}$,

$$\frac{\hbar k}{M\bar{v}} = \sqrt{\frac{T_r}{T}} << 1 \tag{3}$$

Thus the scattering of a single photon has a negligibly small effect on the motion of thermal atoms, but repeated cycles of absorption and emission can cause a large change of the atomic momenta and velocities.

20.3 THEORETICAL DESCRIPTION

Force on a Two-Level Atom

We begin the calculation of the optical force on atoms by considering the simplest schemes, namely, a single-frequency light field interacting with a two-level atom confined to one dimension. It is based on the interaction of two-level atoms with a laser field as discussed in many textbooks.[1]

The philosophy of the correspondence principle requires a smooth transition between quantum and classical mechanics. Thus the force F on an atom is defined as the expectation value of the quantum mechanical force operator $\mathcal{F}$, as defined by $F=\langle\mathcal{F}\rangle=d\langle p\rangle/dt$. The time evolution of the expectation value of a time-independent quantum mechanical operator $\mathcal{A}$ is given by

$$\frac{d}{dt}\langle\mathcal{A}\rangle=\frac{i}{\hbar}\langle[\mathcal{H},\mathcal{A}]\rangle \tag{4}$$

The commutator of $\mathcal{H}$ and P is given by $[\mathcal{H},p]=i\hbar(\partial\mathcal{H}/\partial z)$, where the operator p has been replaced by $-i\hbar(\partial/\partial z)$. The force on an atom is then given by

$$F=-\left\langle\frac{\partial\mathcal{H}}{\partial z}\right\rangle \tag{5}$$

This relation is a specific example of the Ehrenfest theorem and forms the quantum mechanical analog of the classical expression that the force is the negative gradient of the potential.

Discussion of the force on atoms caused by light fields begins with that part of the Hamiltonian that describes the electric dipole interaction between the atom and the light field. The electric field of the light is written as $\vec{\mathcal{E}}(\vec{r},t)=E_0\hat{\varepsilon}\cos(kz-\omega t)$ and the interaction Hamiltonian is $\mathcal{H}'=e\vec{\mathcal{E}}(\vec{r},t)\cdot\vec{r}$ where $\vec{r}$ is the electron coordinate. It has only off-diagonal matrix elements given by $\mathcal{H}'_{eg}=-eE_0\hat{\varepsilon}\cdot\langle e|\vec{r}\,|g\rangle$ where e and g represent the excited and ground states respectively. The force depends on the atomic state as determined by its interaction with the light, and is calculated from the expectation value $\langle\mathcal{A}\rangle=Tr(\rho\mathcal{A})$ as in Eq. (4), where ρ is the density matrix found by solving the optical Bloch equations (OBE).[1] Then

$$F=\hbar\left(\frac{\partial\Omega}{\partial z}\rho^*_{eg}+\frac{\partial\Omega^*}{\partial z}\rho_{eg}\right) \tag{6}$$

where the Rabi frequency is defined as $\hbar\Omega\equiv\mathcal{H}'_{eg}$. Note that the force depends on the state of the atom, and in particular, on the optical coherence between the ground and excited states, ρ_{eg}.

Although it may seem a bit artificial, it is instructive to split $\partial\Omega/\partial z$ into its real and imaginary parts (the matrix element that defines Ω can certainly be complex):

$$\frac{\partial\Omega}{\partial z}=(q_r+iq_i)\Omega \tag{7}$$

Here q_r+iq_i is the logarithmic derivative of Ω. In general, for a field $E(z)=E_0(z)\exp(i\phi(z))+\text{c.c.}$, the real part of the logarithmic derivative corresponds to a gradient of the amplitude $E_0(z)$ and the imaginary part to a gradient of the phase $\phi(z)$. Then the expression for the force becomes

$$F=\hbar q_r(\Omega\rho^*_{eg}+\Omega^*\rho_{eg})+i\hbar q_i(\Omega\rho^*_{eg}-\Omega^*\rho_{eg}) \tag{8}$$

Equation (8) is a very general result that can be used to find the force for any particular situation as long as the OBE for ρ_{eg} can be solved. In spite of the chosen complex expression for Ω, it is important to note that the force itself is real, and that first term of the force is proportional to the real part of $\Omega\rho_{eg}^{*}$, whereas the second term is proportional to the imaginary part.

A Two-Level Atom at Rest

There are two important special optical arrangements to consider. The first one is a traveling wave whose electric field is $E(z) = (E_0/2)(e^{i(kz-\omega t} + \text{c.c})$. In calculating the Rabi frequency from this, the rotating wave approximation (RWA) causes the positive frequency component of $E(z)$ to drop out. Then the gradient of the Rabi frequency becomes proportional to the gradient of the surviving negative frequency component, so that $q_r = 0$ and $q_i = k$. For such a traveling wave the amplitude is constant but the phase is not, and this leads to the nonzero value of q_i.

This is in direct contrast to the case of a standing wave, composed of two counterpropagating traveling waves so its amplitude is twice as large, for which the electric field is given by $E(z) = E_0 \cos(kz)(e^{-i\omega t} + \text{c.c})$, so that $q_r = -k\tan(kz)$ and $q_i = 0$. Again, only the negative frequency part survives the RWA, but the gradient does not depend on it. Thus a standing wave has an amplitude gradient, but not a phase gradient.

The steady-state solutions of the OBE for a two-level atom at rest provide simple expressions for ρ.[1] Substituting the solution for ρ_{eg} into Eq. (8) gives

$$F = \frac{\hbar s}{1+s}\left(-\delta q_r + \frac{1}{2}\gamma q_i\right) \tag{9}$$

where $s \equiv s_0/[1 + (2\delta/\gamma)^2]$ is the off-resonance saturation parameter. Note that the first term is proportional to the detuning δ, whereas the second term is proportional to the decay rate γ. For zero detuning, the force for a traveling wave becomes $F = (\hbar k\gamma/2)[s_0/(s_0+1)]$, a very satisfying result because it is simply the momentum per photon $\hbar k$, times the scattering rate γ_p at resonance of Eq. (2).

It is instructive to identify the origin of both terms in Eq. (9). Absorption of light leads to the transfer of momentum from the optical field to the atoms. If the atoms decay by spontaneous emission, the recoil associated with the spontaneous fluorescence is in a random direction, so its average over many emission events results in zero net effect on the atomic momentum. Thus the force from absorption followed by spontaneous emission can be written as $F_{\text{sp}} = \hbar k\gamma\rho_{ee}$, where $\hbar k$ is the momentum transfer for each photon, γ is the rate for the process, and ρ_{ee} is the probability for the atoms to be in the excited state. Using Eq. (2), the force resulting from absorption followed by spontaneous emission becomes

$$F_{\text{sp}} = \frac{\hbar k s_0 \gamma/2}{1+s_0+(2\delta/\gamma)^2} \tag{10}$$

which saturates at large intensity as a result of the term s_0 in the denominator. Increasing the rate of absorption by increasing the intensity does not increase the force without limit, since that would only increase the rate of stimulated emission, where the transfer of momentum is opposite in direction compared to the absorption. Thus the force saturates to a maximum value of $\hbar k\gamma/2$, because ρ_{ee} has a maximum value of 1/2.

Examination of Eq. (10) shows that it clearly corresponds to the second term of Eq. (8). This term is called the *light pressure force, radiation pressure force, scattering force*, or *dissipative force*, since it relies on the scattering of light out of the laser beam. It vanishes for an atom at rest in a standing wave where $q_i = 0$, and this can be understood because atoms can absorb light from either of the two counterpropagating beams that make up the standing wave, and the average momentum transfer then vanishes. This force is dissipative because the reverse of spontaneous emission is not possible, and therefore the action of the force cannot be reversed. It plays a very important role in the slowing and cooling of atoms.

By contrast, the first term in Eq. (8) derives from the light shifts of the ground and excited states that depend on the strength of the optical electric field. A standing wave is composed of two counter-propagating laser beams, and their interference produces an amplitude gradient that is not present in a traveling wave. The force is proportional to the gradient of the light shift, and the ground-state light shift $\Delta E_g = \hbar\Omega^2/4\delta$ can be used to find the force on ground-state atoms in low-intensity light:

$$F_{\text{dip}} = -\frac{\partial(\Delta E_g)}{\partial z} = \frac{\hbar\Omega}{2\delta}\frac{\partial\Omega}{\partial z} \tag{11}$$

For an amplitude-gradient light field such as a standing wave, $\partial\Omega/\partial z = q_r\Omega$, and this force corresponds to the first term in Eq. (8) in the limit of low saturation ($s << 1$).

For the case of a standing wave Eq. (9) becomes

$$F_{\text{dip}} = \frac{2\hbar k\delta s_0 \sin 2kz}{1+4s_0\cos^2 kz+(2\delta/\gamma)^2} \tag{12}$$

where s_0 is the saturation parameter of each of the two beams that form the standing wave. For $\delta < 0$ the force drives the atoms to positions where the intensity has a maximum, whereas for $\delta > 0$ the atoms are attracted to the intensity minima. The force is conservative and therefore cannot be used for cooling. This is called the *dipole force, reactive force, gradient force*, or *redistribution force*. It has the same origin as the force of an inhomogeneous DC electric field on a classical dipole, but relies on the redistribution of photons from one laser beam to the other.

It needs to be emphasized that the forces of Eqs. (10) and (12) are two fundamentally different kinds of forces. For an atom at rest, the scattering force vanishes for a standing wave, whereas the dipole force vanishes for a traveling wave. The scattering force is dissipative, and can be used to cool, whereas the dipole force is conservative, and can be used to trap. Dipole forces can be made large by using high-intensity light because they do not saturate. However, since the forces are conservative, they cannot be used to cool a sample of atoms. Nevertheless, they can be combined with the dissipative scattering force to enhance cooling in several different ways. By contrast, scattering forces are always limited by the rate of spontaneous emission γ and cannot be made arbitrarily strong, but they are dissipative and are required for cooling.

Atoms in Motion

Laser cooling requires dissipative or velocity-dependent forces that cannot be conservative. The procedure followed here is to treat the velocity of the atoms as a small perturbation, and make first-order corrections to the solutions of the OBE obtained for atoms at rest.[2] It begins by adding drift terms in the expressions for the relevant quantities. Thus the Rabi frequency satisfies

$$\frac{d\Omega}{dt} = \frac{\partial\Omega}{\partial t} + v\frac{\partial\Omega}{\partial z} = \frac{\partial\Omega}{\partial t} + v(q_r + iq_i)\Omega \tag{13}$$

where Eq. (7) has been used to separate the gradient of Ω into real and imaginary parts. Differentiating the steadystate density matrix elements found by solving the OBE[1] leads to

$$\frac{dw}{dt} = \frac{\partial w}{\partial t} + v\frac{\partial w}{\partial z} = \frac{\partial w}{\partial t} - \frac{2vq_r s}{(1+s)^2} \tag{14}$$

since $s_0 = 2|\Omega|^2/\gamma^2$ and Ω depends on z. Here $w \equiv \rho_{gg} - \rho_{ee}$. Similarly,

$$\frac{d\rho_{eg}}{dt} = \frac{\partial\rho_{eg}}{\partial t} + v\frac{\partial\rho_{eg}}{\partial z} = \frac{\partial\rho_{eg}}{\partial t} - \frac{iv\Omega}{2(\gamma/2 - i\delta)(1+s)}\left[q_r\left(\frac{1-s}{1+s}\right) + iq_i\right] \tag{15}$$

Since neither w nor ρ_{eg} is explicitly time-dependent, both $\partial w/\partial t$ and $\partial \rho_{eg}/\partial t$ vanish. Equations (14) and (15) are still difficult to solve analytically for a general optical field, and the results are not very instructive. However, the solution for the two special cases of the standing and traveling waves provide considerable insight.

For a traveling wave $q_r = 0$, and the velocity-dependent force can be found by combining Eqs. (14) and (15) with the OBE to eliminate the time derivatives. The resulting coupled equations can be separated and substituted into Eq. (8) for the force to find, after considerable algebra,

$$F = \hbar q_i \frac{s\gamma/2}{1+s}\left(1+\frac{2\delta v q_i}{(1+s)(\delta^2+\gamma^2/4)}\right) \equiv F_0 - \beta v \tag{16}$$

The first term is the velocity-independent force F_0 for an atom at rest given by Eq. (9). The second term is velocity-dependent and can lead to compression of the velocity distribution. For a traveling wave $q_i = k$ and thus the damping coefficient β is given by

$$\beta = -\hbar k^2 \frac{4s_0(\delta/\gamma)}{(1+s_0+(2\delta/\gamma)^2)^2} \tag{17}$$

Such a force can compress the velocity distribution of an atomic sample for negative values of δ (i.e., for red detuned light). For small detuning and low intensity the damping coefficient β is linear in both parameters. However, for detunings much larger than γ and intensities much larger than I_s, β saturates and even decreases as a result of the dominance of δ in the denominator of Eq. (17). This behavior can be seen in Fig. 1, where the damping coefficient β has been plotted as a function of detuning for different saturation parameters. The decrease of β for large detunings and intensities is caused by saturation of the transition, in which case the absorption rate becomes only weakly dependent on the velocity. The maximum value of β is obtained for $\delta = -\gamma/2$ and $s_0 = 2$, and is given by $\beta_{\max} = \hbar k^2/4$. The damping rate Γ is given by $\Gamma = \beta/M$, and its maximum value is $\Gamma_{\max} = \omega_r/2$, where ω_r is the recoil frequency. For the alkalis this rate is of the order of 10^4–10^5 s^{-1}, indicating that atomic velocity distributions can be compressed in about 10 to 100 μs. Furthermore, F_0 in Eq. (16) is always present and so the atoms are *not* damped toward any constant velocity.

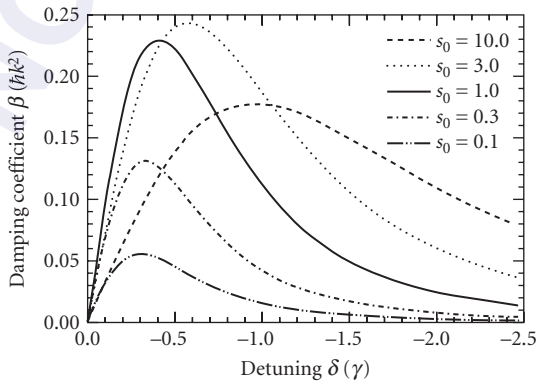

FIGURE 1 The damping coefficient β for an atom in a traveling wave as a function of the detuning for different values of the saturation parameter s_0. The damping coefficient is maximum for intermediate detunings and intensities.

For a standing wave $q_i = 0$, and just as above, the velocity-dependent force can be found by combining Eqs. (14) and (15) with the OBE to eliminate the time derivatives. The resulting coupled equations can again be separated and substituted into Eq. (8) for the force to find

$$F = -\hbar q_r \frac{s\delta}{1+s}\left(1 - v q_r \frac{(1-s)\gamma^2 - 2s^2(\delta^2+\gamma^2/4)}{(\delta^2+\gamma^2/4)(1+s)^2\gamma}\right) \tag{18}$$

where $q_r = -k \tan(kz)$. In the limit of $s << 1$, this force is

$$F = \hbar k \frac{s_0 \delta \gamma^2}{2(\delta^2+\gamma^2/4)}\left(\sin 2kz + kv\frac{\gamma}{(\delta^2+\gamma^2/4)}(1-\cos 2kz)\right) \tag{19}$$

Here s_0 is the saturation parameter of each of the two beams that compose the standing wave. The first term is the velocity-independent part of Eq. (9) and is sinusoidal in space, with a period of $\lambda/2$. Thus its spatial average vanishes. The force remaining after such averaging is $F_{av} = -\beta v$, where the damping coefficient β is given by

$$\beta = -\hbar k^2 \frac{8 s_0 (\delta/\gamma)}{(1+(2\delta/\gamma)^2)^2} \tag{20}$$

In contrast to the traveling-wave case, this is a true damping force because there is no F_0, so atoms are slowed toward $v = 0$ independent of their initial velocities. Note that this expression for β is valid only for $s << 1$ because it depends on spontaneous emission to return atoms to their ground state.

There is an appealing description of the mechanism for this kind of cooling in a standing wave. With light detuned below resonance, atoms traveling toward one laser beam see it Doppler shifted upward, closer to resonance. Since such atoms are traveling away from the other laser beam, they see its light Doppler shifted further downward, hence further out of resonance. Atoms therefore scatter more light from the beam counterpropagating to their velocity, so their velocity is reduced. This damping mechanism is called *optical molasses*, and is one of the most important tools of laser cooling.

Needless to say, such a pure damping force would reduce the atomic velocities, and hence the absolute temperature, to zero. Since this violates thermodynamics, there must be something left out of the description. It is the discreteness of the momentum changes in each case, $\Delta p = \hbar k$, that results in a minimum velocity change. The consequences of this discreteness can be described as a diffusion of the atomic momenta in momentum space by finite steps as discussed earlier.

The Fokker-Planck Equation

The random walk in momentum space associated with spontaneous emission is similar to Brownian motion in coordinate space. There is an analogous momentum diffusion constant D, and so the atomic motion in momentum space can be described by the Fokker-Planck equation

$$\frac{\partial W(p,t)}{\partial t} = -\frac{\partial [F(p,t)W(p,t)]}{\partial p} + \frac{\partial^2 [D(p,t)W(p,t)]}{\partial p^2} \tag{21}$$

where $W(p, t)$ is the momentum distribution of the atoms. For the special case when both the force and the diffusion are independent of time, the formal stationary solution is

$$\bar{W}(p) = \frac{C}{D(p)} \exp\left(\int_0^p \frac{F(p')}{D(p')} dp'\right) \tag{22}$$

where C is an integration constant. Once the force and diffusion are known, the stationary solution of the Fokker-Planck equation emerges easily.

In the simplest and most common case in laser cooling the force is proportional to the velocity and the diffusion is independent of velocity:

$$F(v)=-\beta v \quad \text{and} \quad D(v)=D_0 \tag{23}$$

Then the stationary solution of Eq. (21) for $\bar{W}(v)$ is

$$\bar{W}(p)\propto e^{-\beta p^2/2MD_0} \tag{24}$$

This is indeed a Maxwell-Boltzmann distribution. For low intensity where spontaneous emission dominates, $D_0=s\gamma(\hbar k)^2/2$, so the steady-state temperature is given by $k_BT=D_0/\beta=\hbar\gamma/2$ for $\delta=-\gamma/2$, its optimum value.[1] This is called the *Doppler temperature* because the velocity dependence of the cooling mechanism derives from the Doppler shift. The fact that the conditions of Eq. (23) for the force and diffusion are often approximately correct explains why the notion of temperature often appears as a description of a laser-cooled sample.

One of the most important properties of laser cooling is its ability to change the phase space density of an atomic sample. Changing the phase space density provides a most important distinction between light optics and atom optics. The Hamiltonian description of geometrical optics leads to the brightness theorem, that can be found in many optics books. Thus bundles of light rays obey a similar phase space density conservation. But there is a fundamental difference between light and atom optics. In the first case, the "forces" that determine the behavior of bundles of rays are "conservative" and phase space density is conserved. For instance, a lens can be used to focus a light beam to a small spot; however, at the same time the divergence of the beam must be increased, thus conserving phase space density. By contrast, in atom optics dissipative forces that are velocity-dependent can be used, and thus phase space density is no longer conserved. Optical elements corresponding to such forces cannot exist for light, but in addition to the atom optic elements of lenses, collimators, and others, phase space compressors can also be built. Such compression is essential in a large number of cases, such as atomic beam brightening for collision studies or cooling for the achievement of Bose-Einstein condensation.

20.4 SLOWING ATOMIC BEAMS

Among the earliest laser cooling experiments was deceleration of atoms in a beam.[3] The authors exploited the Doppler shift to make the momentum exchange (hence the force) velocity-dependent. It worked by directing a laser beam opposite to an atomic beam so the atoms could absorb light, and hence momentum $\hbar k$, very many times along their paths through the apparatus as shown in Fig. 2.[3,4] Of course, excited-state atoms cannot absorb light efficiently from the laser that excited them, so between absorptions they must return to the ground state by spontaneous decay, accompanied by emission of fluorescent light. The spatial symmetry of the emitted fluorescence results in an average of zero net momentum transfer from many such fluorescence events. Thus the net force on the atoms is in the direction of the laser beam, and the maximum deceleration is limited by the spontaneous emission rate γ.

The maximum attainable deceleration is obtained for very high light intensities, and is limited because the atom must then divide its time equally between ground and excited states. High-intensity light can produce faster absorption, but it also causes equally fast stimulated emission; the combination produces neither deceleration nor cooling because the momentum transfer to the atom in emission is then in the opposite direction to what it was in absorption. The force is limited to $F=\hbar k\gamma_p$, and so the deceleration therefore saturates at a value $\vec{a}_{\max}=\hbar\vec{k}\gamma/2M$ [see Eq. (2)]. Since the maximum deceleration $\vec{a}_{\max}$ is fixed by atomic parameters, it is straightforward to calculate the minimum stopping length $L_{\min}$ and time $t_{\min}$ for the rms velocity of atoms $\bar{v}=2\sqrt{k_BT/M}$ at the chosen temperature. The result is $L_{\min}=\bar{v}^2/2a_{\max}$ and $t_{\min}=\bar{v}/a_{\max}$. In Table 1 are some of the parameters for slowing a few atomic species of interest from the peak of the thermal velocity distribution.

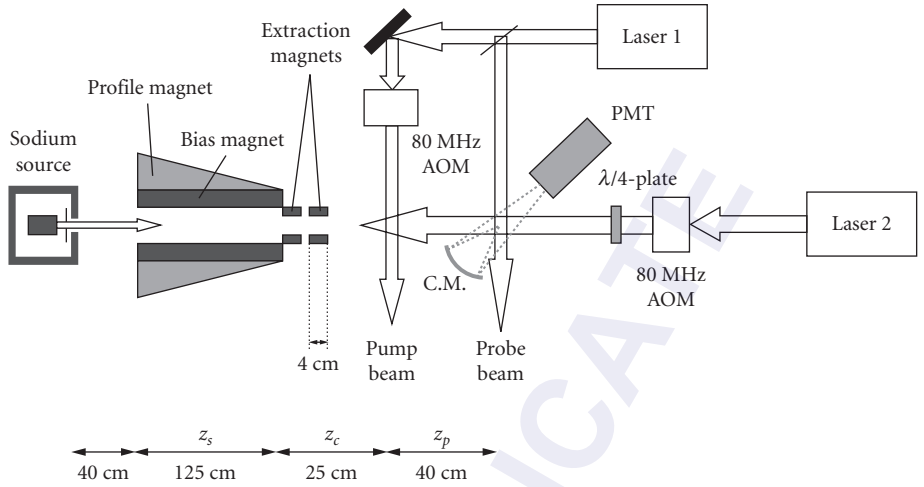

FIGURE 2 Schematic diagram of the apparatus for beam slowing. The tapered magnetic field is produced by layers of varying length on the solenoid, and the bias field is produced by full-length windings. The TOF aspect is implemented with Laser 1 whose beams optically pump the atoms between the hfs states.

TABLE 1 Parameters of Interest for Slowing Various Atoms

Atom	T_{oven} (K)	$\bar{v}$ (m/s)	L_{min} (m)	t_{min} (ms)
H	1000	5000	0.012	0.005
He*	4	158	0.03	0.34
He*	650	2013	4.4	4.4
Li	1017	2051	1.15	1.12
Na	712	876	0.42	0.96
K	617	626	0.77	2.45
Rb	568	402	0.75	3.72
Cs	544	319	0.93	5.82

The stopping length L_{min} and time t_{min} are minimum values. The oven temperature T_{oven} that determines the peak velocity is chosen to give a vapor pressure of 1 Torr. Special cases are H at 1000 K and He in the metastable triplet state, for which two rows are shown: one for a 4-K source and another for the typical discharge temperature.

Maximizing the scattering rate γ_p requires $\delta = -\omega_D$ in Eq. (2). If δ is chosen for a particular atomic velocity in the beam, then as the atoms slow down, their changing Doppler shift will take them out of resonance. They will eventually cease deceleration after their Doppler shift has been decreased by a few times the power-broadened width $\gamma' = \gamma\sqrt{1+s_0}$, corresponding to $\Delta\nu$ of a few times γ'/k. Although this $\Delta\nu$ of a few m/s is considerably larger than the typical atomic recoil velocity $\hbar k/M$ of a few cm/s, it is still only a small fraction of the atoms' average thermal velocity $\bar{v}$, so that significant further cooling or deceleration cannot be accomplished.

In order to achieve deceleration that changes the atomic speeds by hundreds of m/s, it is necessary to maintain $(\delta + \omega_D) << \gamma$ by compensating such large changes of the Doppler shift. This can be done by changing ω_D, or δ via either ω_ℓ or ω_a. The two most common methods for maintaining this resonance are sweeping the laser frequency ω_ℓ along with the changing ω_D of the decelerating atoms,[5–7] or by spatially varying the atomic resonance frequency with an inhomogeneous DC magnetic field to keep the decelerating atoms in resonance with the fixed frequency laser.[1,3,8]

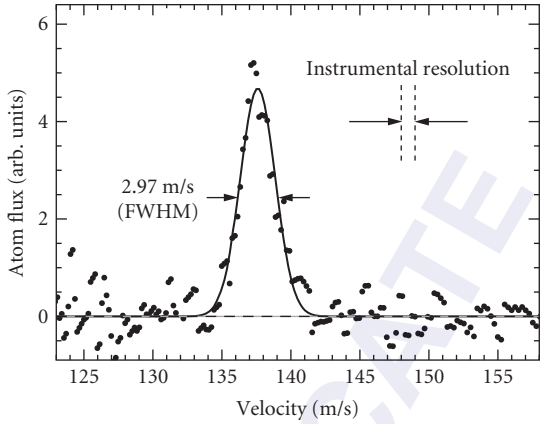

FIGURE 3 The velocity distribution measured with the time-of-flight (TOF) method. The experimental width of approximately $\frac{1}{6}(\gamma/k)$ is shown by the dashed vertical lines between the arrows. The Gaussian fit through the data yields a FWHM of 2.97 m/*s*. (*Figure from Ref. 78.*)

The use of a spatially varying magnetic field to tune the atomic levels along the beam path was the first method to succeed in slowing atoms.[3] It works as long as the Zeeman shifts of the ground and excited states are different so that the resonant frequency is shifted. The field can be tailored to provide the appropriate Doppler shift along the moving atom's path. For uniform deceleration $a \equiv \eta a_{\max}$ from initial velocity v_0, the appropriate field profile is $B(z) = B_0\sqrt{1 - z/z_0}$, where $z_0 \equiv Mv_0^2/\eta\hbar k\gamma$ is the length of the magnet, $B_0 = \hbar k v_0/\mu'$, $\mu' \equiv (g_e M_e - g_g M_g)\mu_B$, subscripts g and e refer to ground and excited states, $g_{g,e}$ is the Landé g-factor, μ_B is the Bohr magneton, and $M_{g,e}$ is the magnetic quantum number. The design parameter $\eta < 1$ determines the length of the magnet z_0. A solenoid that can produce such a spatially varying field has layers of decreasing lengths as shown schematically in Fig. 2. The technical problem of extracting the beam of slow atoms from the end of the solenoid can be simplified by reversing the field gradient and choosing a transition whose frequency decreases with increasing field.[9]

For alkali atoms such as Na, a time-of-flight (TOF) method can be used to measure the velocity distribution of atoms in the beam. It employs two additional beams labeled *pump* and *probe* from laser 1 as shown in Fig. 2. Because these beams cross the atomic beam at 90°, $\omega_D = -\vec{k} \cdot \vec{v} = 0$ and they excite atoms at all velocities. The pump beam is tuned to excite and empty a selected ground hyperfine state (hfs), and it transfers more than 98 percent of the population as the atoms pass through its 0.5 mm width. To measure the velocity distribution of atoms in the selected hfs, this pump laser beam is interrupted for a period $\Delta t =$ 10 to 50 μs with an acoustic optical modulator (AOM). A pulse of atoms in the selected hfs passes the pump region and travels to the probe beam. The time dependence of the fluorescence induced by the probe laser, tuned to excite the selected hfs, gives the time of arrival, and this signal is readily converted to a velocity distribution. Figure 3 shows the measured velocity distribution of the atoms slowed by laser 2.

20.5 OPTICAL MOLASSES

Doppler Cooling

In Sec. 20.3 there was a discussion of the radiative force on atoms moving in a standing wave (counterpropagating laser beams). The slowing force is proportional to velocity for small enough velocities, resulting in viscous damping[10,11] that gives this technique the name *optical molasses* (OM). By

using three intersecting orthogonal pairs of oppositely directed beams, the movement of atoms in the intersection region can be severely restricted in all three dimensions, and many atoms can thereby be collected and cooled in a small volume. OM has been demonstrated at several laboratories,[12] often with the use of low-cost diode lasers.[13]

It is straightforward to estimate the force on atoms in OM from Eq. (10). The discussion here is limited to the case where the light intensity is low enough so that stimulated emission is not important. In this low-intensity case the forces from the two light beams are simply added to give $\vec{F}_{\mathrm{OM}} = \vec{F}_{+} + \vec{F}_{-}$, where

$$\vec{F}_{\pm} = \pm \frac{\hbar \vec{k} \gamma}{2} \frac{s_0}{1 + s_0 + [2(\delta \mp |\omega_D|)/\gamma]^2} \tag{25}$$

Then the sum of the two forces is

$$\vec{F}_{\mathrm{OM}} \cong \frac{8\hbar k^2 \delta s_0 \vec{v}}{\gamma(1 + s_0 + (2\delta/\gamma)^2)^2} \equiv -\beta \vec{v} \tag{26}$$

where terms of order $(kv/\gamma)^4$ and higher have been neglected [see Eq. (20)].

These forces are plotted in Fig. 4. For $\delta < 0$, this force opposes the velocity and therefore viscously damps the atomic motion. $\vec{F}_{\mathrm{OM}}$ has maxima near $v \approx \pm \gamma'/2k$ and decreases rapidly for larger velocities.

If there were no other influence on the atomic motion, all atoms would quickly decelerate to $v = 0$, and the sample would reach $T = 0$, a clearly unphysical result. There is also some heating caused by the light beams that must be considered, and it derives from the discrete size of the momentum steps the atoms undergo with each emission or absorption as previously discussed for Brownian motion (see Sec. 20.3). Since the atomic momentum changes by $\hbar k$, their kinetic energy changes on the average by at least the recoil energy $E_r = \hbar^2 k^2 / 2M = \hbar \omega_r$. This means that the average frequency of each absorption is $\omega_{\mathrm{abs}} = \omega_a + \omega_r$ and the average frequency of each emission is $\omega_{\mathrm{emit}} = \omega_a + \omega_r$. Thus the light field loses an average energy of $\hbar(\omega_{\mathrm{abs}} - \omega_{\mathrm{emit}}) = 2\hbar\omega_r$ for each scattering. This loss occurs at a rate $2\gamma_p$ (two beams), and the energy is converted to atomic kinetic energy because the atoms recoil from each event. The atomic sample is thereby heated because these recoils are in random directions.

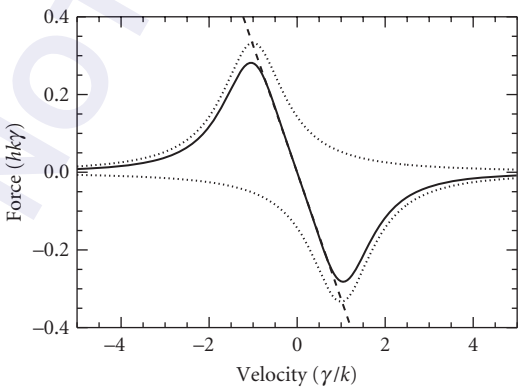

FIGURE 4 Velocity dependence of the optical damping forces for one-dimensional optical molasses. The two dotted traces show the force from each beam, and the solid curve is their sum. The straight line shows how this force mimics a pure damping force over a restricted velocity range. These are calculated for $s_0 = 2$ and $\delta = -\gamma$ so there is some power-broadening evident.

The competition between this heating with the damping force of Eq. (26) results in a nonzero kinetic energy in steady state where the rates of heating and cooling are equal. Equating the cooling rate, $\vec{F}\cdot\vec{v}$, to the heating rate, $4\hbar\omega_r\gamma_p$, the steady-state kinetic energy is $(\hbar\gamma/8)(2|\delta|/\gamma+\gamma/2|\delta|)$. This result is dependent on $|\delta|$, and it has a minimum at $2|\delta|/\gamma = 1$, whence $\delta = -\gamma/2$. The temperature found from the kinetic energy is then $T_D = \hbar\gamma/2k_B$, where T_D is called the *Doppler temperature* or *the Doppler cooling limit*. For ordinary atomic transitions, T_D is typically below 1 mK.

Another instructive way to determine T_D is to note that the average momentum transfer of many spontaneous emissions is zero, but the rms scatter of these about zero is finite. One can imagine these decays as causing a random walk in momentum space with step size $\hbar k$ and step frequency $2\gamma_p$, where the factor of 2 arises because of the two beams. The random walk results in diffusion in momentum space with diffusion coefficient $D_0 \equiv 2(\Delta p)^2/\Delta t = 4\gamma_p(\hbar k)^2$ as discussed in Sec. 20.3. Then Brownian motion theory gives the steady-state temperature in terms of the damping coefficient β to be $k_B T = D_0/\beta$. This turns out to be $\hbar\gamma/2$ as above for the case $s_0 << 1$ when $\delta = -\gamma/2$. This remarkable result predicts that the final temperature of atoms in OM is independent of the optical wavelength, atomic mass, and laser intensity (as long as it is not too large).

Atomic Beam Collimation—One-Dimensional Optical Molasses

When an atomic beam crosses a one-dimensional OM as shown in Fig. 5, the transverse motion of the atoms is quickly damped while the longitudinal component is essentially unchanged. This transverse cooling of an atomic beam is an example of a method that can actually increase its brightness (atoms/sec-sr-cm^2) because such active collimation uses dissipative forces to compress the phase space volume occupied by the atoms. By contrast, the usual realm of beam focusing or collimation techniques for light beams and most particle beams is restricted to selection by apertures or conservative forces that preserve the phase space density of atoms in the beam.

This velocity compression at low intensity in one dimension can be simply estimated for two-level atoms in 1D to be about $v_c/v_D = \sqrt{\gamma/\omega_r} = \sqrt{1/\varepsilon}$. For Rb, $v_D = 12$ cm/s, $v_c = \gamma/k \simeq 4.6$ m/s, $\omega_r \simeq 2\pi\times 3.8$ kHz, and $1/\varepsilon \simeq 1600$. Including two transverse directions along with the longitudinal slowing and cooling just discussed, the decrease in phase space volume from the momentum contribution alone for laser cooling of a Rb atomic beam can exceed 10^6.

Clearly optical techniques can create atomic beams enormously more times intense than ordinary thermal beams, and also many orders of magnitude brighter. Furthermore, this number could be increased by several orders of magnitude if the transverse cooling could produce temperatures

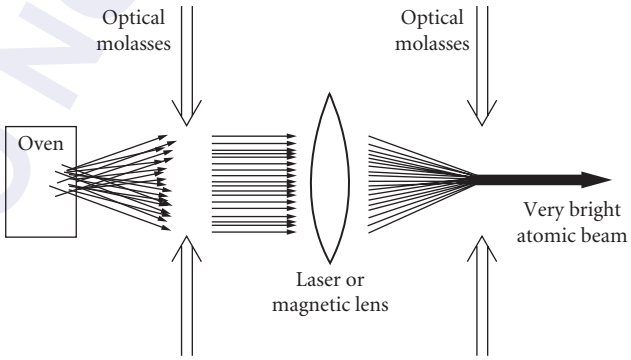

FIGURE 5 Scheme for optical brightening of an atomic beam. First the transverse velocity components of the atoms are damped out by an optical molasses, then the atoms are focused to a spot, and finally the atoms are recollimated in a second optical molasses. (*Figure from Ref. 79.*)

below the Doppler temperature. For atoms cooled to the recoil temperature $T_r = \hbar\omega_r/k_B$ where $\Delta p = \hbar k$ and $\Delta x = \lambda/\pi$, the brightness increase could be 10^{17}.

Experiments in Three-Dimensional Optical Molasses

Optical molasses experiments can also work in three dimensions at the intersection of three mutually orthogonal pairs of opposing laser beams (see Fig. 6). Even though atoms can be collected and cooled in the intersection region, it is important to stress again that this is *not* a trap. That is, atoms that wander away from the center experience no force directing them back. They are allowed to diffuse freely and even escape, as long as there is enough time for their very slow diffusive movement to allow them to reach the edge of the region of the intersection of the laser beams. Because the atomic velocities are randomized during the damping time $M/\beta = 2/\omega_r$, atoms execute a random walk with a step size of $2v_D/\omega_r = \lambda/\pi\sqrt{2\varepsilon} \cong$ few μm. To diffuse a distance of 1 cm requires about 10^7 steps or about 30 s.[14,15]

Three-dimensional OM was first observed in 1985.[11] Preliminary measurements of the average kinetic energy of the atoms were done by blinking off the laser beams for a fixed interval. Comparison of the brightness of the fluorescence before and after the turnoff was used to calculate the fraction of atoms that left the region while it was in the dark. The dependence of this fraction on the duration of the dark interval was used to estimate the velocity distribution and hence the temperature. The result was not inconsistent with the two-level atom theory previously described.

A few months later a more sensitive ballistic technique was devised at the National Institute of Standards and Technology (NIST) that showed the astounding result that the temperature of the atoms in OM was very much lower than T_D.[16] These experiments also found that OM was less sensitive to perturbations and more tolerant of alignment errors than was predicted by the 1D, two-level atom theory. For example, if the intensities of the two counter-propagating laser beams forming an OM were unequal, then the force on atoms at rest would not vanish, but the force on atoms with some nonzero drift velocity *would* vanish. This drift velocity can be easily calculated by using Eq. (25) with unequal intensities s_{0+} and s_{0-}, and following the derivation of Eq. (26). Thus atoms would drift out of an OM, and the calculated rate would be much faster than observed by deliberately unbalancing the beams in the experiments.[12]

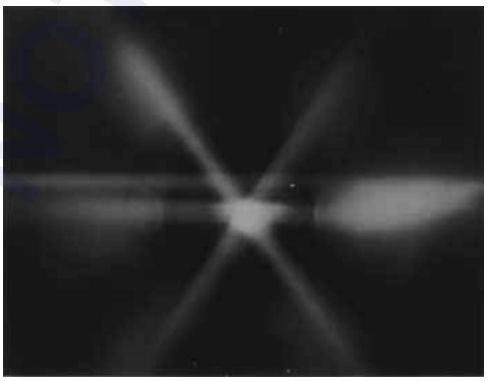

FIGURE 6 Photograph of optical molasses in Na taken under ordinary snapshot conditions in the lab at NIST. The upper horizontal streak is from the slowing laser while the three beams that cross at the center are on mutually orthogonal axes viewed from the (111) direction. Atoms in the optical molasses glow brightly at the center. (*Figure from Ref. 19.*)

It was an enormous surprise to observe that the ballistically measured temperature of the Na atoms was as much as 10 times *lower* than $T_D = 240\ \mu K$,[16] the temperature minimum calculated from the theory. This breaching of the Doppler limit forced the development of an entirely new picture of OM that accounts for the fact that in three dimensions, a two-level picture of atomic structure is inadequate. The multilevel structure of atomic states, and optical pumping among these sublevels, must be considered in the description of 3D OM, as discussed in the text that follows.

20.6 COOLING BELOW THE DOPPLER LIMIT

Introduction

In response to the surprising measurements of temperatures below T_D, two groups developed a model of laser cooling that could explain the lower temperatures.[17,18] The key feature of this model that distinguishes it from the earlier picture was the inclusion of the multiplicity of sublevels that make up an atomic state (e.g., Zeeman and hfs). The dynamics of optically pumping atoms among these sublevels provides the new mechanism for producing the ultralow temperatures.[19]

The dominant feature of these models is the nonadiabatic response of moving atoms to the light field. Atoms at rest in a steady state have ground-state orientations caused by optical pumping processes that distribute the populations over the different ground-state sublevels. In the presence of polarization gradients, these orientations reflect the local light field. In the low-light-intensity regime, the orientation of stationary atoms is completely determined by the ground-state distribution: The optical coherences and the exited-state population follow the ground-state distribution adiabatically.

For atoms moving in a light field that varies in space, optical pumping acts to adjust the atomic orientation to the changing conditions of the light field. In a weak pumping process, the orientation of moving atoms always lags behind the orientation that would exist for stationary atoms. It is this phenomenon of nonadiabatic following that is the essential feature of the new cooling process.

Production of spatially dependent optical pumping processes can be achieved in several different ways. As an example, consider two counterpropagating laser beams that have orthogonal polarizations (as will be discussed shortly). The superposition of the two beams results in a light field having a polarization that varies on the wavelength scale along the direction of the laser beams. Laser cooling by such a light field is called *polarization gradient cooling*. In a three-dimensional optical molasses, the transverse wave character of light requires that the light field always has polarization gradients.

Linear ⊥ Linear Polarization Gradient Cooling

One of the most instructive models for discussion of sub-Doppler laser cooling was introduced in Ref. 17 and very well described in Ref. 19. If the polarizations of two counterpropagating laser beams are identical, the two beams interfere and produce a standing wave. When the two beams have orthogonal linear polarizations (same frequency ω_ℓ) with their $\hat{\varepsilon}$ vectors perpendicular (e.g., $\hat{x}$ and $\hat{y}$), the configuration is called *lin* ⊥ *lin* or *lin-perp-lin*. Then the total field is the sum of the two counterpropagating beams given by

$$\begin{aligned}\vec{E} &= E_0\hat{x}\cos(\omega_\ell t - kz) + E_0\hat{y}\cos(\omega_\ell t + kz)\\ &= E_0[(\hat{x}+\hat{y})\cos\omega_\ell t\cos kz + (\hat{x}-\hat{y})\sin\omega_\ell t\sin kz]\end{aligned} \tag{27}$$

At the origin, where $z = 0$, this becomes

$$\vec{E} = E_0(\hat{x}+\hat{y})\cos\omega_\ell t \tag{28}$$

which corresponds to linearly polarized light at an angle $+\pi/4$ to the x-axis. The amplitude of this field is $\sqrt{2}E_0$. Similarly, for $z = \lambda/4$, where $kz = \pi/2$, the field is also linearly polarized but at an angle $-\pi/4$ to the x-axis.

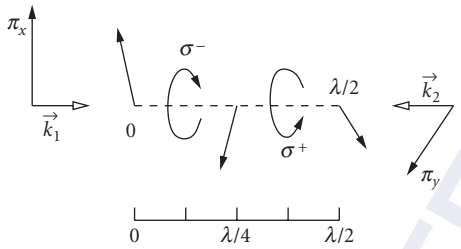

FIGURE 7 Polarization gradient field for the lin ⊥ lin configuration.

Between these two points, at $z = \lambda/8$, where $kz = \pi/4$, the total field is

$$\vec{E} = E_0[\hat{x}\sin(\omega_\ell t + \pi/4) - \hat{y}\cos(\omega_\ell t + \pi/4)] \tag{29}$$

Since the $\hat{x}$ and $\hat{y}$ components have sine and cosine temporal dependence, they are $\pi/2$ out of phase, and so Eq. (29) represents circularly polarized light rotating about the z-axis in the negative sense. Similarly, at $z = 3\lambda/8$ where $kz = 3\pi/4$, the polarization is circular but in the positive sense. Thus in this lin ⊥ lin scheme the polarization cycles from linear to circular to orthogonal linear to opposite circular in the space of only half a wavelength of light, as shown in Fig. 7. It truly has a very strong polarization gradient.

Since the coupling of the different states of multilevel atoms to the light field depends on its polarization, atoms moving in a polarization gradient will be coupled differently at different positions, and this will have important consequences for laser cooling. For the $J_g = {}^1/_2 \rightarrow J_e = {}^3/_2$ transition (the simplest transition that shows sub-Doppler cooling), the optical pumping process in purely σ^+ light drives the ground-state population to the $M_g = +{}^1/_2$ sublevel. This optical pumping occurs because absorption always produces $\Delta M = +1$ transitions, whereas the subsequent spontaneous emission produces $\Delta M = \pm 1, 0$. Thus the average $\Delta M \geq 0$ for each scattering event. For σ^--light the population is pumped toward the $M_g = -{}^1/_2$ sublevel. Thus atoms traveling through only a half wavelength in the light field need to readjust their population completely from $M_g = +{}^1/_2$ to $M_g = -{}^1/_2$ and back again.

The interaction between nearly resonant light and atoms not only drives transitions between atomic energy levels, but also shifts their energies. This light shift of the atomic energy levels plays a crucial role in this scheme of sub-Doppler cooling, and the changing polarization has a strong influence on the light shifts. In the low-intensity limit of two laser beams, each of intensity $s_0 I_s$, the light shifts ΔE_g of the ground magnetic substates are given by[1]

$$\Delta E_g = \frac{\hbar \delta s_0 C_{ge}^2}{1 + (2\delta/\gamma)^2} \tag{30}$$

where C_{ge} is the Clebsch-Gordan coefficient that describes the coupling between the atom and the light field.

In the present case of orthogonal linear polarizations and $J = {}^1/_2 \rightarrow {}^3/_2$, the light shift for the magnetic substate $M_g = {}^1/_2$ is three times larger than that of the $M_g = -{}^1/_2$ substate when the light field is completely σ^+. On the other hand, when an atom moves to a place where the light field is σ^-, the shift of $M_g = -{}^1/_2$ is three times larger. So in this case the optical pumping previously discussed causes there to be a larger population in the state with the larger light shift. This is generally true for any transition J_g to $J_e = J_g + 1$. A schematic diagram showing the populations and light shifts for this particular case of negative detuning is shown in Fig. 8.

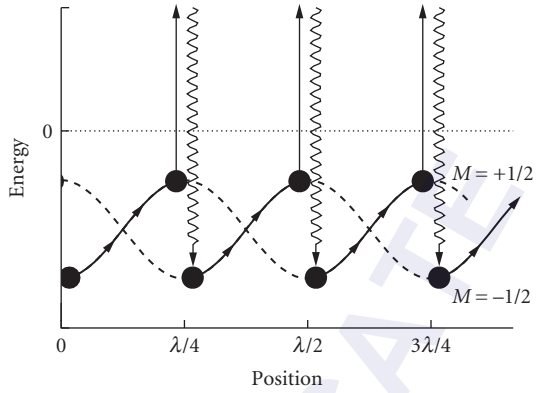

FIGURE 8 The spatial dependence of the light shifts of the ground-state sublevels of the $J = {}^1/_2 \Leftrightarrow {}^3/_2$ transition for the case of the lin ⊥ lin polarization configuration. The arrows show the path followed by atoms being cooled in this arrangement. Atoms starting at $z = 0$ in the $M_g = +{}^1/_2$ sublevel must climb the potential hill as they approach the $z = \lambda/4$ point where the light becomes σ^- polarized, and there they are optically pumped to the $M_g = -{}^1/_2$ sublevel. Then they must begin climbing another hill toward the $z = \lambda/2$ point where the light is σ^+ polarized and they are optically pumped back to the $M_g = +{}^1/_2$ sublevel. The process repeats until the atomic kinetic energy is too small to climb the next hill. Each optical pumping event results in absorption of light at a lower frequency than emission, thus dissipating energy to the radiation field.

Origin of the Damping Force

To discuss the origin of the cooling process in this polarization gradient scheme, consider atoms with a velocity v at a position where the light is σ^+-polarized, as shown at the lower left of Fig. 8. The light optically pumps such atoms to the strongly negative light-shifted $M_g = +{}^1/_2$ state. In moving through the light field, atoms must increase their potential energy (climb a hill) because the polarization of the light is changing and the state $M_g = {}^1/_2$ becomes less strongly coupled to the light field. After traveling a distance $\lambda/4$, atoms arrive at a position where the light field is σ^--polarized, and are optically pumped to $M_g = -{}^1/_2$, which is now lower than the $M_g = {}^1/_2$ state. Again the moving atoms are at the bottom of a hill and start to climb. In climbing the hills, the kinetic energy is converted to potential energy, and in the optical pumping process, the potential energy is radiated away because the spontaneous emission is at a higher frequency than the absorption (see Fig. 8). Thus atoms seem to be always climbing hills and losing energy in the process. This process brings to mind a Greek myth, and is thus called *Sisyphus laser cooling*.

The cooling process just described is effective over a limited range of atomic velocities. The force is maximum for atoms that undergo one optical pumping process while traveling over a distance $\lambda/4$. Slower atoms will not reach the hilltop before the pumping process occurs, and faster atoms will already be descending the hill before being pumped toward the other sublevel. In both cases the energy loss is smaller and therefore the cooling process less efficient. Nevertheless, the damping constant β for this process is much larger than for Doppler cooling, and therefore the final steady-state temperature is lower.[17,19]

In the experiments of Ref. 20, the temperature was measured in a 3D molasses under various configurations of the polarization. Temperatures were measured by a ballistic technique, where

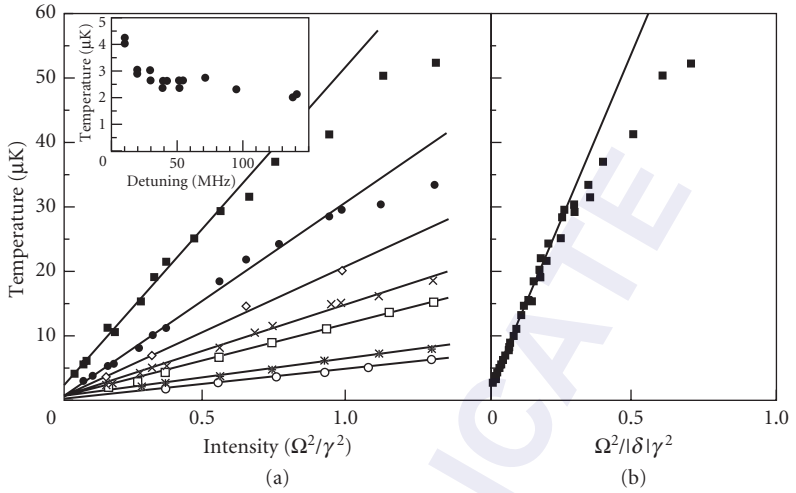

FIGURE 9 Temperature as a function of laser intensity and detuning for Cs atoms in an optical molasses from Ref. 20. (*a*) Temperature as a function of the detuning for various intensities. (*b*) Temperature as a function of the light shift. All the data points are on a universal straight line.

the flight time of the released atoms was measured as they fell through a probe a few cm below the molasses region. Results of their measurements are shown in Fig. 9*a*, where the measured temperature is plotted for different detunings as a function of the intensity. For each detuning, the data lie on a straight line through the origin. The lowest temperature obtained is 3 μK, which is a factor 40 below the Doppler temperature and a factor 15 above the recoil temperature of Cs. If the temperature is plotted as a function of the light shift (see Fig. 9*b*), all the data are on a single universal straight line.

The Limits of Laser Cooling

The lower limit to Doppler laser cooling of two-level atoms arises from the competition with heating. This cooling limit is described as a random walk in momentum space whose steps are of size $\hbar k$ and whose rate is the scattering rate, $\gamma_p = s_0\gamma/2$ for zero detuning and $s_0 << 1$. As long as the force can be accurately described as a damping force, then the Fokker-Planck equation is applicable, and the outcome is a lower limit to the temperature of laser cooling given by the Doppler temperature $k_B T_D \equiv \hbar\gamma/2$.

The extension of this kind of thinking to the sub-Doppler processes described in Sec. 20.5 must be done with some care, because a naive application of the consequences of the Fokker-Planck equation would lead to an arbitrarily low final temperature. In the derivation of the Fokker-Planck equation it is explicitly assumed that each scattering event changes the atomic momentum p by an amount that is a small fraction p as embodied in Eq. (3), and this clearly fails when the velocity is reduced to the region of $v_r \equiv \hbar k/M$.

This limitation of the minimum steady-state value of the average kinetic energy to a few times $2E_r \equiv k_B T_r = Mv_r^2$ is intuitively comforting for two reasons. First, one might expect that the last spontaneous emission in a cooling process would leave atoms with a residual momentum of the order of $\hbar k$, since there is no control over its direction. Thus the randomness associated with this would put a lower limit on such cooling of $v_{\min} \sim v_r$. Second, the polarization gradient cooling mechanism just described requires that atoms be localizable within the scale of $\sim\lambda/2\pi$ in order to

be subject to only a single polarization in the spatially inhomogeneous light field. The uncertainty principle then requires that these atoms have a momentum spread of at least $\hbar k$.

The recoil limit discussed here has been surpassed by evaporative cooling of trapped atoms[21] and two different optical cooling methods, neither of which can be based in simple notions. One of these uses optical pumping into a velocity-selective dark state and is described in Ref. 1. The other one uses carefully chosen, counterpropagating laser pulses to induce velocity-selective Raman transitions, and is called *Raman cooling*.[22]

20.7 TRAPPING OF NEUTRAL ATOMS

Introduction

Although ion trapping, laser cooling of trapped ions, and trapped ion spectroscopy were known for many years,[23] it was only in 1985 that neutral atoms were first trapped.[24] Confinement of neutral atoms depends on the interaction between an inhomogeneous electromagnetic field and an atomic multipole moment. Unperturbed atoms do not have electric dipole moments because of their inversion symmetry, and therefore electric (e.g., optical) traps require induced dipole moments. This is often done with nearly resonant optical fields, thus producing the optical traps that will be discussed shortly. On the other hand, many atoms have ground- or metastable-state magnetic dipole moments that may be used for trapping them magnetically.

In order to confine any object, it is necessary to exchange kinetic for potential energy in the trapping field, and in neutral atom traps the potential energy must be stored as internal atomic energy. There are two immediate and extremely important consequences of this requirement. First, the atomic energy levels will necessarily shift as the atoms move in the trap, and these shifts will affect the precision of spectroscopic measurements, perhaps severely. Second, practical traps for ground-state neutral atoms are necessarily very shallow compared with thermal energy because the energy level shifts that result from convenient size fields are typically considerably smaller than $k_B T$ for $T = 1$ K. Neutral atom trapping therefore depends on substantial cooling of a thermal atomic sample, and is often connected with the cooling process.

The small depth of neutral atom traps also dictates stringent vacuum requirements, because an atom cannot remain trapped after a collision with a thermal energy background gas molecule. Since these atoms are vulnerable targets for thermal energy background gas, the mean free time between collisions must exceed the desired trapping time. The cross section for destructive collisions is quite large because even a gentle collision (i.e., large impact parameter) can impart enough energy to eject an atom from a trap. At pressure P sufficiently low to be of practical interest, the trapping time is $\sim(10^{-8}/P)$ s, where P is in Torr.

Magnetic Traps

An atom with a magnetic moment $\vec{\mu}$ can be confined by an inhomogeneous magnetic field because of an interaction between the moment and the field. This produces a force given by $\vec{F} = \vec{\nabla}(\vec{\mu} \cdot \vec{B})$. Several different magnetic traps with varying geometries that exploit this force have been studied in some detail, and their general features have been presented.[25] The simplest magnetic trap is a quadrupole comprised of two identical coils carrying opposite currents (see Fig. 10) that has a single center where the field is zero. When the coils are separated by 1.25 times their radius, such a trap has equal depth in the radial (x-y plane) and longitudinal (z-axis) directions.[25] Its experimental simplicity makes it most attractive, both because of ease of construction and of optical access to the interior. Such a trap was used in the first neutral atom trapping experiments at NIST.

The magnitude of the field is zero at the center of this trap, and increases in all directions as $B = A\sqrt{\rho^2 + 4z^2}$, where $\rho^2 \equiv x^2 + y^2$, and the field gradient A is constant. The field gradient is fixed along any line through the origin, but has different values in different polar directions. Therefore the

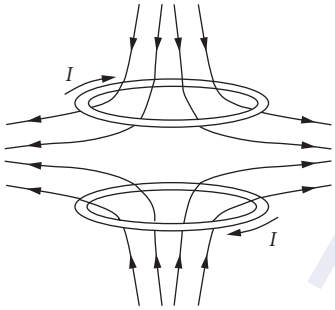

FIGURE 10 Schematic diagram of the coil configuration used in the quadrupole trap and the resultant magnetic field lines. Because the currents in the two coils are in opposite directions, there is a $|\vec{B}|=0$ point at the center.

force that confines the atoms in the trap is neither harmonic nor central, and angular momentum is not conserved. There are several motivations for studying the motion of atoms in a magnetic trap. Knowing their positions may be important for trapped atom spectroscopy. Moreover, simply studying the motion for its own sake has turned out to be an interesting problem because the distorted conical potential of the quadrupole trap does not have analytic solutions, and its bound states are not well known. For the two-coil quadrupole magnetic trap of Fig. 10, stable circular orbits can be found classically.[1] The fastest trappable atoms in circular orbits have $v_{\max} \sim 1$ m/s, so the orbital frequency becomes $\omega_T/2\pi \sim 20$ Hz. Because of the anharmonicity of the potential, the orbital frequencies depend on the orbit size, but in general, atoms in lower energy orbits have higher frequencies.

Because of the dependence of the trapping force on the angle between the field and the atomic moment the orientation of the magnetic moment with respect to the field must be preserved as the atoms move about in the trap. This requires velocities low enough to ensure that the interaction between the atomic moment $\vec{\mu}$ and the field $\vec{B}$ is adiabatic, especially when the atom's path passes through a region where the field magnitude is small. This is especially critical at the low temperatures of the Bose condensation experiments. Therefore energy considerations that focus only on the trap depth are not sufficient to determine the stability of a neutral atom trap: orbit and/or quantum state calculations and their consequences must also be considered.

The condition for adiabatic motion can be written as $\omega_z >> |dB/dt|/B$, where $\omega_z = \mu B/\hbar$ is the Larmor precession rate in the field. The orbital frequency for circular motion is $\omega_T = v/\rho$, and since $v/\rho = |dB/dt|/B$ for a uniform field gradient, the adiabaticity condition is $\omega_z >> \omega_T$. For the two-coil quadrupole trap, the adiabaticity condition can be easily calculated.[1] A practical trap ($A \sim 1$ T/m) requires $\rho >> 1$ μm as well as $v >> 1$ cm/s. Note that violation of these conditions results in the onset of quantum dynamics for the motion (deBroglie wavelength ≈ orbit size). Since the nonadiabatic region of the trap is so small (less than 10^{-18} m^3 compared with typical sizes of ~2 cm corresponding to 10^{-5} m^3), nearly all the orbits of most atoms are restricted to regions where they are adiabatic.

Modern techniques of laser and evaporative cooling have the capability to cool atoms to energies where their deBroglie wavelengths are on the micron scale. Such cold atoms may be readily confined to micron-size regions in magnetic traps with easily achievable field gradients, and in such cases, the notion of classical orbits is inappropriate. The motional dynamics must be described in terms of quantum mechanical variables and suitable wave functions. Furthermore, the distribution of atoms confined in various quantum states of motion in quadrupole as well as other magnetic traps is critical for interpreting the measurements on Bose condensates.

Studying the behavior of extremely slow (cold) atoms in the two-coil quadrupole trap begins with a heuristic quantization of the orbital angular momentum using $Mr^2\omega_T = n\hbar$ for circular orbits.[1] For velocities of optically cooled atoms of a few cm/s, $n \sim 10 - 100$. By contrast, evaporative cooling[21] can produce velocities ~1 mm/s resulting in $n \sim 1$. It is readily found that $\omega_z = n\omega_T$, so that

the adiabatic condition is satisfied only for $n >> 1$. The separation of the rapid precession from the slower orbital motion is reminiscent of the Born-Oppenheimer approximation for molecules, and three-dimensional quantum calculations have also been described.[1]

Optical Traps

Optical trapping of neutral atoms by electrical interaction must proceed by inducing a dipole moment. For dipole optical traps, the oscillating electric field of a laser induces an oscillating atomic electric dipole moment that interacts with the laser field. If the laser field is spatially inhomogeneous, the interaction and associated energy level shift of the atoms varies in space and therefore produces a potential. When the laser frequency is tuned below atomic resonance ($\delta < 0$), the sign of the interaction is such that atoms are attracted to the maximum of laser field intensity, whereas if $\delta > 0$, the attraction is to the minimum of field intensity.

The simplest imaginable trap (see Fig. 11) consists of a single, strongly focused Gaussian laser beam[26,27] whose intensity at the focus varies transversely with r as $I(r) = I_0 e^{-r^2/w_0^2}$, where w_0 is the beam waist size. Such a trap has a well-studied and important macroscopic classical analog in a phenomenon called *optical tweezers*.[28–30] With the laser light tuned below resonance ($\delta < 0$), the ground-state light shift is everywhere negative, but is largest at the center of the Gaussian beam waist. Ground-state atoms therefore experience a force attracting them toward this center given by the gradient of the light shift. In the longitudinal direction there is also an attractive force that depends on the details of the focusing. Thus this trap produces an attractive force on atoms in three dimensions.

The first optical trap was demonstrated in Na with light detuned below the D-lines.[27] With 220 mW of dye laser light tuned about 650 GHz below the Na transition and focused to a ~10 μm waist, the trap depth was about $15\hbar\gamma$ corresponding to 7 mK. Single-beam dipole force traps can be made with the light detuned by a significant fraction of its frequency from the atomic transition. Such a far-off-resonance trap (FORT) has been developed for Rb atoms using light detuned by nearly 10 percent to the red of the D_1 transition at $\lambda = 795$ nm.[31] Between 0.5 and 1 W of power was focused to a spot about 10 μm in size, resulting in a trap 6 mK deep where the light scattering rate was only a few hundred/s. The trap lifetime was more than half a second.

The dipole force for blue light repels atoms from the high-intensity region, and offers the advantage that trapped atoms will be confined where the perturbations of the light field are minimized.[1] On the other hand, it is not as easy to produce hollow light beams compared with Gaussian beams, and special optical techniques need to be employed.

In a standing wave the light intensity varies from zero at a node to a maximum at an antinode in a distance of $\lambda/4$. Since the light shift, and thus the optical potential, vary on this same scale, it is possible to confine atoms in wavelength-size regions of space. Of course, such tiny traps are usually very shallow, so loading them requires cooling to the μK regime. The momentum of such cold atoms is then so small that their deBroglie wavelengths are comparable to the optical wavelength, and hence to the trap size. In fact, the deBroglie wavelength equals the size of the optical traps ($\lambda/2$) when the momentum is $2\hbar k$, corresponding to a kinetic energy of a few μK. Thus the atomic motion in the trapping volume is not classical, but must be described quantum mechanically. Even atoms whose energy exceeds the trap depth must be described as quantum mechanical particles moving in a periodic potential that display energy band structure.[32]

Atoms trapped in wavelength-sized spaces occupy vibrational levels similar to those of molecules. The optical spectrum can show Raman-like sidebands that result from transitions among the

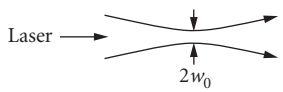

FIGURE 11 A single focused laser beam produces the simplest type of optical trap.

quantized vibrational levels[33,34] as shown in Fig. 19. These quantum states of atomic motion can also be observed by spontaneous or stimulated emission.[33,35] Considerably more detail about atoms in such optical lattices is to be found in Ref. 34.

Magneto-Optical Traps

The most widely used trap for neutral atoms is a hybrid, employing both optical and magnetic fields. The resultant *magneto-optical trap* (MOT) was first demonstrated in 1987.[36] The operation of an MOT depends on both inhomogeneous magnetic fields and radiative selection rules to exploit both optical pumping and the strong radiative force.[1,36] The radiative interaction provides cooling that helps in loading the trap, and enables very easy operation. The MOT is a very robust trap that does not depend on precise balancing of the counter-propagating laser beams or on a very high degree of polarization. The magnetic field gradients are modest and can readily be achieved with simple, air-cooled coils. The trap is easy to construct because it can be operated with a room-temperature cell where alkali atoms are captured from the vapor. Furthermore, low-cost diode lasers can be used to produce the light appropriate for all the alkalis except Na, so the MOT has become one of the least expensive ways to produce atomic samples with temperatures below 1 mK. For these and other reasons it has become the workhorse of cold atom physics, and has also appeared in dozens of undergraduate laboratories.

Trapping in an MOT works by optical pumping of slowly moving atoms in a linearly inhomogeneous magnetic field $B = B(z) \equiv Az$, such as that formed by a magnetic quadrupole field. Atomic transitions with the simple scheme of $J_g = 0 \rightarrow J_e = 1$ have three Zeeman components in a magnetic field, excited by each of three polarizations, whose frequencies tune with field (and therefore with position) as shown in Fig. 12 for one dimension. Two counter-propagating laser beams of opposite circular polarization, each detuned below the zero field atomic resonance by δ, are incident as shown.

Because of the Zeeman shift, the excited state $M_e = +1$ is shifted up for $B > 0$, whereas the state with $M_e = -1$ is shifted down. At position z' in Fig. 12 the magnetic field therefore tunes the

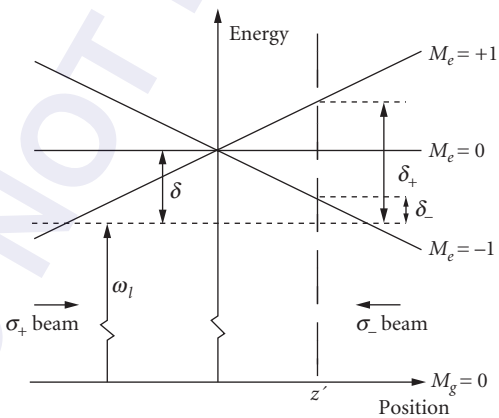

FIGURE 12 Arrangement for a magneto-optical trap (MOT) in 1D. The horizontal dashed line represents the laser frequency seen by an atom at rest in the center of the trap. Because of the Zeeman shifts of the atomic transition frequencies in the inhomogeneous magnetic field, atoms at $z = z'$ are closer to resonance with the σ^- laser beam than with the σ^+ beam, and are therefore driven toward the center of the trap.

$\Delta M = -1$ transition closer to resonance and the $\Delta M = +1$ transition further out of resonance. If the polarization of the laser beam incident from the right is chosen to be σ^- and correspondingly σ^+ for the other beam, then more light is scattered from the σ^- beam than from the σ^+ beam. Thus the atoms are driven toward the center of the trap, where the magnetic field is zero. On the other side of the center of the trap, the roles of the $M_e = \pm 1$ states are reversed, and now more light is scattered from the σ^+ beam, again driving the atoms toward the center.

The situation is analogous to the velocity damping in an optical molasses from the Doppler effect as previously discussed, but here the effect operates in position space, whereas for molasses it operates in velocity space. Since the laser light is detuned below the atomic resonance in both cases, compression and cooling of the atoms is obtained simultaneously in an MOT.

For a description of the motion of the atoms in an MOT, consider the radiative force in the low-intensity limit [see Eq. (10)]. The total force on the atoms is given by $\vec{F} = \vec{F}_+ + \vec{F}_-$, where

$$\vec{F}_\pm = \pm \frac{\hbar \vec{k} \gamma}{2} \frac{s_0}{1 + s_0 + (2\delta_\pm/\gamma)^2} \tag{31}$$

and the detuning $\delta_\pm$ for each laser beam is given by

$$\delta_\pm = \delta \mp \vec{k} \cdot \vec{v} \pm \mu' B/\hbar \tag{32}$$

Here $\mu' \equiv (g_e M_e - g_g M_g)\mu_B$ is the effective magnetic moment for the transition used. Note that the Doppler shift $\omega_D \equiv -\vec{k} \cdot \vec{v}$ and the Zeeman shift $\omega_z = \mu' B/\hbar$ both have opposite signs for opposite beams.

When both the Doppler and Zeeman shifts are small compared to the detuning δ, the denominator of the force can be expanded and the result becomes $\vec{F} = -\beta \vec{v} - \kappa \vec{r}$, where β is the damping coefficient. The spring constant κ arises from the similar dependence of $\vec{F}$ on the Doppler and Zeeman shifts, and is given by $\kappa = \mu' A \beta/\hbar k$. This force leads to damped harmonic motion of the atoms, where the damping rate is given by $\Gamma_{\text{MOT}} = \beta/M$ and the oscillation frequency $\omega_{\text{MOT}} = \sqrt{\kappa/M}$. For magnetic field gradients $A \approx 10$ G/cm, the oscillation frequency is typically a few kHz, and this is much smaller than the damping rate that is typically a few hundred kHz. Thus the motion is overdamped, with a characteristic restoring time to the center of the trap of $2\Gamma_{\text{MOT}}/\omega_{\text{MOT}}^2 \sim$ several ms for typical values of the detuning and intensity of the lasers.

Since the MOT constants β and κ are proportional, the size of the atomic cloud can easily be deduced from the temperature of the sample. The equipartition of the energy of the system over the degrees of freedom requires that the velocity spread and the position spread are related by $k_B T = m v_{\text{rms}}^2 = \kappa z_{\text{rms}}^2$. For a temperature in the range of the Doppler temperature, the size of the MOT should be of the order of a few tenths of a mm, which is generally the case in experiments.

So far the discussion has been limited to the motion of atoms in one dimension. However, the MOT scheme can easily be extended to 3D by using six instead of two laser beams (see Fig. 13). Furthermore, even though very few atomic species have transitions as simple as $J_g = 0 \rightarrow J_e = 1$, the scheme works for any $J_g \rightarrow J_e = J_g + 1$ transition. Atoms that scatter mainly from the σ^+ laser beam will be optically pumped toward the $M_g = +J_g$ substate, which forms a closed system with the $M_e = +J_e$ substate.

The atomic density in an MOT cannot increase without limit as more atoms are added. The density is limited to $\sim 10^{11}/\text{cm}^3$ because the fluorescent light emitted by some trapped atoms is absorbed by others, and this diffusion of radiation presents a repulsive force between the atoms.[37,38] Another limitation lies in the collisions between the atoms, and the collision rate for excited atoms is much larger than for ground-state atoms. Adding atoms to an MOT thus increases the density up to some point, but adding more atoms then expands the volume of the trapped sample.

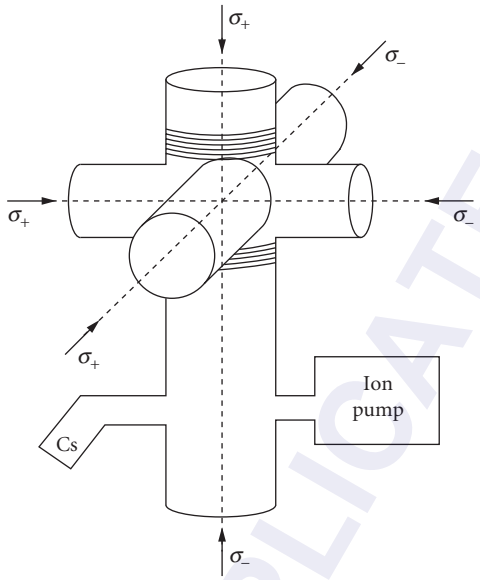

FIGURE 13 The schematic diagram of an MOT shows the coils and the directions of polarization of the six light beams. It has an axial symmetry and various rotational symmetries, so some exchanges would still result in a trap that works, but not all configurations are possible. Atoms are trapped from the background vapor of Cs that arises from a piece of solid Cs in one of the arms of the setup.

20.8 APPLICATIONS

Introduction

The techniques of laser cooling and trapping as described in the previous sections have been used to manipulate the positions and velocities of atoms with unprecedented variety and precision.[1] These techniques are currently used in the laboratories to design new, highly sensitive experiments that move experimental atomic physics research to completely new regimes. In this section only of few of these topics will be discussed. One of the most straightforward of these is the use of laser cooling to increase the brightness of atomic beams, which can subsequently be used for different types of experiments. Since laser cooling produces atoms at very low temperatures, the interaction between these atoms also takes place at such very low energies. The study of these interactions, called *ultracold collisions*, has been a very fruitful area of research in the last decade.

The atom-laser interaction not only produces a viscous environment for cooling the atoms down to very low velocities, but also provides a trapping field for the atoms. In the case of interfering laser beams, the size of such traps can be of the order of a wavelength, thus providing microscopic atomic traps with a periodic structure. These optical lattices described later in this section provide a versatile playground to study the effects of a periodic potential on the motion of atoms and thus simulate the physics of condensed matter. Another topic of considerable interest that will be discussed exists only because laser cooling has paved the way to the observation of Bose-Einstein condensation. This was predicted theoretically more than 80 years ago, but was observed in a dilute gas for the first time in 1996. Finally, the physics of dark states is also discussed in this section. These show a rich variety of effects caused by the coupling of internal and external coordinates of atoms.

Atomic Beam Brightening

In considering the utility of atomic beams for the purposes of lithography, collision studies, or a host of other applications, maximizing the beam intensity may not be the best option. Laser cooling can be used for increasing the phase space density, and this notion applies to both atomic traps and atomic beams. In the case of atomic beams, other quantities than phase space density have been defined as well, but these are not always consistently used. The geometrical solid angle occupied by atoms in a beam is $\Delta\Omega=(\Delta v_\perp/\bar{v})^2$, where $\bar{v}$ is some measure of the longitudinal velocity of atoms in the beam and $\Delta v_\perp$ is a measure of the width of the transverse velocity distribution of the atoms. The total current or flux of the beam is Φ, and the flux density or intensity is $\Phi/\pi(\Delta x)^2$ where Δx is a measure of the beam's radius. Then the beam brightness or radiance R is given by $R = \Phi/\pi(\lambda x_\perp)^2\Delta\Omega$. Optical beams are often characterized by their frequency spread, and, because of the deBroglie relation $\lambda = h/p$, the appropriate analogy for atomic beams is the longitudinal velocity spread. Thus the spectral brightness or brilliance B is given by $B=R\bar{v}/\Delta v_z$. Note that both R and B have the same dimensions as flux density, and this is often a source of confusion. Finally, B is simply related to the 6D phase space density. Recently a summary of these beam properties has been presented in the context of phase space (see Fig. 14).

One of the first beam-brightening experiments was performed by Nellesen et al.[39,40] where a thermal beam of Na was slowed with the chirp technique.[1] Then the slow atoms were deflected out of the main atomic beam and transversely cooled. In a later experiment[41] this beam was fed into a two-dimensional MOT where the atoms were cooled and compressed in the transverse direction by an optical molasses of $\sigma^+ - \sigma^-$ polarized light. Another approach was used by Riis et al. who directed a slowed atomic beam into a hairpin-shaped coil that they called an *atomic funnel*.[42] The wires of this coil generated a two-dimensional quadrupole field that was used as a two-dimensional MOT as described before.

These approaches yield intense beams when the number of atoms in the uncooled beam is already high. However, if the density in the beam is initially low, for example in the case of metastable noble gases or radioactive isotopes, one has to capture more atoms from the source in order

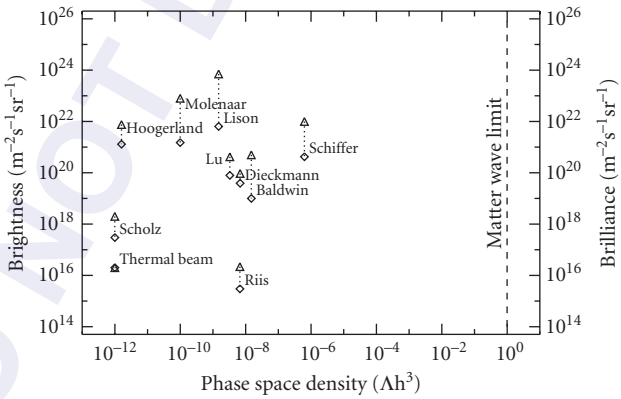

FIGURE 14 Plot of brightness (diamonds) and brilliance (triangles) versus phase space density for various atomic beams cited in the literature. The lower-left point is for a normal thermal beam, and the progression toward the top and right has been steady since the advent of laser cooling. The experimental results are from Riis et al.,[42] Scholz et al.,[80] Hoogerland et al.,[44] Lu et al.,[81] Baldwin et al.,[82] Molenaar et al.,[78] Schiffer et al.,[83] Lison et al.,[84] and Dieckmann et al.[85] The quantum boundary for Bose-Einstein condensation, where the phase space density is unity, is shown by the dashed line on the right. (*Figure adapted from Ref. 84.*)

to obtain an intense beam. Aspect et al.[43] have used a quasi-standing wave of converging laser beams whose incidence angle varied from 87° to 90° to the atomic beam direction, so that a larger solid angle of the source could be captured. In this case they used a few mW of laser light over a distance of 75 mm. One of the most sophisticated approaches to this problem has been developed for metastable Ne by Hoogerland et al.[44] They used a three-stage process to provide a large solid angle capture range and produce a high brightness beam.

Applications to Atomic Clocks

Perhaps one of the most important practical applications of laser cooling is the improvement of atomic clocks. The limitation to both the accuracy and precision of such clocks is imposed by the thermal motion of the atoms, so a sample of laser-cooled atoms could provide a substantial improvement in clocks and in spectroscopic resolution.

The first experiments intended to provide slower atoms for better precision or clocks were attempts at an atomic fountain by Zacharias in the 1950s.[1,45] This failed because collisions depleted the slow atom population, but the advent of laser cooling enabled an atomic fountain because the slow atoms far outnumber the faster ones. The first rf spectroscopy experiments in such a fountain using laser-cooled atoms were reported in 1989 and 1991,[46,47] and soon after that some other laboratories also reported successes.

Some of the early best results were reported by Gibble and Chu.[48,49] They used an MOT with laser beams 6 cm in diameter to capture Cs atoms from a vapor at room temperature. These atoms were launched upward at 2.5 m/s by varying the frequencies of the MOT lasers to form a moving optical molasses as described in Sec. 20.5, and subsequently cooled to below 3 μK. The atoms were optically pumped into one hfs sublevel, then passed through a 9.2-GHz microwave cavity on their way up and again later on their way down. The number of atoms that were driven to change their hfs state by the microwaves was measured versus microwave frequency, and the signal showed the familiar Ramsey oscillations. See Chap. 11, "Coherent Optical Transients," for a discussion of Ramsey fringes. The width of the central feature was 1.4 Hz and the S/N was over 50. Thus the ultimate precision was 1.5 mHz corresponding to $\delta\nu/\nu \cong 10^{-12}/\tau^{1/2}$, where τ is the number of seconds for averaging.

The ultimate limitation to the accuracy of this experiment as an atomic clock was collisions between Cs atoms in the beam. Because of the extremely low relative velocities of the atoms, the cross sections are very large (see the next subsection) and there is a measurable frequency shift.[50] By varying the density of Cs atoms in the fountain, the authors found frequency shifts of the order of a few mHz for atomic density of $10^9/\text{cm}^3$, depending on the magnetic sublevels connected by the microwaves. Extrapolation of the data to zero density provided a frequency determination of $\delta\nu/\nu \cong 4 \times 10^{-14}$. More recently the frequency shift has been used to determine a scattering length of $-400a_0$[51] so that the expected frequency shift is 10^4 times larger than other limitations to the clock at an atomic density of $n = 10^9/\text{cm}^3$. Thus the authors suggest possible improvements to atomic timekeeping of a factor of 1000 in the near future. Even more promising are cold atom clocks in orbit (microgravity) where the interaction time can be very much longer than 1 s.[52]

Ultracold Collisions

Laser-cooling techniques were developed in the early 1980s for a variety of reasons, such as high-resolution spectroscopy.[1] During the development of the techniques to cool and trap atoms, it became apparent that collisions between cold atoms in optical traps was one of the limiting factors in the achievement of high-density samples. Trap loss experiments revealed that the main loss mechanisms were caused by laser-induced collisions. Further cooling and compression could only be achieved by techniques not exploiting laser light, such as evaporative cooling in magnetic traps. Elastic collisions between atoms in the ground state are essential in that case for the rethermalization of the sample, whereas inelastic collisions lead to destruction of the sample. Knowledge about collision physics at these low energies is therefore essential for the development of high-density samples of atoms using either laser or evaporative cooling techniques.

Ground-state collisions play an important role in evaporative cooling. Such elastic collisions are necessary to obtain a thermalization of the gas after the trap depth has been lowered, and a large elastic cross section is essential to obtain a rapid thermalization. Inelastic collisions, on the other hand, can release enough energy to accelerate the atoms to energies too high to remain trapped. Ground-state collisions for evaporative cooling can be described by one parameter, the scattering length a. At temperatures below T_D, these collisions are in the s-wave scattering regime where only the phase shift δ_0 of the lowest partial wave $\ell=0$ is important. Moreover, for sufficiently low energies, such collisions are governed by the Wigner threshold laws where the phase shift δ_0 is inversely proportional to the wavevector k of the particle motion. Taking the limit for low energy gives the proportionality constant, defined as the scattering length $a=-\lim_{k\to 0}(\delta_0/k)$. The scattering length plays an important role not only in ultracold collisions, but also in the formation of Bose-Einstein condensates. In the Wigner threshold regime the cross section approaches a constant, $\sigma = 8\pi a^2$.[53]

Although ground-state collisions are important for evaporative cooling and BEC, they do *not* provide a very versatile research field from a collision physics point of view. The situation is completely different for the excited-state collisions. For typical temperatures in optical traps, the velocity of the atoms is sufficiently low that atoms excited at long range by laser light decay before the collision takes place. Laser excitation for low-energy collisions has to take place during the collision. By tuning the laser frequency, the collision dynamics can be altered and information on the states formed in the molecular system can be obtained. This is the basis of the new technique of photoassociative spectroscopy, which for the first time has identified purely long-range states in diatomic molecules.[1,54]

For atoms colliding in laser light closely tuned to the S-P transition, the potential is a C_3/R^3 dipole-dipole interaction when one of the atoms is excited. Absorption takes place at the Condon point R_C given by $\hbar\delta=-C_3/R_C^3$ or $R_C=(C_3/\hbar|\delta|)^{1/3}$. Note that the light has to be tuned below resonance, which is mostly the case for laser cooling. The Condon point for laser light detuned a few γ below resonance is typical 1000 to 2000 a_0.

Once the molecular complex becomes excited, it can evolve to smaller internuclear distances before emission takes place. Two particular cases are important for trap loss: (1) the emission of the molecular complex takes place at much smaller internuclear distance, and the energy gained between absorption and emission of the photon is converted into kinetic energy, or (2) the complex undergoes a transition to another state and the potential energy difference between the two states is converted into kinetic energy. In both cases the energy gain can be sufficient to eject one or both atoms out of the trap. In the case of the alkalis, the second reaction can take place because of the different fine-structure states and the reaction is denoted as a fine-structure changing collision. The first reaction is referred to as *radiative escape*.

Trap loss collisions in MOTs have been studied to great extent, but results of these studies have to be considered with care. In most cases, trap loss is studied by changing either the frequency or the intensity of the trapping laser, which also changes the conditions of the trap. The collision rate is not only changed because of a change in the collision cross section, but also because of changes in both the density and temperature of the atoms in the trap. Since these parameters cannot be determined with high accuracy in a high-density trap, where effects like radiation trapping can play an important role, obtaining accurate results this way is very difficult.

The first description of such processes was given by Gallagher and Pritchard.[55] In their semiclassical model (the GP-model), the laser light is assumed to be weak enough that the excitation rate can be described by a quasi-static excitation probability. Atoms in the excited state are accelerated toward one another by the C_3/R^3 potential. In order to calculate the survival of the atoms in the excited state, the elapsed time between excitation and arrival is calculated. The total number of collisions is then given by the number of atoms at a certain distance, the fraction of atoms in the excited state, and the survival rate, integrated over all distances. For small detunings, corresponding to large internuclear distances, the excitation rate is appreciable over a very large range of internuclear distances. However the excitation occurs at large internuclear distances, so the survival rate of the excited atoms is small. For large detunings the excitation is located in a small region at small internuclear distances, so the total excitation rate is small, but the survival rate is large. As a result of this competition, the collision rate peaks at intermediate detunings.

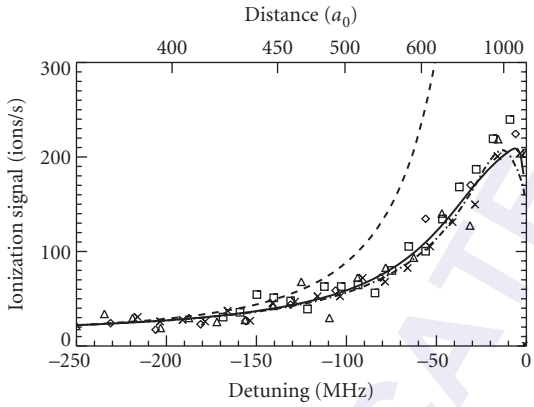

FIGURE 15 The frequency dependence for the associative ionization rate of cold He* collisions. The experimental results (symbols) are compared with the semiclassical model (solid line), JV-model (dashed line), and modified JV-model (dashed-dotted line). The axis on top of the plot shows the Condon point, where the excitation takes place.

Another description of optical collisions is given by Julienne and Vigue.[56] Their description of optical collisions (JV model) is quantum mechanical for the collision process, where they make a partial wave expansion of the incoming wavefunction. The authors describe the excitation process in the same way as it was done in the GP model. Thus the excitation is localized around the Condon point with a probability given by the quasi-static Lorentz formula.

In still another approach, a completely semiclassical description of optical collisions has been given by Mastwijk et al.[57] These authors start from the GP model, but make several important modifications. First, the Lorentz formula is replaced by the Landau-Zener formula. Second, the authors consider the motion of the atoms in the collision plane. At the Condon point, where the excitation takes place, the trajectory of the atom in the excited state is calculated by integration of the equation of motion. The results for their model are shown in Fig. 15, and are compared with experiment and the JV model. The agreement between the theory and experiment is rather good. For the JV model two curves are shown. The first curve shows the situation for the original JV model. The second curve shows the result of a modified JV model, where the quasi-static excitation rate is replaced by the Landau-Zener formula. The large discrepancies between the results for these two models indicates that it is important to use the correct model for the excitation. The agreement between the modified JV model and the semiclassical model is good, indicating that the dynamics of optical collisions can be described correctly quantum mechanically or semiclassically. Since the number of partial waves in the case of He* is in the order of 10, this is to be expected.

The previous description of optical collisions applies to the situation that the quasi-molecule can be excited for each frequency of the laser light. However, the quasi-molecule has well-defined vibrational and rotational states and the excitation frequency has to match the transition frequency between the ground and excited rovibrational states. Far from the dissociation limit, the rovibrational states are well-resolved and many resonances are observed. This has been the basis of the method of photo-associative spectroscopy (PAS) for alkali-metal atoms, where detailed information on molecular states of alkali dimers have been obtained recently. Here *photo-association* refers to the process where a photon is absorbed to transfer the system from the ground to the excited state where the two atoms are bound by their mutual attraction.

The process of PAS is depicted graphically in Fig. 16. When two atoms collide in the ground state, they can be excited at a certain internuclear distance to the excited molecular state and the two atoms may remain bound after the excitation and form a molecule. This transient molecule lives as long as the system remains excited. The number of rotational states that can contribute to the spectrum is

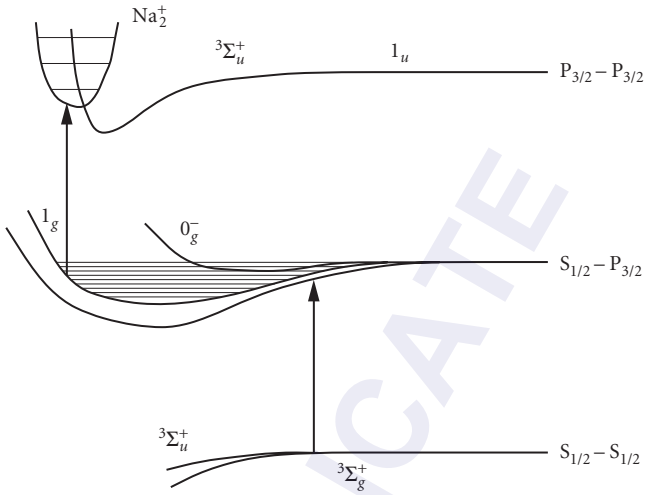

FIGURE 16 Photoassociation spectroscopy of Na. By tuning the laser below atomic resonance, molecular systems can be excited to the first excited state in which they are bound. By absorption of a second photon the system can be ionized, providing a high detection efficiency.

small for low temperature. The resolution is limited only by the linewidth of the transition, which is comparable to the natural linewidth of the atomic transition. With PAS, molecular states can be detected with a resolution of ≈ 10 MHz, which is many orders of magnitude better than traditional molecular spectroscopy. The formation of the molecules is probed by absorption of a second photon of the same color, which can ionize the molecule.

PAS has also been discussed in the literature as a technique to produce cold molecules. The methods discussed employ a double resonance technique, where the first color is used to create a well-defined rovibrational state of the molecule and a second color causes stimulated emission of the system to a well-defined vibrational level in the ground state. Although such a technique has not yet been shown to work experimentally, cold molecules have been produced in PAS recently using a simpler method.[58] The 0_g^- state in Cs_2 has a double-well structure, where the top of the barrier is accidentally close to the asymptotic limit. Thus atoms created in the outer well by PAS can tunnel through the barrier to the inner well, where there is a large overlap of the wavefunction with the vibrational levels in the ground state. These molecules are then stabilized against spontaneous decay and can be observed. The temperature of the cold molecules has been detected and is close to the temperature of the atoms. This technique and similar techniques will be very important for the production and study of cold molecules.

Optical Lattices

In 1968, Letokhov[59] suggested that it is possible to confine atoms in the wavelength-size regions of a standing wave by means of the dipole force that arises from the light shift. This was first accomplished in 1987 in one dimension with an atomic beam traversing an intense standing wave.[60] Since then, the study of atoms confined in wavelength-size potential wells has become an important topic in optical control of atomic motion because it opens up configurations previously accessible only in condensed matter physics using crystals.

The basic ideas of the quantum mechanical motion of particles in a periodic potential were laid out in the 1930s with the Kronig-Penney model and Bloch's theorem, and optical lattices offer important opportunities for their study. For example, these lattices can be made essentially free of

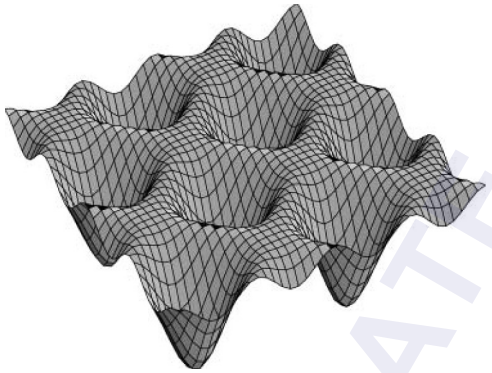

FIGURE 17 The "egg-crate" potential of an optical lattice shown in two dimensions. The potential wells are separated by $\lambda/2$.

defects with only moderate care in spatially filtering the laser beams to assure a single transverse mode structure. Furthermore, the shape of the potential is exactly known, and doesn't depend on the effect of the crystal field or the ionic energy level scheme. Finally, the laser parameters can be varied to modify the depth of the potential wells without changing the lattice vectors, and the lattice vectors can be changed independently by redirecting the laser beams. The simplest optical lattice to consider is a one-dimensional pair of counter-propagating beams of the same polarization, as was used in the first experiment.[60]

Because of the transverse nature of light, any mixture of beams with different $\vec{k}$-vectors necessarily produces a spatially periodic, inhomogeneous light field. The importance of the "egg-crate" array of potential wells arises because the associated atomic light shifts can easily be comparable to the very low average atomic kinetic energy of laser-cooled atoms. A typical example projected against two dimensions is shown in Fig. 17.

The name *optical lattice* is used rather than *optical crystal* because the filling fraction of the lattice sites is typically only a few percent (as of 1999). The limit arises because the loading of atoms into the lattice is typically done from a sample of trapped and cooled atoms, such as an MOT for atom collection, followed by an optical molasses for laser cooling. The atomic density in such experiments is limited to a few times $10^{11}/\text{cm}^3$ by collisions and multiple light scattering. Since the density of lattice sites of size $\lambda/2$ is a few times $10^{13}/\text{cm}^3$, the filling fraction is necessarily small.

At first thought it would seem that a rectangular 2D or 3D optical lattice could be readily constructed from two or three mutually perpendicular standing waves.[61,62] However, a sub-wavelength movement of a mirror caused by a small vibration could change the relative phase of the standing waves. In 1993 a very clever scheme was described.[63] It was realized that an N-dimensional lattice could be created by only $n + 1$ traveling waves rather than $2n$. Instead of producing optical wells in 2D with four beams (two standing waves), these authors used only three. The $\vec{k}$-vectors of the coplanar beams were separated by $2\pi/3$, and they were all linearly polarized in their common plane (not parallel to one another). The same immunity to vibrations was established for a 3D optical lattice by using only four beams arranged in a quasi-tetrahedral configuration. The three linearly polarized beams of the 2D arrangement just described were directed out of the plane toward a common vertex, and a fourth circularly polarized beam was added. All four beams were polarized in the same plane.[63] The authors showed that such a configuration produced the desired potential wells in 3D.

The NIST group studied atoms loaded into an optical lattice using Bragg diffraction of laser light from the spatially ordered array.[64] They cut off the laser beams that formed the lattice, and before the atoms had time to move away from their positions, they pulsed on a probe laser beam at the Bragg angle appropriate for one of the sets of lattice planes. The Bragg diffraction not only enhanced the reflection of the probe beam by a factor of 10^5, but by varying the time between the shut-off of the lattice and turn-on of the probe, they could measure the "temperature" of the atoms

in the lattice. The reduction of the amplitude of the Bragg scattered beam with time provided some measure of the diffusion of the atoms away from the lattice sites, much like the Debye-Waller factor in X-ray diffraction.

Laser cooling has brought the study of the motion of atoms into an entirely new domain where the quantum mechanical nature of their center-of-mass motion must be considered.[1] Such exotic behavior for the motion of whole atoms, as opposed to electrons in the atoms, has not been considered before the advent of laser cooling simply because it is too far out of the range of ordinary experiments. A series of experiments in the early 1990s provided dramatic evidence for these new quantum states of motion of neutral atoms, and led to the debut of de Broglie wave atom optics.

The limits of laser cooling discussed in Sec. 20.6 suggest that atomic momenta can be reduced to a "few" times $\hbar k$. This means that their de Broglie wavelengths are equal to the optical wavelengths divided by a "few." If the depth of the optical potential wells is high enough to contain such very slow atoms, then their motion in potential wells of size $\lambda/2$ must be described quantum mechanically, since they are confined to a space of size comparable to their de Broglie wavelengths. Thus they do not oscillate in the sinusoidal wells as classical localizable particles, but instead occupy discrete, quantum-mechanical bound states, as shown in the lower part of Fig. 18.

The group at NIST also developed a new method that superposed a weak probe beam of light directly from the laser upon some of the fluorescent light from the atoms in a 3D optical molasses, and directed the light from these combined sources onto on a fast photodetector.[65] The resulting beat signal carried information about the Doppler shifts of the atoms in the optical lattices.[34] These Doppler shifts were expected to be in the sub-MHz range for atoms with the previously measured 50 μK temperatures. The observed features confirmed the quantum nature of the motion of atoms in the wavelength-size potential wells (see Fig. 19).[16]

In the 1930s Bloch realized that applying a uniform force to a particle in a periodic potential would not accelerate it beyond a certain speed, but instead would result in Bragg reflection when its

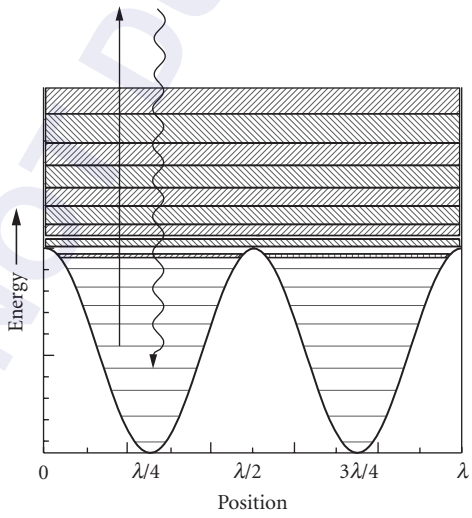

FIGURE 18 Energy levels of atoms moving in the periodic potential of the light shift in a standing wave. There are discrete bound states deep in the wells that broaden at higher energy, and become bands separated by forbidden energies above the tops of the wells. Under conditions appropriate to laser cooling, optical pumping among these states favors populating the lowest ones as indicated schematically by the arrows.

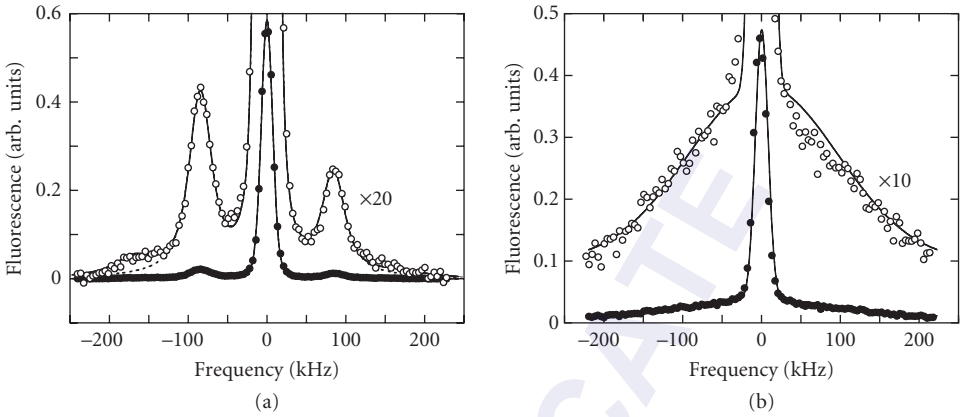

FIGURE 19 (*a*) Fluorescence spectrum in a 1D lin ⊥ lin optical molasses. Atoms are first captured and cooled in an MOT, then the MOT light beams are switched off leaving a pair of lin ⊥ lin beams. Then the measurements are made with $\delta = -4\gamma$ at low intensity. (*b*) Same as (*a*) except the 1D molasses is $\sigma^+ - \sigma^-$ which has no spatially dependent light shift and hence no vibrational motion. (*Figure from Ref. 34.*)

de Broglie wavelength became equal to the lattice period. Thus an electric field applied to a conductor could not accelerate electrons to a speed faster than that corresponding to the edge of a Brillouin zone, and that at longer times the particles would execute oscillatory motion. Ever since then, experimentalists have tried to observe these Bloch oscillations in increasingly pure and/or defect-free crystals.

Atoms moving in optical lattices are ideally suited for such an experiment, as was beautifully demonstrated in 1996.[66] The authors loaded a one-dimensional lattice with atoms from a 3D molasses, further narrowed the velocity distribution, and then instead of applying a constant force, simply changed the frequency of one of the beams of the ID lattice with respect to the other in a controlled way, thereby creating an accelerating lattice. Seen from the atomic reference frame, this was the equivalent of a constant force trying to accelerate them. After a variable time t_a the 1D lattice beams were shut off and the measured atomic velocity distribution showed beautiful Bloch oscillations as a function of t_a. The centroid of the very narrow velocity distribution was seen to shift in velocity space at a constant rate until it reached $v_r = \hbar k/M$, and then it vanished and reappeared at $-v_r$ as shown in Fig. 20. The shape of the "dispersion curve" allowed measurement of the "effective mass" of the atoms bound in the lattice.

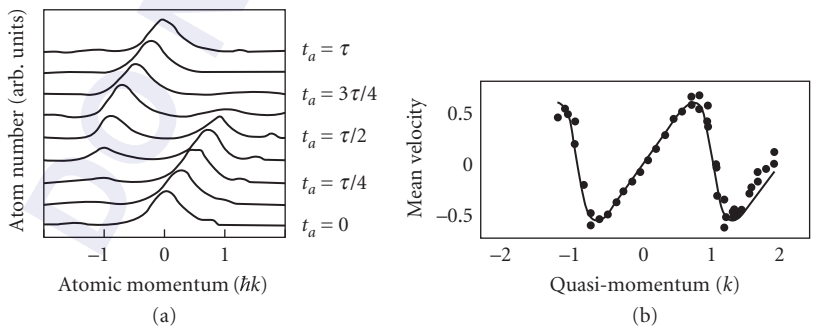

FIGURE 20 Plot of the measured velocity distribution versus time in the accelerated 1D lattice. The atoms accelerate only to the edge of the Brillouin zone where the velocity is $+v_r$ and then the velocity distribution appears at $-v_r$. (*Figure from Ref. 66.*)

Bose-Einstein Condensation

In 1924 S. Bose found the correct way to evaluate the distribution of identical entities, such as Planck's radiation quanta, that allowed him to calculate the Planck spectrum using the methods of statistical mechanics. Within a year Einstein had seized upon this idea, and generalized it to identical particles with discrete energies. This distribution is

$$N(E)=\frac{1}{e^{\beta(E-\mu)}-1} \tag{33}$$

where $\beta \equiv 1/k_B T$ and μ is the chemical potential that vanishes for photons: Eq. (33) with $\mu = 0$ is exactly the Planck distribution. Einstein observed that this distribution has the peculiar property that for sufficiently low average energy (i.e., low temperature), the total energy could be minimized by having a discontinuity in the distribution for the population of the lowest allowed state.

The condition for this Bose-Einstein condensation (BEC) in a gas can be expressed in terms of the de Broglie wavelength λ_{dB} associated with the thermal motion of the atoms as $n\lambda_{\mathrm{dB}}^3 \geq 2.612\ldots$, where n is the spatial density of the atoms. In essence, this means that the atomic wave functions must overlap one another.

The most familiar elementary textbook description of BEC focuses on noninteracting particles. However, particles *do* interact, and the lowest order approximation that is widely used to account for the interaction takes the form of a mean-field repulsive force. It is inserted into the Hamiltonian for the motion of each atom in the trap (*n.b.*, not for the internal structure of the atom) as a term V_{int} proportional to the local density of atoms. Since this local density is itself $|\Psi|^2$, it makes the Schrödinger equation for the atomic motion nonlinear, and the result bears the name *Gross-Pitaevski equation*. For N atoms in the condensate it is written

$$\left[-\frac{\hbar^2}{2M}\nabla_{\vec{R}}^2 + V_{\mathrm{trap}}(\vec{R}) + NV_{\mathrm{int}}|\Psi(\vec{R})|^2\right]\Psi(\vec{R}) = E_N\Psi(\vec{R}) \tag{34}$$

where $\vec{R}$ is the coordinate of the atom in the trap, $V_{\mathrm{trap}}(\vec{R})$ is the potential associated with the trap that confines the atoms in the BEC, and $V_{\mathrm{int}} \equiv 4\pi\hbar^2 a/M$ is the coefficient associated with strength of the mean field interaction between the atoms. Here a is the scattering length, and M is the atomic mass.

For $a > 0$ the interaction is repulsive so that a BEC would tend to disperse. This is manifest for a BEC confined in a harmonic trap by having its wavefunction somewhat more spread out and flatter than a Gaussian. By contrast, for $a < 0$ the interaction is attractive and the BEC eventually collapses. However, it has been shown that there is metastability for a sufficiently small number of particles with $a < 0$ in a harmonic trap, and that a BEC can be observed in vapors of atoms with such negative scattering length as ^{7}Li.[67–69] This was initially somewhat controversial.

Solutions to this highly nonlinear Eq. (34), and the ramifications of those solutions, form a major part of the theoretical research into BEC. Note that the condensate atoms all have exactly the same wave function, which means that adding atoms to the condensate does not increase its volume, just like the increase of atoms to the liquid phase of a liquid-gas mixture makes only an infinitesimal volume increase of the sample. The consequences of this predicted condensation are indeed profound. For example, in a harmonic trap, the lowest state's wavefunction is a Gaussian. With so many atoms having *exactly* the same wave function they form a new state of matter, unlike anything in the familiar experience.

Achieving the conditions required for BEC in a low-density atomic vapor requires a long and difficult series of cooling steps. First, note that an atomic sample cooled to the recoil limit T_r would need to have a density of a few times 10^{13} atoms/cm^3 in order to satisfy BEC. However, atoms cannot be optically cooled at this density because the resulting vapor would have an

absorption length for on-resonance radiation approximately equal to the optical wavelength. Furthermore, collisions between ground- and excited-state atoms have such a large cross section that at this density the optical cooling would be extremely ineffective. In fact, the practical upper limit to the atomic density for laser cooling in a 3D optical molasses (see Sec. 20.6) or MOT (see Sec. 20.7) corresponds to $n \sim 10^{10}$ atoms/cm^3. Thus it is clear that the final stage of cooling toward a BEC must be done in the dark. The process typically begins with an MOT for efficient capture of atoms from a slowed beam or from the low-velocity tail of a Maxwell-Boltzmann distribution of atoms at room temperature. Then a polarization gradient optical molasses stage is initiated that cools the atomic sample from the mK temperatures of the MOT to a few times T_r. For the final cooling stage, the cold atoms are confined in the dark in a purely magnetic trap and a forced evaporative cooling process is used to cool.[1]

The observation of BEC in trapped alkali atoms in 1995 has been the largest impetus to research in this exciting field. As of this writing (1999), the only atoms that have been condensed are Rb,[70] Na,[71] Li,[72] and H.[73] The case of Cs is special because, although BEC is certainly possible, the presence of a near-zero energy resonance severely hampers its evaporative cooling rate.

The first observations of BEC were in Rb,[70] Li,[72] and Na,[71] and the observation was done using ballistic techniques. The results from one of the first experiments are shown in Fig. 21. The three panels show the spatial distribution of atoms some time after release from the trap. From the ballistic parameters, the size of the BEC sample as well as its shape and the velocity distribution of its atoms could be inferred. For temperatures too high for BEC, the velocity distribution is Gaussian but asymmetrical. For temperatures below the transition to BEC, the distribution is also not symmetrical, but now shows the distinct peak of a disproportionate number of very slow atoms corresponding to the ground state of the trap from which they were released. As the temperature is lowered further, the number of atoms in the narrow feature increases very rapidly, a sure signature that this is truly a BEC and not just very efficient cooling.

The study of this "new form" of matter has spawned innumerable subtopics and has attracted enormous interest. Both theorists and experimentalists are addressing the questions of its behavior

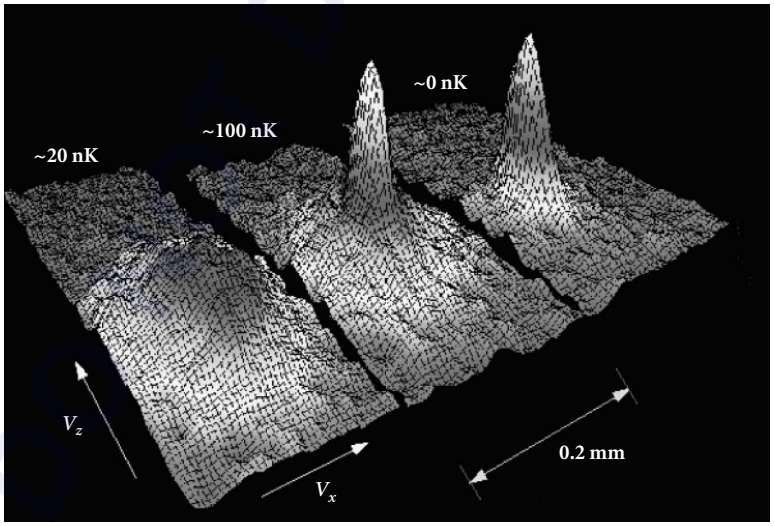

FIGURE 21 Three panels showing the spatial distribution of atoms after release from the magnetostatic trap following various degrees of evaporative cooling. In the first one, the atoms were cooled to just before the condition for BEC was met, in the second one, to just after this condition, and in the third one to the lowest accessible temperature consistent with leaving some atoms still in the trap. (*Figure taken from the JILA Web page.*)

in terms of rigidity, acoustics, coherence, and a host of other properties. Extraction of a coherent beam of atoms from a BEC has been labeled an "atom laser" and will surely open the way for new developments in atom optics.[1]

Dark States

The BEC discussed in the previous subsection is an example of the importance of quantum effects on atomic motion. It occurs when the atomic de Broglie wavelength λ_{dB} and the interatomic distances are comparable. Other fascinating quantum effects occur when atoms are in the light and λ_{dB} is comparable to the optical wavelength. Some topics connected with optical lattices have already been discussed, and the *dark states* described here are another important example. These are atomic states that cannot be excited by the light field.

The quantum description of atomic motion requires that the energy of such motion be included in the Hamiltonian. The total Hamiltonian for atoms moving in a light field would then be given by

$$\mathcal{H} = \mathcal{H}_{\text{atom}} + \mathcal{H}_{\text{rad}} + \mathcal{H}_{\text{int}} + \mathcal{H}_{\text{kin}} \tag{35}$$

where $\mathcal{H}_{\text{atom}}$ describes the motion of the atomic electrons and gives the internal atomic energy levels, $\mathcal{H}_{\text{rad}}$ is the energy of the radiation field and is of no concern here because the field is not quantized, $\mathcal{H}_{\text{int}}$ describes the excitation of atoms by the light field and the concomitant light shifts, and $\mathcal{H}_{\text{kin}}$ is the kinetic energy E_k of the motion of the atoms' center of mass. This Hamiltonian has eigenstates of not only the internal energy levels and the atom-laser interaction that connects them, but also of the kinetic energy operator $\mathcal{H}_{\text{kin}} \equiv \mathcal{P}^2/2M$. These eigenstates will therefore be labeled by quantum numbers of the atomic states as well as the center of mass momentum p. For example, an atom in the ground state, $|g;p\rangle$, has energy $E_g + p^2/2M$ which can take on a continuous range of values.

To see how the quantization of the motion of a two-level atom in a monochromatic field allows the existence of a velocity-selective dark state, consider the states of a two-level atom with single internal ground and excited levels, $|g;p\rangle$ and $|e;p'\rangle$. Two ground eigenstates $|g;p\rangle$ and $|g;p''\rangle$ are generally not coupled to one another by an optical field except in certain cases. For example, in oppositely propagating light beams (1D) there can be absorption-stimulated emission cycles that connect $|g;p\rangle$ to itself or to $|g;p\pm 2\rangle$ (in this section, momentum is measured in units of $\hbar k$). The initial and final E_k of the atom differ by $\pm 2(\mathrm{p} \pm 1)/M$ so energy conservation requires $p = \mp 1$ and is therefore velocity-selective (the energy of the light field is unchanged by the interaction since all the photons in the field have energy $\hbar\omega_\ell$).

The coupling of these two degenerate states by the light field produces off-diagonal matrix elements of the total Hamiltonian $\mathcal{H}$ of Eq. (35), and subsequent diagonalization of it results in the new ground eigenstates of $\mathcal{H}$ given by (see Fig. 22) $|\pm\rangle \equiv (|g;-1\rangle \pm |g;+1\rangle)/\sqrt{2}$. The excitation rate of these eigenstates $|\pm\rangle$ to $|e;0\rangle$ is proportional to the square of the electric dipole matrix element $\vec{\mu}$ given by

$$|\langle e;0|\vec{\mu}|\pm\rangle|^2 = |\langle e;0|\vec{\mu}|g;-1\rangle \pm \langle e;0|\vec{\mu}|g;+1\rangle|^2/2 \tag{36}$$

This vanishes for $|-\rangle$ because the two terms on the right-hand side of Eq. (36) are equal since $\vec{\mu}$ does not operate on the external momentum of the atom (dotted line of Fig. 22). Excitation of $|\pm\rangle$ to $|e;\pm 2\rangle$ is much weaker since it's off resonance because its energy is higher by $4\hbar\omega_r = 2\hbar^2k^2/M$, so that the required frequency is higher than to $|e;0\rangle$. The resultant detuning is $4\omega_r = 8\varepsilon(\gamma/2)$, and for $\varepsilon \sim 0.5$, this is large enough so that the excitation rate is small, making $|-\rangle$ quite dark. Excitation to any state other than $|e;\pm 2\rangle$ or $|e;0\rangle$ is forbidden by momentum conservation. Atoms are therefore optically pumped into the dark state $|-\rangle$ where they stay trapped, and since their momentum components are fixed, the result is velocity-selective coherent population trapping (VSCPT).

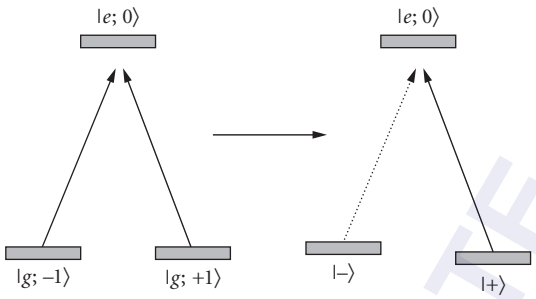

FIGURE 22 Schematic diagram of the transformation of the eigenfunctions from the internal atomic states $|g;p\rangle$ to the eigenstates $|\pm\rangle$. The coupling between the two states $|g;p\rangle$ and $|g;p''\rangle$ by Raman transitions mixes them, and since they are degenerate, the eigenstates of $\mathcal{H}$ are the nondegenerate states $|\pm\rangle$.

A useful view of this dark state can be obtained by considering that its components $|g;\pm1\rangle$ have well-defined momenta, and are therefore completely delocalized. Thus they can be viewed as waves traveling in opposite directions but having the same frequency, and therefore they form a standing de Broglie wave. The fixed spatial phase of this standing wave relative to the optical standing wave formed by the counterpropagating light beams results in the vanishing of the spatial integral of the dipole transition matrix element so that the state cannot be excited. This view can also help to explain the consequences of p not exactly equal ±1, where the de Broglie wave would be slowly drifting in space. It is common to label the average of the momenta of the coupled states as the *family momentum*, $\mathcal{P}$, and to say that these states form a *closed family*, having family momentum $\mathcal{P} = 0$.[74,75]

In the usual case of laser cooling, atoms are subject to both a damping force and to random impulses arising from the discrete photon momenta $\hbar k$ of the absorbed and emitted light. These can be combined to make a force versus velocity curve as shown in Fig. 23*a*. Atoms with $\mathcal{P} \neq 0$ are always subject to the light field that optically pumps them into the dark state and thus produces random impulses as shown in Fig. 23*b*. There is no damping force in the most commonly studied case of a real atom, the $J = 1 \rightarrow 1$ transition in He^*, because the Doppler and polarization gradient cooling cancel one another as a result of a numerical "accident" for this particular case.

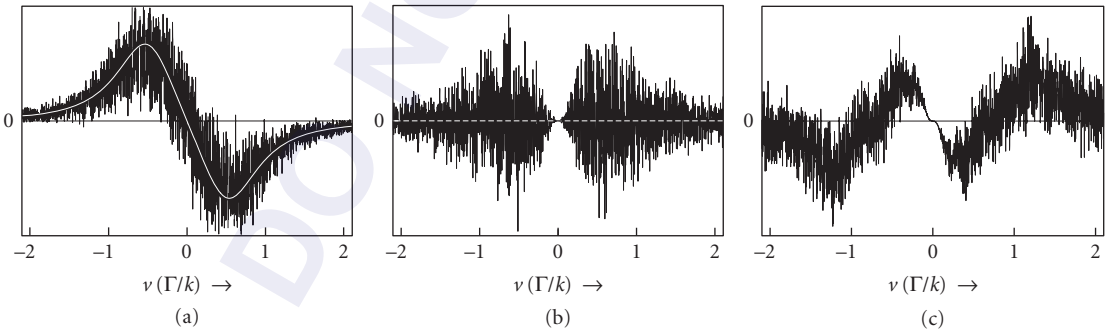

FIGURE 23 Calculated force versus velocity curves for different laser configurations showing both the average force and a typical set of simulated fluctuations. Part (*a*) shows the usual Doppler cooling scheme that produces an atomic sample in steady state whose energy width is $\hbar\gamma/2$. Part (*b*) shows VSCPT as originally studied in Ref. 74 with no damping force. Note that the fluctuations vanish for $\mathcal{P} = 0$ because the atoms are in the dark state. Part (*c*) shows the presence of both a damping force and VSCPT. The fluctuations vanish for $\mathcal{P} = 0$, and both damping *and* fluctuations are present at $\mathcal{P} \neq 0$.

Figures 23*a* and *b* should be compared to show the velocity dependence of the sum of the damping and random forces for the two cases of ordinary laser cooling and VSCPT. Note that for VSCPT the momentum diffusion vanishes when the atoms are in the dark state at $\mathcal{P} = 0$, so they can collect there. In the best of both worlds, a damping force would be combined with VSCPT as shown in Fig. 23*c*. Such a force was predicted in Ref. 76 and was first observed in 1996.[77]

21.1 GLOSSARY

a_0	normalized peak vector potential of the intense laser pulse
a_{Bohr}	Bohr radius
b	confocal parameter
c	speed of light
e	charge of the electron
$\boldsymbol{f}_p$	relativistic ponderomotive force
E_a	atomic field strength
E_{cr}	Schwinger critical electric field
E_0	peak electric field amplitude of the intense laser pulse
f_x	laser fractional absorption for x process
k_0	laser wavenumber
k_e	electron wavenumber
$\text{KE}_{e\text{-,ATI}}$	kinetic energy of electrons
I	laser intensity
I_{H}	ionization potential of hydrogen
I_p	ionization potential
ℓ	plasma scale length
L_c	coherence length
m_e, m_i	mass of the electron, ion
n	refractive index
n_2	nonlinear refractive index
n_{crit}	electron critical density
n_e, n_i	electron and ion density
p	effective harmonic nonlinear order

$P_{\|\|,\perp}$	polarizability tensor of a molecule parallel and perpendicular to molecular axis
P_C	critical power for self-focusing
q	harmonic order
Q_{clust}	charge on cluster from outer ionization
R_0	initial radius of a cluster
R_c	critical ionization distance in molecules
u_{ion}	ion velocity
U_p	ponderomotive potential energy
v_g	laser group velocity
v_{osc}	electron oscillation velocity
v_D	electron drift velocity
w	$1/e^2$ focal spot radius of a focused Gaussian laser beam
W_x	ionization rate for x process
z_R	Rayleigh range of focused laser
Z	charge state of ions
α	fine structure constant
β_{Rot}	molecular rotation constant
Δk	phase mismatch
ε_{CE}	Coulomb explosion energy
ε_D	dielectric function
γ	relativistic Lorentz factor for electrons
γ_{osc}	cycle-averaged relativistic Lorentz factor for electrons in strong field
γ_{SRS}	stimulated Raman scattering growth rate
Λ	Coulomb logarithm
λ_{Debye}	plasma Debye length
λ_p	optical scale length in an overdense plasma
ν_{ei}	electron-ion collision frequency
σ_N	generalized N-photon cross section for multiphoton ionization
σ_T	Thomson scattering cross section
τ_p	laser pulse duration
ω_a	atomic unit of frequency
ω_{BG}	Bohm-Gross frequency
ω_0	angular oscillation frequency of the intense laser pulse
ω_p	plasma frequency
$\omega_{S,A}$	Stokes, anti-Stokes frequency

21.2 INTRODUCTION AND HISTORY

Strong field physics (or "high field physics" in much of the literature) refers to the phenomena that occur during the interaction of intense electromagnetic waves with matter of various forms. It is characterized by interactions that are often highly nonlinear. While such interactions have been accessed with microwave radiation,[1] traditionally, strong field physics has been studied with intense optical and near-infrared (IR) pulses generated by high-intensity lasers. These interactions occur in a regime in which the electric field of the optical wave dominates the motion and dynamics of electrons subject to these fields. At the highest intensities that are now accessible, the motion of

electrons can become relativistic during each optical cycle, and the magnetic field of the light pulse starts to become important in affecting the motion of electrons in the field.

While it is possible to access strong field effects with what are presently considered rather modest intensities in certain situations, it is customary to consider strong field physics as the regime in which the light intensity is high enough that the peak electric field of the wave $E_0 = \sqrt{8\pi I/c}$ becomes comparable to the atomic unit of electric field $E_a = e/a_{\text{Bohr}}^2 = 5.1\times10^9$ V/cm, the field felt by an electron in a hydrogen atom. Light acquires this electric field at an intensity of 3.5×10^{16} W/cm^2, though there are many strong field physics effects which manifest themselves at fields of about 10 percent of E_a (at intensity ~10^{14} W/cm^2). At these intensities light interaction with atoms can no longer be described by standard perturbation theory, and light interactions with electrons in a plasma dominate the thermal motion of the free electrons. At higher intensities, beyond 10^{18} W/cm^2, the field becomes high enough that an electron in an optical frequency wave can be accelerated to relativistic velocity in less than one optical cycle. Such intensities are also characterized by high magnetic fields and optical forces. For example, in a pulse with intensity of 10^{18} W/cm^2, an intensity quite modest by modern standards, the peak electric field is 3×10^{10} V/cm and the optical magnetic field is 100 MG. The light pressure, I/c, is ~ 0.3 Gbar. The highest intensity lasers can now reach intensity approaching 10^{22} W/cm^2.

The theoretical study of high field physics can be said to have started in earnest with a classic paper by L. V. Keldysh in 1964.[2] In this paper, the rate of ionization of an atom or ion in a strong laser field was first derived with a nonperturbative theory. The first real experimental observation of nonperturbative high-field effects occurred in the ground breaking experiment of Agostini et al. in 1979.[3] Their experiment observed, for the first time, truly nonperturbative multiphoton effects in laser-atom interactions by examining photo-electron production from intense 6-photon ionization of Xe atoms at intensity up to 4×10^{13} W/cm^2. They found that electrons were ejected during ionization with energy higher than that expected from absorption of the minimum number of photons needed for ionization, an effect that came to be known as above threshold ionization.[4] This observation sparked a long campaign of experiments and theoretical work on strong laser field ionization of atoms and ions that continues to this day. These early experiments in strong field multiphoton ionization were followed by the first observation of nonperturbative nonlinear optical phenomena in high order harmonic generation by Rhodes et al. in 1987[5] in which highly nonlinear interactions of an intense laser pulse with a gas of atoms led to emission of a range of high harmonics of the laser frequency. The initial observations of high harmonics were striking in that a range of harmonics extended to very high orders with almost constant intensity, completely at odds with lowest order perturbation theory. In fact, very high nonlinear orders, >100, have been reported in studies of this effect,[6,7] resulting in the production of coherent light into the soft x-ray region. High harmonic generation with intense laser pulses continues to be studied actively and has led to a revolution in the production of electromagnetic pulses with durations of a few hundred attoseconds.[8,9]

These early nonlinear multiphoton discoveries were followed by the realization that much of these effects could be understood by treating the field classically and the interaction with electrons semiclassically. This simplification in describing strong-field interactions occurred nearly simultaneously by Corkum et al.[10] and Kulander.[11] The semiclassical treatment is now the basis for much of our understanding of strong field ionization, above threshold ionization and high harmonic generation.

While the study of strong field physics has its origins in the study of atomic ionization, it was also realized early on that strong field interactions with plasmas would manifest unique effects, not only through the ionization of atoms and ions in the plasma but in the collective motion of the plasma electrons driven by the strong forces of an intense laser pulse. The study of intense laser interactions with plasmas has been a very important aspect of strong field physics leading to numerous breakthroughs, such as the development of compact x-ray lasers[12,13] and plasma accelerators.[14] For example, it was realized as early as 1979, in a classic paper by Tajima and Dawson,[15] that an intense laser pulse could be used to drive a plasma wave that could, in turn, accelerate electrons with very high gradient, far above that of traditional accelerators.[16] This has led to a steady advance in understanding intense laser light propagation in underdense plasma. Recent years have seen other important advances in strong field laser interactions. The latest developments in laser technology now enable experiments in plasmas at intensities in which the free electron velocity becomes relativistic.

This has led to new range of nonlinear phenomena created by the relativistic mass increase of the electron in the strong laser field. For example, absorption of light in plasmas becomes much more complicated in the high-field regime, with collective effects playing a much bigger role. This leads to plasma interactions that exhibit large "anomalous absorption" deviating from simple linear kinetic theories of light interactions with plasmas.

This chapter is intended to introduce many of the fundamental concepts underlying the modern strong field physics research. These concepts span descriptions of intense light interactions with single electrons, individual atoms, ensembles of atoms in molecules and clusters, and many charged particles in plasmas. This chapter does not represent a comprehensive review of modern strong field physics research and is not a survey of recent results in the field. No attempt is made to discuss specific experimental results that confirm the phenomena presented (though citations to such work are given). Instead, the basic phenomena underlying the more complex effects observed in strong field physics will be discussed, and the basic equations needed to describe these high-field effects will be presented. (Equations here are presented without proof; the reader is encouraged to seek detailed derivations from the references provided.) If a more detailed review of the various aspects of strong field physics is desired, there have been a number of excellent review articles published in recent years (including a number of older articles which are still relevant). A listing of some of these review articles appears in Sec. 21.12 in Refs. 17 to 41 for the interested reader. (In the remainder of this chapter all units are CGS unless otherwise stated.)

21.3 LASER TECHNOLOGY USED IN STRONG FIELD PHYSICS

Before discussing strong field phenomena, it is important to note that advances in this area of physics have been driven by many important leaps in laser technology over the last 20 years. The enabling technology advancement for creating the increasingly higher intensities needed to access strong fields was the invention of chirped pulse amplification (CPA) lasers.[42] The CPA technique, first demonstrated by Strickland and Mourou in 1985,[42] is illustrated in Fig. 1. The goal of CPA is to amplify picosecond to femtosecond duration pulses to high energy in laser gain media, thereby

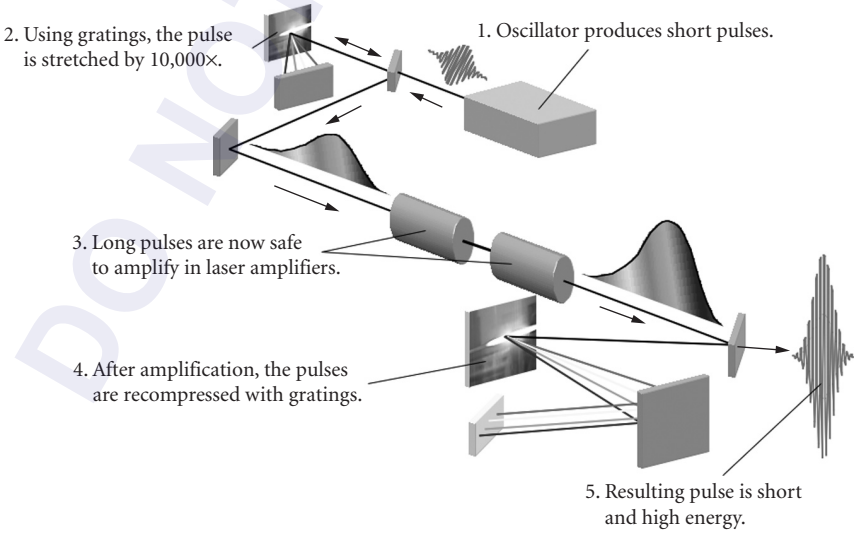

FIGURE 1 Architecture used for chirped pulse amplification (CPA) lasers.

reaching the terawatts to petawatts of peak power needed to access strong field phenomena. As illustrated in Fig. 1 a broad bandwidth, mode-locked laser produces a low power, ultrafast pulse of light, usually with duration of 20 to 500 fs. This short pulse is first stretched in time by a factor of around 10 thousand from its original duration using diffraction gratings. This allows the pulses, now of much lower peak power, to be safely amplified in the laser, avoiding the deleterious nonlinear effects which would occur if the pulses had higher peak power.[43] These amplified pulses are, finally, recompressed in time, (again using gratings) in a manner that preserves the phase relationship between the component frequencies in the pulse. The CPA laser pulse output has a duration near that of the original pulse but with an energy greater by the amplification factor of the laser chain. In high-energy CPA systems ($> \sim 1$ J), severe nonlinearities occurring when the pulse propagates in air can be a major problem, so the pulse must be recompressed in an evacuated chamber. The state of the art in CPA now enables focused intensity of up to 10^{21} W/cm^2 (Ref. 44) with peak intensity up to 1 PW (10^{15} W).[45] Table top CPA lasers can usually access intensity of $\sim 10^{19}$ W/cm^2 and high repetition rate (~1 kHz) lasers usually operate with peak intensity of $\sim 10^{16}$ W/cm^2.

The first generation of CPA lasers was based primarily on flashlamp pumped Nd:glass amplifiers.[42,46–48] These glass-based lasers, operating at a wavelength near 1 μm, are usually limited to pulse duration of greater than about 400 fs because of gain narrowing in the amplifiers.[49] The most significant scaling of this approach to CPA was demonstrated by the petawatt laser at Lawrence Livermore National Laboratory in the late 1990s.[50] This laser demonstrated the production of 500 J of energy per pulse with duration of under 500 fs, yielding over 10^{15} W of peak power. Since this demonstration, a number of petawatt laser projects have been undertaken around the world.[51]

The second common approach to CPA uses Ti:sapphire as the amplifier material. This material permits amplification of 800 nm wavelength pulses with much shorter pulse durations, often down to ~30 fs. However, the short excited state lifetime of Ti:sapphire (3 μs) requires that the material be pumped by a second laser (usually a frequency doubled Nd:YAG or Nd:glass laser). The inherent inefficiencies of this two-step pumping usually limit the output energy of such a laser to under a few joules of energy per pulse. A number of multiterawatt lasers based on Ti:sapphire now operate in many high-intensity laser labs worldwide.[52–55] These laser typically yield energy of 1 mJ to 1 J (though higher energy examples with energy ~10 J do exist), and they typically exhibit repetition rate of 1 kHz at the 1 mJ level or ~10 Hz at the 0.1 to 1 J level.[56] To date, the largest scaling of Ti:sapphire technology has been to power levels approaching 1 PW.[54,57]

The third major technology now commonly used in CPA lasers is based on a technique known as optical parametric chirped pulse amplification (OPCPA).[58] In this approach, amplification of the stretched pulses occurs not with an energy storage medium like Nd:glass or Ti:sapphire but via parametric interactions in a nonlinear crystal. This approach is quite attractive because of the very high gain per stage possible (often in excess of 10^4 per pass) and the very broad gain bandwidth possible, in principal. To date, a number of CPA lasers based on OPCPA have been demonstrated.[59–61]

21.4 STRONG FIELD INTERACTIONS WITH SINGLE ELECTRONS

We begin our discussion of the various strong field phenomena by considering strong field interactions with individual, free electrons (which encompasses the situation in which the electrons are not affected by the electrostatic forces of a collective electron plasma). This discussion will be followed in the next sections by overviews of strong laser field interactions with atoms, molecules, clusters, and then plasmas.

The Ponderomotive Force

When a strong laser field interacts with a free electron, the field can almost always be treated classically and the trajectory of the electron can be found using classical mechanics. If the intensity is

not too high, below about 10^{18} W/cm^2 for optical and near-infrared frequencies, then motion of the electron can be treated nonrelativistically and the magnetic field of the laser can be ignored. In that case, the electron oscillates at the laser frequency in the direction of the laser polarization. Solution of Newton's equation yields for electron velocity $v(t) = (eE_0/m_e\omega_0)\sin(\omega_0 t)$, where E_0 is the laser's peak electric field, ω_0 is the frequency of the laser light, and $v_{osc} = (eE_0/m_e\omega_0)$ is the classical electron oscillation velocity amplitude. While complications arise for very short laser pulses (with envelope comparable to the wavelength) or tightly focused pulses, in a plane wave it is useful to consider the cycle-averaged kinetic energy of this oscillating electron. This energy, called the ponderomotive potential, is

$$U_p = \frac{e^2 E_0^2}{4 m_e \omega_0^2} \tag{1}$$

In practical units, the ponderomotive energy is equal to $9.33 \times 10^{-14}\, I$ (W/cm^2) λ^2 (μm) in eV and is, for example, roughly 10 keV in a Nd:glass laser field at 1.054 μm focused to intensity of 10^{17} W/cm^2. This ponderomotive energy usually sets the energy scale for most strong field interactions. In a focused laser beam a force $-\nabla U_p$, called the ponderomotive force, will act on an electron. The ponderomotive force will tend to accelerate electrons transversely out of the focus from high to low intensity (increasing the electron's energy by $\sim U_p$). In the absence of a strong transverse intensity gradient, a free electron illuminated by a strong laser field will begin to oscillate as the field amplitude increases, but will then come back completely to rest as the intensity falls back to zero, acquiring no net energy from the laser field.

Relativistic Effects in Strong Field Interactions with Free Electrons

The dynamics of electrons in field strengths at which relativistic effects become important are considerably more complicated. These effects become important when the classical, *nonrelativistic* quantity v_{osc} becomes comparable to or greater than c. At optical and near-IR wavelengths relativistic effects become important at intensity approaching 10^{18} W/cm^2 [where Eq. (1) predicts that the ponderomotive energy exceeds 100 keV in near-IR fields and is, therefore, a large fraction of the 511 keV electron rest mass]. The extent to which the field interaction with the electron is relativistic can be quantified by the dimensionless *normalized vector potential*, a_0, which is v_{osc}/c, and given by

$$a_0 = \frac{eE_0}{m_e c \omega_0} \tag{2}$$

When a_0 approaches 1 (which occurs for 1 μm light at intensity equal to 1.4×10^{18} W/cm^2), Eq. (1) breaks down. In this regime, the electron motion in the strong field becomes significantly affected by the laser's magnetic field, and, while complex, has been solved analytically by a number of authors.[62–65]

The electron's motion deviates from the simple harmonic oscillation described above because the $\mathbf{v} \times \mathbf{B}$ force drives the electron forward. The electron now acquires a significant velocity component in the laser's k direction and, as a result, no longer experiences linearly varying phase and a perfectly sinusoidal oscillation of the electric field. The electron's motion becomes highly anharmonic. Figure 2 illustrates the trajectory of an electron irradiated by a laser field of 1 μm wavelength at intensity of 10^{19} W/cm^2, ($a_0 = 2.7$). The longitudinal momentum, p_z can be easily derived from the relativistic equations of motion for the electron in an EM wave. For an electron initially at rest, the field will yield forward momentum such that

$$p_z = \frac{p_x^2}{2 m_e c} \tag{3}$$

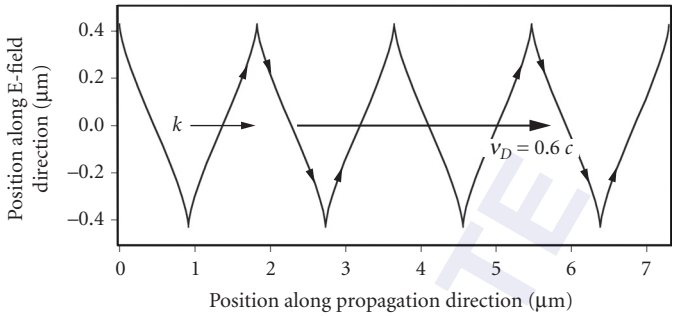

FIGURE 2 Trajectory of an electron driven by a relativistic laser field with 1 μm wavelength at an intensity of 10^{19} W/cm^2, ($a^0 = 2.7$ and $\gamma^{osc} = 2.1$). This illustrates that the electron acquires significant drift velocity along the laser propagation direction and oscillates anharmonically.

if p_x is the transverse, E-field driven momentum.[66–68] For an electron in a plane wave, a cycle-averaged forward drift velocity v_D will be acquired in the lab frame, as pictured in Fig. 2. This *average* forward drift velocity is

$$\frac{v_D}{c} = \frac{a_0^2}{4 + a_0^2} \tag{4}$$

This equation indicates that the electron will drift in the forward direction at nearly the speed of light when a_0 is roughly 10, corresponding to a near-IR intensity of about 10^{20} W/cm^2.

Finding the transverse oscillation velocity is more complex, but a useful result can be found for weak relativistic fields (when a_0 is between ~0.3 and 3 or intensity is in the 10^{17} to 10^{19} W/cm^2 range for near-IR light). In this regime, one can neglect the longitudinal velocity in the relativistic equations of motion to find an approximate result for the transverse oscillation velocity

$$\frac{v_x}{c} = \frac{a_0}{1 + a_0} \tag{5}$$

which reduces to v_{osc} when $a_0 << 1$.

It is now possible to talk in terms of a relativistic ponderomotive energy which can be written as[22]

$$U_p^{rel} = (\gamma_{osc} - 1)mc^2 \tag{6}$$

where $\gamma_{osc} = \sqrt{1 + a_0^2/2}$ is the effective cycle-averaged relativistic Lorentz factor (ignoring the contribution from the slower drift of the electron) for linearly polarized light. (Note that in circularly polarized light $\gamma_{osc}^{circ} = \sqrt{1 + a_0^2}$.) Equation (6) reduces to Eq. (1) when $a_0 << 1$. Deriving a "ponderomotive force" in a relativistic light beam is a less concrete concept, as the idea of a cycle-averaged force in a weak intensity gradient is of limited utility when, at strongly relativistic intensity, the electron surfs along, almost in phase with the light field at *c*. However, a heuristic treatment of the electron dynamics yields a relativistic ponderomotive force that can be written as[69]

$$\mathbf{f_p} = -m_e c^2 \nabla \gamma_{osc} \tag{7}$$

Finally, we note that this relativistic motion will also eject electrons from the focus of an intense laser. However, unlike the nonrelativistic case in which the ponderomotive force drives the electrons out of the focus at 90° to the laser propagation, the magnetic force causes ejection along an axis folded forward toward the *k* direction. This ejection angle can be simply calculated by considering the relativistic kinematics of the absorption of many photons of momentum $\hbar k$ and the relativistic

relationship between transverse and longitudinal momentum in the EM field, Eq. (3). This yields an ejection angle, θ, of electrons with Lorentz factor outside the laser focus of γ,

$$\theta = \arctan\left[\frac{2}{\gamma - 1}\right] \tag{8}$$

It should be noted that this equation is only valid for purely plane wave interactions. The field near a real focus will contain longitudinal components which alter the ejection angle of the electrons somewhat.[70] Nonetheless, Eq. (8) correctly indicates that in a strongly relativistic focus, electrons will be ejected with high Lorentz factor and will come out in a cone around the propagation axis of the laser, having surfed along with the field through the laser focus. If electrons are ejected into the field at the peak of an oscillation, a situation that occurs when highly charged ions are ionized by the field (see the next section) the relativistic electrons propagating with small ejection angle θ can pick up substantial energy from the laser field. A useful estimate for *maximum* ejected electron energy derived from this relativistic free-wave acceleration mechanism is[71]

$$\gamma_{\max} \approx \frac{eE_0 \theta z_R}{2m_e c^2} \tag{9}$$

where $z_R = \pi w^2/\lambda$ is the Rayleigh range of the Gaussian focus. Equation (9) indicates that the ejected electron in the relativistic intensity regime acquire energy proportional to the laser's electric field ($\sim I^{1/2}$) and not its square, as they do in the nonrelativistic case [see Eq. (1)]. When $a_0 >> 1$, θ will be small, and electrons will gain substantial energy from the field. For example, calculations show that an electron produced by ionization at intensity of 5×10^{21} W/cm^2 in a 1-μm wavelength laser field focused to a 5-μm Gaussian spot can acquire energy up to ~1 GeV and are ejected at an angle of ~3°.[71]

Nonlinear Thomson Scattering by Electrons in an Intense Laser Field

The acceleration associated with oscillation of a free electron in an electromagnetic wave gives rise to emitted radiation, a process known as Thomson scattering, which has the well-known scattering cross section $\sigma_T = 8\pi e^2/3m_e c^2$.[72] The *anharmonic* motion of an electron in a strong laser field, as illustrated in Fig. 2, alters the Thomson scattering in an important manner. First, the light scattered from the electron has an emission pattern folded forward toward the laser propagation axis, and second, the radiated light from the electron will contain higher harmonic components.[64,73–77] In a strongly relativistic field ($a_0 >> 1$), the radiated emission will be forward folded by the effective Lorentz boost, into an angle $\theta \approx 3/a_0$. In addition, the anharmonic motion of the electron induced by the magnetic field results in scattered light at even and odd harmonics of the incident light field. It can be shown that the total integrated scattered power into the first three harmonics of the laser field are[74]

$$P_1 \cong \frac{e^2\omega_0^2 c}{3} a_0^2 \qquad P_2 \cong \frac{7e^2\omega_0^2 c}{20} a_0^4 \qquad P_3 \cong \frac{621e^2\omega_0^2 c}{1792} a_0^6 \tag{10}$$

illustrating the nonlinear intensity dependence of the second and third harmonic. These equations also illustrate that as $a_0 \to 1$ the power scattered into harmonics (P_2, P_3) will be comparable to the power scattered by linear Thomson scattering, P_1. The angular distribution of the scattered radiation for linearly polarized light is analytically complex. Figure 3 illustrates the polar distribution of light from the second and third harmonics of nonlinear Thomson scattering at $a_0 = 1$. A simple formula for the angular distribution, $D(\theta)$, of scattered light from a circularly polarized beam as a function of polar angle θ with respect to the laser propagation direction can be derived,[74] where

$$D(a_0, \theta) = \frac{1}{\left(1 + \frac{a_0^2}{2}\sin^2\frac{\theta}{2}\right)^4} \tag{11}$$

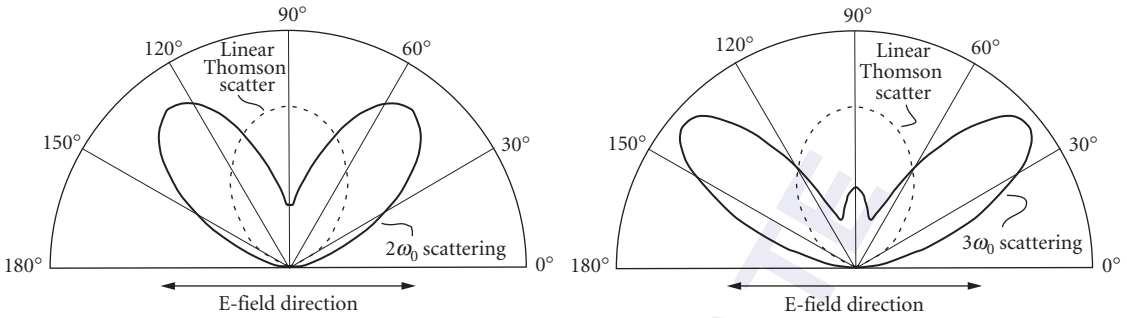

FIGURE 3 Azimuthal angular distribution (in the plane perpendicular to the laser propagation direction) of nonlinear relativistic Thomson scattering by an electron in a light field with $a_0 = 1$. The dipole distribution from linear Thomson scattering from an electron is shown for comparison. *(These plots were adapted from Ref. 75.)*

which, of course, reduces to the isotropic polar emission of Thomson scattered light in a weak circularly polarized field.[72]

High-Field Interactions with Relativistic Electron Beams

The previous discussion considered the interaction of intense light radiation with electrons at rest or nearly at rest initially in the laboratory frame. If the laser collides with electrons that are already relativistic, which occurs when an intense laser pulse interacts with a beam of electrons from a high energy accelerator or synchrotron, the scattered radiation is altered by the fact that the electron sees a laser photon whose energy is upshifted by a factor γ, the Lorentz factor of the relativistic electron beam. If the scattering is linear Thomson scattering, the scattered photon will acquire another factor of γ in its energy when transformed back into the laboratory frame. This γ^2 upshift in photon energy can be exploited to produce femtosecond pulses in the x-ray regime by colliding an ultrashort pulse with a relativistic electron beam.[78] The scattered photon will have photon energy given by

$$\hbar\omega_{\text{scat}} = 2\gamma^2\hbar\omega_0\frac{1-\cos\phi}{1+\gamma^2\theta^2} \tag{12}$$

where ϕ is the angle between the laser and the electron beam and θ is the angle of the scattered photon with respect to the electron propagation direction. This indicates that if a laser is scattered from the electron beam at a 180° angle, the photons scattered can be upshifted by as much as $4\gamma^2$. Furthermore, Eq. (12) indicates that the scattered photons will be emitted in a directed cone with angle $\sim 1/\gamma$, with an angular dependence on the upshifted photon energy. This picture must be amended somewhat if the electron beam Lorentz factor is high enough that the laser photon in the electron frame is upshifted in the electron rest frame such that $\gamma\hbar\omega_0/m_e c^2 \sim 1$. In this case, the situation becomes that of inverse Compton scattering and the kinematics of the electron recoil from the photon scattering must be considered. This process is, strictly speaking, a linear process; however, practical experimental implementation of this technique has usually been in the high intensity laser regime because of the low scattering cross section of free electrons ($\sigma_T = 6.6 \times 10^{-25}$ cm^2).

The situation becomes more complex when the laser is intense enough to cause multiphoton Compton scattering, whose scattering efficiency will then scale as a_0^{2n}, where n is the multiphoton order.[67] Accessing this regime in the lab is difficult because of the extremely low cross section but is made easier with a very high energy electron beam because an intense laser will have its intensity boosted in the electron frame through relativistic time compression.[79] At relativistic laser intensity

($a_0 \geq 1$) Eq. (12) must be amended, and the maximum scattered photon energy for head on collision and direct backscatter becomes

$$\hbar\omega_{\text{scat}} = \frac{4n\hbar\omega_0\gamma^2}{1+\dfrac{4n\hbar\omega_0\gamma^2}{m_e c^2}+a_0^2} \tag{13}$$

The factor of a_0^2 in the denominator arises from the mass shift of the electron in the strong laser field.

21.5 STRONG FIELD INTERACTIONS WITH ATOMS

Keldysh Parameter and Transition from the Multiphoton to the Quasi-Classical Regime

Perhaps the most fundamental process that occurs when a single atom or ion is immersed in a strong laser field is the ionization of the most weakly bound electron. With the exception of recollision double ionization, discussed below, this ionization process is almost always a single electron process, involving the removal of the outermost bound electron by the light field.[18] (This approach to understanding ionization and nonlinear optical dynamics in strong field atomic interactions is termed the "single active electron approximation," and it underlies most of the theory presented in this section.) High-field interactions with single atoms essentially split into two regimes. The first occurs when the field can be treated quantum mechanically as an ensemble of photons, and the second arises when so many photons participate that the light can be treated as a classical field. In the second case, which occurs at sufficiently long wavelength or high intensity, the motion of electrons in the field can be treated classically. Generally, the second situation arises if the free electron wavepacket is much smaller than its classical oscillation amplitude. In this case a free electron wavepacket is localized to the extent that it can be considered a point particle; in strong field physics this is called the quasi-classical regime. The uncertainty principle implies that this occurs for a free electron when $U_p/\hbar\omega >> 1$.

In the context of atomic ionization, these two pictures of the liberated free electron naturally lead to two regimes of ionization, the multiphoton regime and the semiclassical tunneling regime. These two regimes of ionization can be quantitatively differentiated by the Keldysh parameter[2]

$$\gamma_K = \sqrt{\frac{I_p}{2U_p}} \tag{14}$$

where I_p is the ionization potential of the atom or ion to be ionized. This quantity can be physically thought of as the ratio of the time it takes for an electron wavepacket to tunnel through the potential barrier of an ion immersed in a uniform electric field (see Fig. 5) to the period of the light oscillation. The Keldysh parameter delineates the barrier between the multiphoton ionization regime, which occurs when $\gamma_K >> 1$, and the tunneling regime, which is the predominant ionization mechanism when $\gamma_K << 1$. Note that, given the scaling of U_p from Eq. (1), the latter situation predominates at higher intensity and longer wavelength. In practice, γ_K is a "soft" parameter in which tunneling ionization (described below) can be considered to be a very good approximation, even when γ_K is only slightly less than 1.

Multiphoton Ionization

When the Keldysh parameter is larger than 1, the ionization of an atom or ion in a strong laser field takes on a predominantly multiphoton character. The atom or ion can be thought of as absorbing a number of discrete photons from the field simultaneously, so that a bound electron acquires enough

energy to be promoted to the continuum.[80–86] This view tends to predominate practically at modest intensities (~10^{13} W/cm^2)[82,85] or with light at wavelengths shorter than optical (UV).[81,84] The most straightforward picture for this process is to say that the ionization rate for N-photon ionization is given by lowest order perturbation theory[4,87,88] so that the ionization rate can be written as

$$W_N = \sigma_N I^N / (\hbar\omega_0)^N \tag{15}$$

where σ_N is the generalized multiphoton ionization (MPI) cross section. Equation (15) indicates that the ionization rate can be extremely nonlinear with laser intensity. For example, $N = 22$ when helium is ionized by a 1-μm wavelength laser,[89] though this multiphoton picture turns out to be accurate only for lower ionization potential atoms irradiated at shorter wavelengths. The practical difficulty with this model is in the calculation of σ_N. Lowest order perturbation theory is accurate for a very limited range of intensities and higher order processes soon become important in the calculation of σ_N as intensity is increased. Figure 4 plots the order of magnitude of the generalized cross section as a function of multiphoton order, N. This plot shows, for example, that the multiphoton ionization cross section for 11 photon ionization of Xe by a 1-μm laser field is about 10^{-350} cm^{22} – s^{10}. This implies a saturation intensity for multiphoton ionization of atomic Xe by 100 fs pulses of about 2×10^{14} W/cm^2.

Calculation in the lowest order perturbation theory framework of σ_N is complicated by other factors as well. Resonances with intermediate states complicate the calculation and drastically affect the multiphoton ionization rate. Furthermore, when the field's ponderomotive potential becomes a significant fraction of the ionization potential, the bound state levels can no longer be thought of as unperturbed ion eigenstates; these levels move in energy via the AC Stark shift.[90] Also, as the ponderomotive potential increases, the minimum number of photons needed for ionization may change. Since the ionized electron is "born" into the continuum which has an oscillating field, it must acquire energy equal to U_p to enter the continuum. As a result, the number of photons needed for ionization is that which overcomes the ionization potential of the unperturbed atom or ion plus the ponderomotive energy, such that $N\hbar\omega_0 = I_p + U_p$.

A great number of nonperturbative approaches have been developed to derive more accurate ionization rates in a strong laser field in the multiphoton regime. One of the best known such approaches derives from the original work of Keldysh.[2] This approach has been extensively

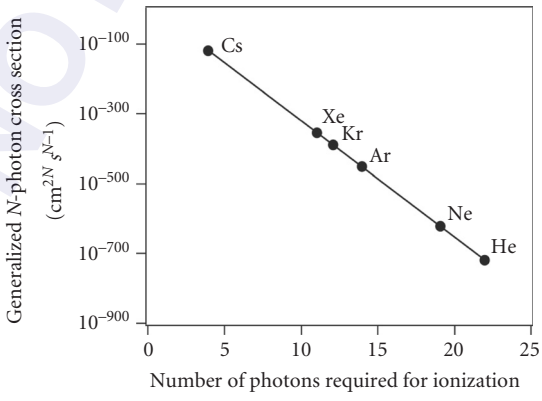

FIGURE 4 Generalized multiphoton cross section for atoms as a function of the multiphoton order, N. The location of the cross section for ionization of various neutral atoms by a laser at a wavelength of 1 μm are plotted to illustrate the increasing nonlinearity of MPI for more tightly bound atoms. *(This plot was adapted from Refs. 80 and 21.)*

developed by F. Faisal[91] and H. Reiss;[92] ionization calculations based on this approach are usually termed KFR theories or the strong field approximation (SFA). In this approximation, the ionization rate is determined by calculating a quantum mechanical transition probability directly between the ground state of the atom or ion and a continuum state. The ground state is assumed to be the field-free eigenstate unperturbed by the field (accurate for a tightly bound electron) and the final continuum state is assumed to be that of a free electron wavefunction in a plane electromagnetic wave (termed a Volkov state), thereby ignoring the effect of the ion Coulomb field on the outgoing ionized electron. A general equation valid for ionization rate for any Keldysh parameter can be derived in this way. In the multiphoton regime ($\gamma_K >> 1$) the ionization rate predicted by this theory is[2]

$$W_K = A\omega_0\left(\frac{I_p}{\hbar\omega_0}\right)^{3/2}\exp\left[2N_{\text{eff}} - \frac{I_p^{\text{eff}}}{\hbar\omega}\left(1+\frac{2U_p}{I_p}\right)\right]\left(\frac{U_p}{2I_p}\right)^{N_{\text{eff}}}\Phi\left[\left(2N_{\text{eff}} - \frac{2I_p^{\text{eff}}}{\hbar\omega_0}\right)^{1/2}\right] \tag{16}$$

where $I_p^{\text{eff}} = I_p + U_p$ is the effective ionization potential of the atom dressed by the light's ponderomotive potential, N_{eff} is the minimum number of photons required to ionize the ion with this I_p^{eff}, $\Phi[z] = \int \exp[y^2\text{-}z^2]dy$ is the probability integral and A is a numerical cofactor of the order of unity that accounts for the weak dependence on the details of the atom. Experiments have illustrated, for example, in 580 nm light that $A = 24$ for the first ionization of Ar, $A = 18$ for Kr and $A = 4$ for Xe.[83] While Eq. (16) is not particularly accurate for most ions and has a rather limited range of applicability, it is useful for estimating the order of magnitude of the ionization rate when $\gamma_K > 1$.

Tunnel Ionization

When the laser field is strong enough and the laser frequency is not too high, γ_K becomes less than 1 and a different picture of strong field ionization emerges. In this regime it is accurate to think of the bound electron wavepacket as evolving in a binding potential that is distorted by the strong light field, a situation known as tunnel ionization, illustrated in Fig. 5. The laser field represents a slowly varying deformation of the ion's confining Coulomb potential which oscillates back and forth. Near the peak of the light field oscillation, the electron can tunnel through the confining potential (pictured at the right in Fig. 5) freeing it and releasing it into the continuum. Because of the exponential nature of the quantum mechanical tunneling rate through a potential barrier, this

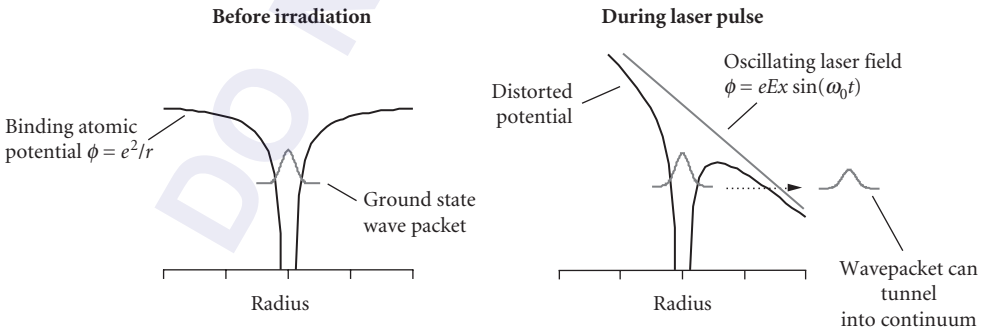

FIGURE 5 Illustration of the potential of an ion distorted by the application of a strong, adiabatically varying electric field. A strong enough field allows tunneling of the bound electron into the continuum thereby ionizing the atom/ion.

method of ionization is strongly nonlinear with increasing electric field. In a Coulomb potential this confining barrier will have a width roughly $\delta r \approx I_p/eE_0$ so the electron will tunnel through this barrier with a time

$$\tau_{\text{tun}} \approx \delta r / v \approx \frac{\sqrt{2I_p m_e}}{eE_0} \tag{17}$$

When this time is faster than a laser oscillation cycle, the tunneling picture is valid (equivalent to $\gamma_K < 1$).

The instantaneous ionization rate from tunneling by an electron from a hydrogenlike ion in a quasi-static field is given by[93]

$$W_{\text{H-like}} = 4\omega_a \left(\frac{I_p}{I_H}\right)^{5/2} \frac{E_a}{E(t)} \exp\left[-\frac{2}{3}\left(\frac{I_p}{I_H}\right)^{3/2} \frac{E_a}{E(t)}\right] \tag{18}$$

where I_H is the ionization potential of hydrogen (13.6 eV), $\omega_a = 4.13 \times 10^{16}$ s^{-1} is the atomic unit of frequency, $E_a = 5.14 \times 10^9$ V/cm is the atomic unit of electric field and $E(t)$ is the instantaneous applied electric field strength. The total ionization rate can be found by integrating Eq. (18) over the entire optical cycle.

There have been many published improvements on this simple tunneling formula.[34,94,95] In fact, the general equation derived by Keldysh retrieves a tunneling rate when it is taken in the limit that $\gamma_K << 1$.[2] All tunneling models result in an ionization rate with the exponential field dependence $\sim\exp[-2a/3E(t)]$, with "a" depending on the model. The most sophisticated and most widely accepted model for the tunnel ionization of a complex atom or ion (i.e., multielectron nonhydrogenic ion) was developed by Ammosov, Delone, and Krainov, usually termed the ADK ionization rate.[95] This model predicts that the tunnel ionization rate averaged over one full optical cycle is

$$W_{\text{ADK}} = \omega_a C_{nl} f(l,m) \frac{3^{1/2}}{2\pi^{1/2}} \left(\frac{I_p}{I_H}\right)^{1/4} \left(\frac{E_0}{E_a}\right)^{1/2} \left[2\frac{E_a}{E_0}\left(\frac{I_p}{I_H}\right)^{3/2}\right]^{2n-|m|-1} \exp\left[-\frac{2}{3}\left(\frac{I_p}{I_H}\right)^{3/2} \frac{E_a}{E_0}\right] \tag{19a}$$

This formula accounts for atomic structure through the principal orbital quantum number n, the orbital angular momentum l, and individual magnetic quantum number m. The atom-dependent cofactors are

$$C_{nl} = (2\exp[1]/n)^n (2\pi n)^{-1/2} \tag{19b}$$

$$f(l,\, m) = \frac{(2l+1)(l+|m|)!}{2^{|m|}(|m|)!(l-|m|)!} \tag{19c}$$

The usual method of deriving a net ionization rate is to sum over all m states of the ionizing ion. The ADK ionization formula has been found experimentally to be quite accurate of over a wide range of intensities and ionic species.[96]

This cycle averaged tunnel ionization rate is very nonlinear. It usually exhibits an intensity dependence that varies as I^6 to I^9. As a result, strong field ionization tends to exhibit a thresholdlike behavior that quickly saturates once the intensity rises slightly above a threshold value. (Saturation in this context means that $W\,\tau_p \approx 1$, where τ_p is the laser pulse duration.) This threshold intensity can be easily estimated by determining when the field becomes high enough to suppress completely the confining Coulomb potential and the electron can freely escape the ion during the peak of the field

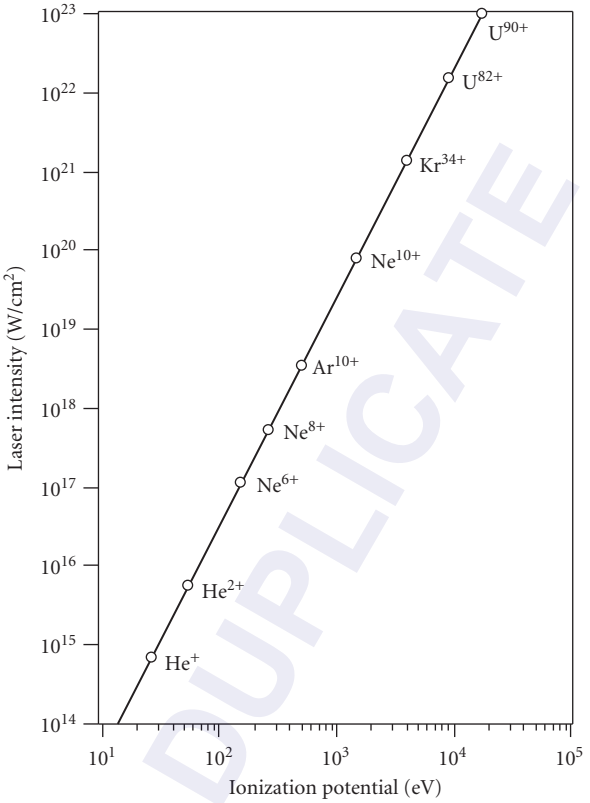

FIGURE 6 Plot of the Barrier Suppression Ionization (BSI) intensity for various ions.

cycle. This simple model, known as the Barrier Suppression Ionization (BSI) model,[96] indicates that the ionization threshold intensity occurs at

$$I_{\mathrm{BSI}} = \frac{cI_p^4}{128\pi Z^2 e^6} \tag{20}$$

where Z is the charge state of the ion being created by the ionization event. In practical units the BSI intensity is $I_{\mathrm{BSI}}[\mathrm{W/cm^2}] = 4.0 \times 10^9\, I_p^4\, [eV]\, Z^{-2}$. Equation (20) turns out to be remarkably accurate despite its simplicity in predicting the intensity of significant ionization in a strong field. The predicted BSI threshold intensity for a variety of ion species is plotted as a function of ionization potential in Fig. 6, illustrating the extent to which very high charge states can be produced by tunneling with modern high intensity lasers.

Above Threshold Ionization

When an atom or ion is subject to a strong ionizing laser field an electron acquires some kinetic energy upon ionization.[3,17,90,97–102] In the weak field regime, the energy acquired by an electron in the light field upon multiphoton ionization can be thought of as a simple extension of the photoelectric effect, in which the electron gains an energy $\mathrm{KE}_{e-} = N\hbar\omega_0 - I_p$, where again, N is the minimum number of photons needed for ionization.[17] However, as the intensity increases and becomes nonperturbative, the

electron can absorb more than the minimum number of photons needed for ionization, a consequence of the electron remaining in the vicinity of the nucleus long enough during ionization to absorb more than N photons. The electron now leaves the ion with energy

$$\mathrm{KE}_{e^-} = (N+s)\hbar\omega_0 - I_p^{\mathrm{eff}} \tag{21}$$

where the ionization potential is dressed (in other words, shifted in a time-averaged sense) by the ponderomotive potential [as in Eq. (16)], and s is the number of additional absorbed laser photons. This effect is termed above threshold ionization (ATI) and leads to electron kinetic energy distributions that look qualitatively like those in Fig. 7. These electrons are typically ejected from the focus along the laser polarization direction (at least in the nonrelativistic limit).[103] The absorption of s additional photons leads to electron energy peaks separated by $\hbar\omega_0$, shifted down by an energy I_p^{eff} (though ponderomotive acceleration in the focus of a long pulse laser can shift these electron energies back to the undressed energy).

At modest field strengths in the multiphoton regime ($\sim 10^{13}$ W/cm^2 at IR wavelengths), the yield of electrons in each peak drops off exponentially, as predicted by lowest order perturbation theory. At nonperturbative intensities, however, the yield in each electron ATI peak flattens out and the ATI spectrum develops a plateau over the first few orders, out to an energy of $\sim U_p$. (illustrated in Fig. 7).[100] There have been many theories published to explain the quantitative behavior of ATI in

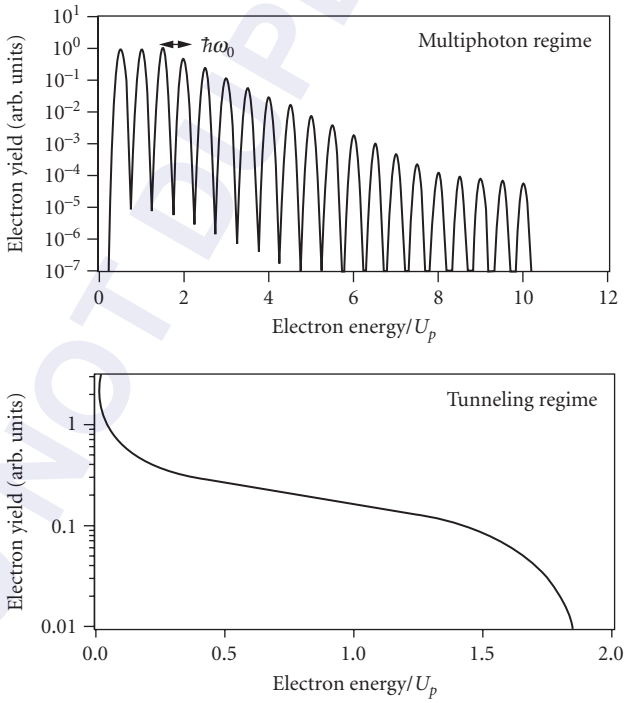

FIGURE 7 Illustration of the general nature of electron energy spectra resulting from intense ionization of atoms, manifesting the phenomenon known as ATI. At the top the spectrum common for ionization in the multiphoton regime is shown. Here the spectrum is composed of peaks, each corresponding to electrons that have absorbed s photons above that needed for ionization. On the bottom, a spectrum characteristic of ATI in the tunneling regime is illustrated showing that the spectrum is smooth and extends out to 2 U_p.

the multiphoton regime. In fact, the strong field approximation of the KFR theories predicts the presence of these multiphoton ATI peaks. Resonances often play an important role in ATI in the multiphoton regime,[104] leading to a rich variety of effects that appear in the ATI energy spectra of optical and near-IR pulses with intensity 10^{13} to 10^{15} W/cm^2.

As the laser field increases, the character of the electron ATI spectrum takes on a qualitatively different character. At intensities entering the quasi-classical tunneling regime ($\gamma_K < 1$) , the spectrum loses its multiphoton character composed of distinct electron energy peaks and becomes a smooth, monotonically decreasing energy distribution, illustrated in Fig. 7. The electron energies have kinetic energy predominantly between 0 and $2U_p$, though there is a small component of electrons with energies that reach up to as much as $10U_p$ through a rescattering process described below.[102] This loss of distinct peaks occurs when the field loses its quantum character and drives the ionization as if it were a classical field.[97,98]

Quasi-Classical ATI When ions are ionized in the tunneling regime, which tends to occur in optical and near-IR laser intensities of 10^{15} to 10^{18} W/cm^2, the shape and energy of electron ATI can be determined by a simple model. As with tunnel and BSI ionization, the field is treated classically and the electron is treated as a compact wavepacket that propagates in the continuum subsequent to tunnel ionization by the classical equations of motion.[105] This so-called quasi-classical model is useful in explaining not only ATI in the strong field, long wavelength regime (i.e., when $\gamma_K < 1$) but also aids in explaining a large number of other strong field phenomena.[10] As such, the quasi-classical model has become one of the major building blocks for understanding modern strong field physics.

In the quasi-classical ATI model, the electron is considered to tunnel into the continuum at a well-defined phase in the oscillating field (see Fig. 8) and propagates in the field as a pointlike charge. When the electron is "born" in to the continuum in this way, it not only oscillates but also acquires some directed drift velocity in the direction of the laser's polarization, with an energy that is a function of the phase in the field at which it was ionized. (This is true for linear polarized fields; in circularly polarized fields, the electron acquires constant drift velocity.) Solution of

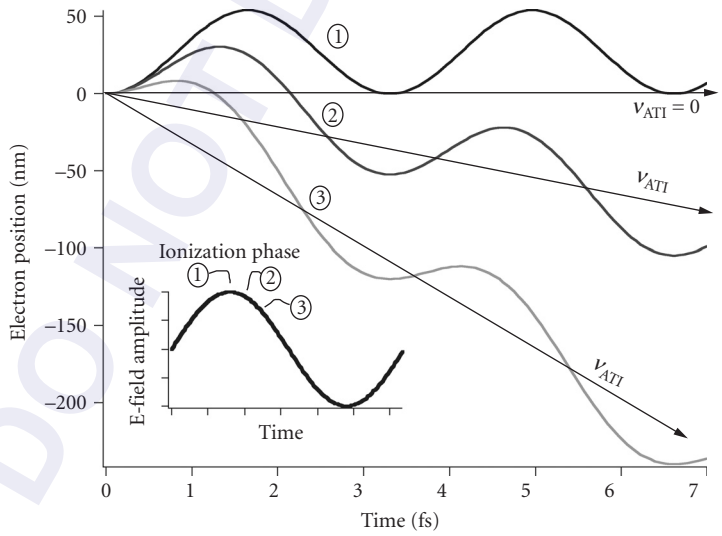

FIGURE 8 Plot of a calculation showing the classical trajectory of electrons born at three different phases in the laser's field. These three phase locations are illustrated in the inset. When born at the peak of the field (trajectory 1), the electron oscillates but acquires no net drift velocity. However, when born off the peak, the electron acquires nonzero drift velocity on top of its quiver velocity.

the nonrelativistic equations of motion indicates that the drift component of the kinetic energy acquired by an electron is

$$\mathrm{KE}_{\mathrm{ATI}} = 2U_p \sin^2 \Delta\phi_0 \tag{22}$$

where $\Delta\phi_0$ is the phase at which the electron is "born" with respect to the peak of the field. Equation (22) indicates that if the electron is born at the peak of the electric field, where the tunnel ionization rate is highest, it will acquire no ATI drift energy. The electron can acquire up to $2U_p$ of kinetic ATI energy if it is ionized well off of the field peak. If Eq. (22) is combined with a model for static tunnel ionization, an electron energy distribution can be derived. Use of the simple H-like tunnel formula of Eq. (18) leads to an ATI energy spectrum from a linearly polarized field of[105]

$$f(\varepsilon) = \frac{a}{(1-\varepsilon/2U_p)(\varepsilon/2U_p)^{1/2}} \exp\left[-\frac{2}{3}\left(\frac{I_p}{I_H}\right)^{3/2}\left(\frac{E_a}{E_0}\right)\left(1-\frac{\varepsilon}{2U_p}\right)^{-1/2}\right] \tag{23}$$

where a is just a normalization constant. The shape of this spectrum for tunnel ionization is illustrated in Fig. 7. This distribution is peaked near zero energy (because the ionization probability is greatest at the peak of the field where $\Delta\phi_0 = 0$ and $\mathrm{KE}_{\mathrm{ATI}} = 0$) but stretches out to a maximum electron energy of $2U_p$. In linearly polarized light, as a rule of thumb, the average electron energy is roughly 10 percent of U_p at the intensity where the ionization rate saturates.[106]

Rescattering Effects

The quasi-classical picture of strong field ionization can be extended to explain other observed effects. In this picture once an electron is liberated from its binding potential by tunneling, its motion in the field can be described classically. Once freed into the continuum, the electron can recollide with its parent ion if it is ionized within a certain range of phase of the field,[21,107–116] a process illustrated in Fig. 9. That this happens can be seen by examining the trajectories shown in Fig. 8, in which the electrons return to the $x = 0$ position in all three cases after ionization at $t = 0$ (though with different return energy in each case).

If the field is linearly polarized and the electron is born by tunnel ionization at some time t_0 and $x = 0$ (the location of the parent ion) in an oscillating electric field $E_0 \cos\omega_0 t$, its position as a function of time is

$$x(t) = -\frac{eE_0}{m\omega_0^2}[\cos\omega_0 t + \omega_0 t \sin\omega_0 t_0 - \cos\omega_0 t_0 - \omega_0 t_0 \sin\omega_0 t_0] \tag{24}$$

This classical trajectory will result in the recollision of the tunnel ionized electron with its parent nuclear core for ionization phases of $\omega_0 t_0 = 0°$ to 90° and 180° to 270°. The highest energy recollisions occur at phases of 17° and 197°. The free electron will have a kinetic energy after it is born by ionization given by

$$\mathrm{KE}(t) = \frac{e^2 E_0^2}{2m_e\omega_0^2}[\sin\omega_0 t - \sin\omega_0 t_0]^2 \tag{25}$$

The energy upon return to the nucleus can be found with Eqs. (24) and (25). The maximum energy an electron can have upon returning to its parent nucleus (corresponding to ionization at 17° and 197°) is $3.17U_p$. The recollision energy and tunnel ionization probability as a function of phase in the laser field is illustrated in Fig. 9. This strong field driven electron recollision can manifest itself in a number of important effects. The generation of short wavelength harmonic radiation in this way is discussed in Sec. 21.7, but there are two other consequences of this effect:

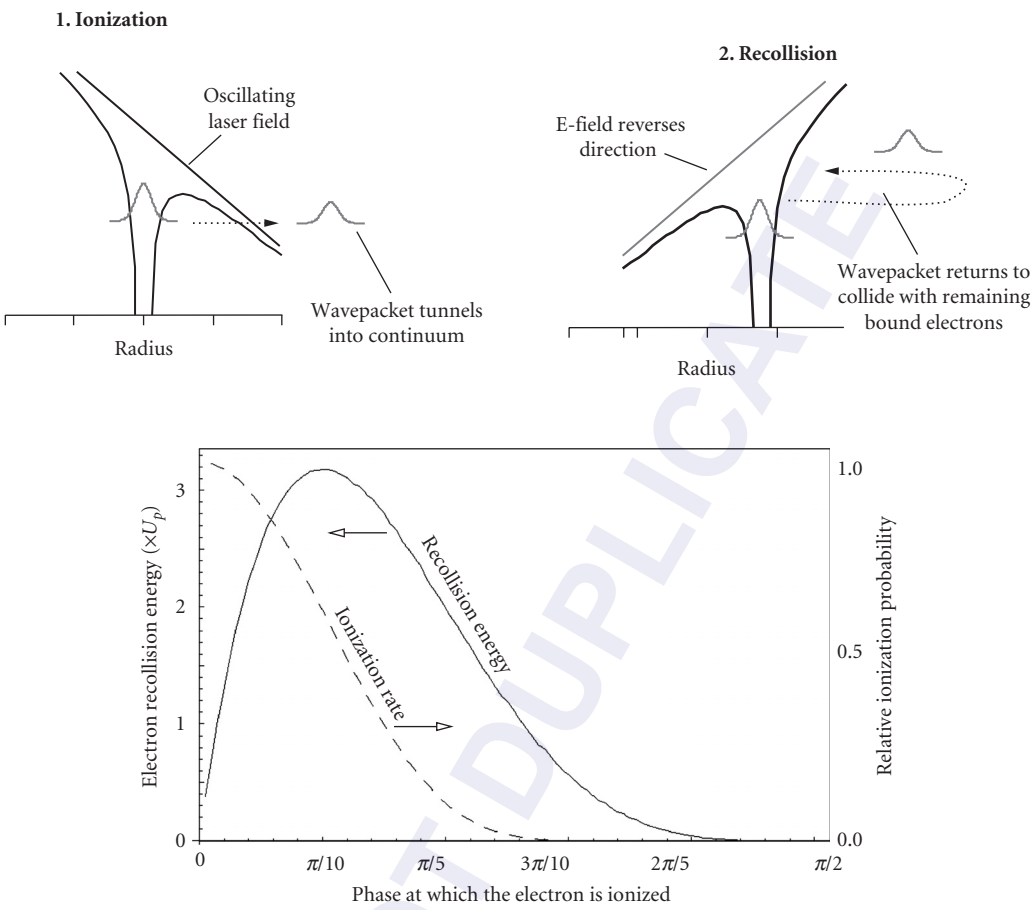

FIGURE 9 The upper illustrations show the process by which a tunnel ionized electron can return to its parent ion and interact with the bound electrons remaining in the ion. The bottom plot shows the energy that such a returning electron will have as a function of the phase in the field at which it was ionized. This shows that the maximum return energy can be $3.17U_p$. The relative ionization probability as a function of the field phase is also shown to illustrate how many electrons will return with the energies indicated.

Strong Field Double Ionization It has been observed for some time that strong field ionization exhibits a small but significant signature of simultaneous double ionization of ions where two electrons are apparently liberated at the same time in the field.[112,115,117] This effect manifests itself experimentally in the yield of a given ion charge as a function of laser intensity, illustrated in Fig. 10. The "knee" that is seen in the ionization yield of a next higher charge state when the ionization of a lower charge state saturates is clear evidence of double ionization. In addition to rescattering, a number of ideas have been forwarded to explain this strong field behavior.[26] These include:

- *Shake off model*, in which the sudden removal of one electron by tunneling leads to a quantum mechanical relaxation of the second electron into a new set of eigenstates, some of which rest in the continuum and, therefore, lead to ionization.[117,118] This effect is well known and documented in single photon photo-ionization.[119]
- *Collective tunneling*, in which two electrons tunnel out simultaneously from the ion.[120]

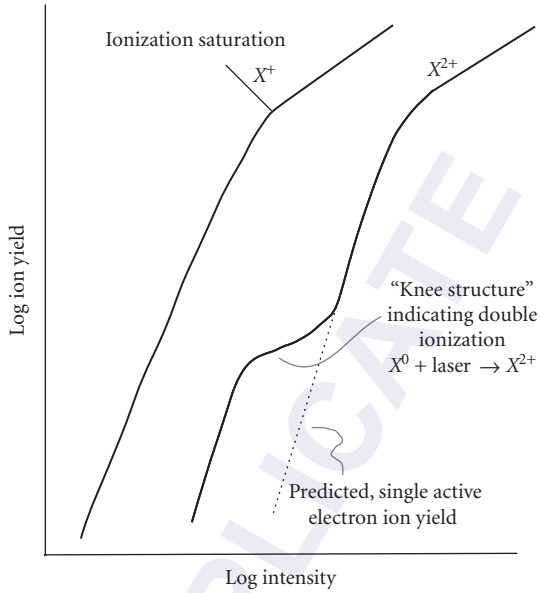

FIGURE 10 Generalized illustration of the ion yield typically measured for ions produced by tunnel ionization, showing the strongly nonlinear increase of ion yield with intensity followed by a roll over at the saturation intensity, where most ions become depleted. The "knee" structure seen in the second ion is the usual experimental signature for nonsequential double ionization.

- *Rescattering,* in which the recolliding electron, described above, collisionally ionizes a second electron. The recolliding electron can acquire sufficient kinetic energy in the field to ionize a second electron through collisional ionization on its return. This is presently the best accepted explanation for strong field double ionization. For example, the double ionization yield is seen to drop dramatically when circularly polarized light is employed.[121] This indicates that the recollision mechanism (at least in the tunneling regime) is likely the dominant mechanism because an electron ionized in circularly polarized light will propagate in such a way that it will not return to the parent ion and cannot ionize a second electron.

ATI Plateau Extension A second consequence of the strong field driven recollision is manifested in the electron ATI energy spectrum. As discussed above, ATI electrons in the quasi-classical regime can acquire up to $2U_p$ of drift energy. However, a laser field-driven recollision can lead to a small number of scattered electrons with energy up to $10U_p$.[102] This rescattering leads to the production of an electron ATI spectrum with a large predominance of electrons with energy below $2U_p$ but with a small fraction of electrons with an energy spectrum plateau that extends out to $10U_p$.

Relativistic Effects

When $a_0 \rightarrow 1$ strong field ionization dynamics are altered in a number of ways.[40] The most significant effects arise from the forward force exerted by the laser magnetic field, though the relativistic mass increase of the electron does play a role in certain effects.

Relativistic Tunnel Ionization It turns out that tunnel ionization rates at relativistic intensity do not deviate significantly from the nonrelativistic rates.[122] The most significant relativistic effects in tunneling occur when the bound state energy I_p becomes comparable to the rest energy $m_e c^2$; it is the Coulomb correction to the mass of the electron in the ground state that is the principal effect. Therefore, relativistic effects will be important for ions of charge $Z > \sim 50$. A relativistic generalization of the Keldysh theory,[34] indicates that the relativistically corrected tunnel ionization rate, W_{Rel}, will be higher than the nonrelativistic rate, $W_{\text{non-Rel}}$, by a factor

$$\frac{W_{\text{Rel}}}{W_{\text{non-Rel}}} \approx \exp\left[-\frac{1}{36}(Z\alpha)^5 \frac{E_{\text{cr}}}{E_0}\right] \tag{26}$$

where α is the fine structure constant (1/137) and E_{cr} is the Schwinger critical field from quantum electro-dynamics theory (1.3×10^{16} V/cm). Using the barrier suppression ionization model to estimate the appropriate Z, Eq. (26) suggests that the nonrelativistic tunneling rates should be good up to an intensity of $\sim 10^{26}$ W/cm^2.

Relativistic Electron ATI The ejection of free electrons following tunnel ionization in a relativistic field can be influenced by the laser's magnetic field. At nonrelativistic intensities, electrons are ejected in a rather narrow distribution along the laser polarization axis. As a_0 approaches 1, the magnetic field pushes the electron distribution toward the k direction of the light propagation, a consequence predicted by Eq. (8).[68] This distribution shift is illustrated in Fig. 11. At highly relativistic intensities (i.e., when $a_0 >> 1$, an intensity of $>10^{21}$ W/cm^2 at near-IR wavelengths) tunnel ionized electrons are quickly bent toward the laser propagation axis by the magnetic field. The electron, which will have a velocity near c, will then "surf" along with the laser pulse acquiring energy from the laser field. Such electrons will be ejected from the laser focus in a narrow cone along the laser direction and will acquire many MeV or even GeV of energy.[71,123] An energy versus angle distribution of electrons ejected in this regime is illustrated in Fig. 11.

Relativistic Suppression of Rescattering Another consequence of the forward ejection of electrons in a relativistic light pulse is that the nonsequential double ionization that normally accompanies rescattering of the electrons on their return after ionization is suppressed.[40,124–126] The forward motion of the electron imparted by the magnetic field (see Fig. 2) forces the electron away from the core and prevents the collisional ionization of a second electron. The fall-off of nonsequential ionization yield occurs at intensity as low as 10^{17} W/cm^2 ($a_0 \approx 0.3$). The rescattering plateau in ATI spectra associated with electrons with energy in the $2U_p$ to $10U_p$ range also decreases in magnitude because of the rescattering suppression. Furthermore, this phenomenon leads to suppression of single atom high harmonic generation at high intensity.

Ionization Stabilization

While experimental evidence is scant, there is a strong theoretical basis for believing that, in certain situations, the ionization rate of an atom in a strong field actually declines with increasing intensity.[27] This phenomena has come to be called ionization stabilization. There are usually two manifestations of this stabilization discussed in the literature.

Adiabatic Stabilization Quantum mechanical calculations of ionization rates have shown that the ionization rate can be stabilized in unionized atoms at field strengths well above one atomic unit. A simple picture to explain this can be constructed if one considers that the electron wavefunction in the ground state of the atom is considerably altered by the strong oscillating field. The wave function is thought to evolve into a time averaged structure with peaks away

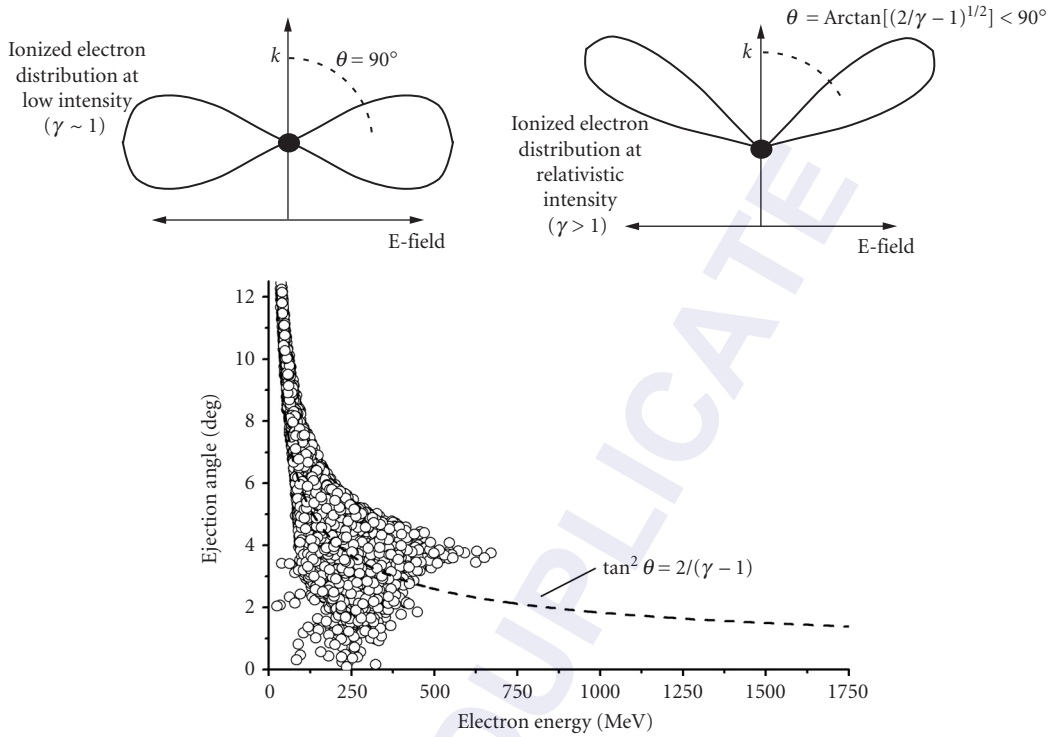

FIGURE 11 The upper illustrations are a generalized illustration of the angular distribution of electrons produced during ionization with respect to the laser field and propagation directions. In the medium intensity regime, electrons are ejected by tunnel ionization along the E-field direction (left); however, at relativistic intensity, the magnetic field pushes the distribution toward the direction of laser propagation. The latter effect can be understood as the conservation of momentum following the absorption of an extremely large number (~10^6) of photons. The bottom plot *(adapted from Ref. 71)* shows the results of a Monte Carlo simulation yielding the ejection angle and energy of electrons produced by irradiation of an Ar ion at intensity of 5×10^{21} W/cm^2. Here the dashed line is the prediction of Eq. (8); the deviation of the simulation from this equation is a consequence of longitudinal fields at the focus.

from the nuclear center. In a time averaged sense, the bound electron sees *two centers* for the atomic potential.[27,127–129] This deformation of the electron wave function away from the nucleus lowers the ionization rate at higher intensity. Figure 12 illustrates the calculated ionization rates of an electron in an excited state of hydrogen as a function of intensity illustrating the fall of ionization rate at high I.

Dynamic Stabilization This mechanism of ionization stabilization, often termed interference stabilization, arises most prominently in calculations of strong field ionization of Rydberg atoms.[129–131] It is thought to arise from quantum destructive interference of pathways into the continuum. There has been some experimental evidence for this form of stabilization in Rydberg atoms[132] but has yet to be demonstrated in atoms in the ground state.

Numerical simulations have suggested that the magnitude of ionization stabilization decreases at relativistic intensity due to the effects of the magnetic field and the Lorentz force on the electron.[133]

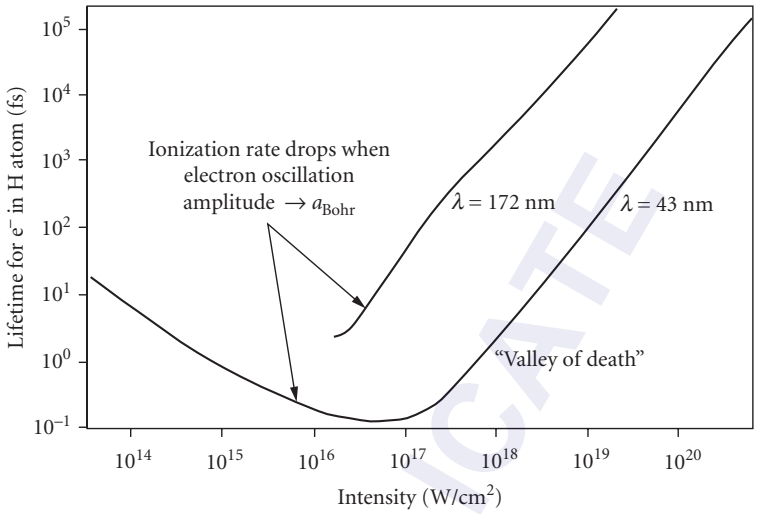

FIGURE 12 Calculation of the ionization rate of a hydrogen atom in an intense, short wavelength field. *(Adapted from Ref. 27.)* This calculation shows that at around the intensity at which the electron quiver amplitude is comparable to the size of the hydrogen ground state (~1 Bohr radius) the ionization rate actually decreases (lifetime increases) as the intensity increases from the delocalization of the electron wavefunction.

21.6 STRONG FIELD INTERACTIONS WITH MOLECULES

The ionization of small molecules (of less than ~10 atoms) by an intense laser field is qualitatively similar to the ionization of single atoms. The two limiting regimes for ionization (multiphoton and tunneling) as discussed in the previous section are still relevant for molecules and the tunnel ionization rate formulas tend to work reasonably well in predicting the ionization rate of electrons in a molecule if appropriately chosen ionization potentials are utilized.[134] Unlike single atoms, however, the motion of the molecule's nuclei during the interaction with the laser pulse can affect the dynamics of the electron ionization and energy gain from the field. Fragmentation of the molecule is one significant consequence of irradiation at high intensity, and the motion of the molecular nuclei has a dynamic impact on the structure of the molecule during its interaction with the intense laser pulse.

Nuclear Motion and Molecular Alignment in Strong Fields

Because small molecules tend to fragment rapidly in an intense light field, the regime of strong field laser interactions with these molecules is usually limited to rather modest intensity, below about 10^{15} W/cm^2. Higher intensity pulses tend to destroy a small molecule well before the high intensity can be reached. Much of current research has concentrated on diatomic molecules.

At modest intensity a small molecule will experience a force by the light field which will tend to align it.[135–137] In the absence of the light field, the molecules are randomly oriented and exist in a range of molecular rotation states with energy eigenvalues of $\varepsilon_{\text{Rot}} = \beta_{\text{Rot}} J(J+1)$ and with rotational quantum number J. Some values of β_{Rot} are tabulated in Table 1.[138] When a moderately strong light

TABLE 1 Rotational Constant, and Alignment Well Depth for Three Example Molecules Irradiated at 10^{15} W/cm^2

Molecule	β_{Rot} (meV)	Max Well Depth (meV)
H_2	3.89	21.9
N_2	0.25	96.8
CO_2	0.048	212

Source: Table Adapted from Ref. 138.

field is applied (below the intensity at which the molecule ionizes), the induced dipole causes the molecule to see a cycle-averaged potential given by[138]

$$V(\theta) = -\frac{I(t)}{2c}[(P_{\|} - P_{\perp})\cos^2(\theta) + P_{\perp}] \tag{27}$$

where the P terms are the parallel and perpendicular components of the polarizibility tensor, θ is the angle between the molecular axis and the polarization axis and $I(t)$ is the time dependant intensity. The maximum well depth for some molecules in a field of intensity 10^{15} W/cm^2 is tabulated in Table 1.

The potential of Eq. (27) will tend to align a linear molecule, such as a diatomic along the polarization axis of a linearly polarized field. Because molecules will usually feel a lower intensity field as the pulse of an intense laser ramps up in time, it is usually a good approximation to say that the nuclei of a linear molecule will be (partially) aligned along the laser electric field at subsequent higher intensity. A molecule with nonzero rotational momentum will evolve, classically speaking, in a pendulumlike motion around the laser electric field axis; these states are often called "pendular" states.

Even at modest intensity, the molecule will begin to dissociate via a process known as bond softening.[35,139,140] In a small diatomic molecule, such as H_2 the first electron will be ionized at the equilibrium distance of the two atoms via multiphoton or tunnel ionization. If the molecule is indeed aligned along the light electric field, the molecular nuclei will then begin to separate by bond softening. Molecular dissociation begins to occur when the potential that binds the nuclear wavepackets couples to photons in the strong laser field. This coupling leads to a ladder of potential curves, each shifted by one photon in energy (described by what is known as Floquet theory[141,142]). If the field-dressed states are treated as if they are quasi-static, the Hamiltonian of the molecule can then be diagonalized, distorting the bound potential curves, in a manner illustrated in Fig. 13 (these distorted potentials are termed adiabatic potentials). As can be seen in this figure, the distorted curves allow molecules in excited vibrational states to dissociate, (and some in lower states can tunnel through the distorted potential barrier). This potential distortion is termed bond softening and is the main mechanism by which a molecule begins to fragment as an intense laser is ramped up in intensity. In H_2 this bond softening occurs, for example, at intensity of ~10^{13} W/cm^2.[35]

There are other means by which molecules can dissociate in midstrength fields ($I < 10^{14}$ W/cm^2). In the picture in which the field is treated as a classical, periodically varying alteration to the Hamiltonian of the molecule, the molecule sees states that are shifted down ("dressed") by an energy equal to the photon energy. The nuclear wavepacket can couple from a bound state to a dissociating state and begin to separate. For example, in H_2^+ immersed in a visible light field of intensity around 10^{13} W/cm^2, this occurs by coupling first to an unbound state shifted by $3h\nu$ and then, after some expansion of the internuclear separation, coupling to the continuum of the bound state dressed by two photons. This multiphoton process is often termed above threshold dissociation[143,144] because it results in the absorption of more photons than are energetically required to dissociate the molecule (much like above threshold ionization is absorption of more photons by an electron than needed to ionize).

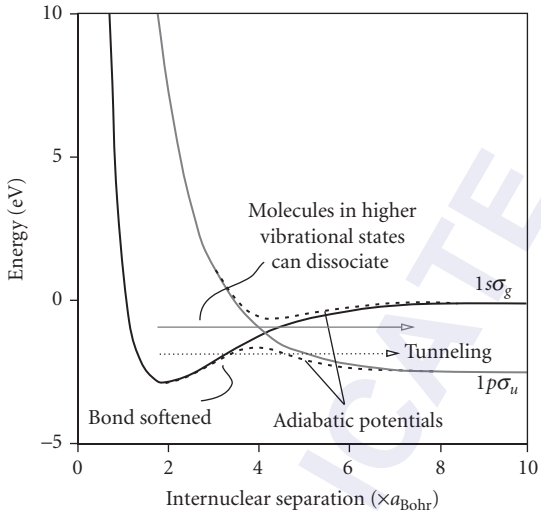

FIGURE 13 Nuclear potential energy curves for the first bound and first unbound state of H_2^+. The coupling of these states to a strong field leads to mixing and new distorted potentials called "adiabatic states," which are pictured as dashed curves. The bond softening resulting from these distorted curves permits molecules left in high laying vibrational states to dissociate immediately and those in lower states to tunnel out on a longer time scale.

Coulomb Explosion

At higher intensity (10^{14} to 10^{15} W/cm^2), multiple ionization of the molecular nuclei will lead to a Coulomb repulsion of the ions, a process known as a Coulomb explosion. This explosion happens very quickly and subsequent multiple ionization of the nuclei while in proximity to each other occurs only if the rise time of the laser is comparable or faster than this Coulomb explosion separation time. The characteristic time for explosion of a diatomic is roughly

$$\tau_{CE} \approx \frac{3}{4}\frac{\mu^{1/2}R_0^{3/2}}{(q_1q_2)^{1/2}e} \tag{28}$$

where $\mu = m_1m_2/(m_1 + m_2)$ is the reduced mass of the repelling system, q_1 and q_2 are the charge states of the ionized nuclei, and R_0 is the initial separation of the exploding nuclei. Equation (28) indicates that H_2^{2+} Coulomb explodes in under 1 fs, while N_2^{2+} explodes in about 5 fs.

Upon Coulomb explosion, the ejected ions acquire a kinetic energy just given by their initial Coulomb potential energy. For a diatomic molecule with ions charged by field ionization to q_1 and q_2, the Coulomb explosion energy is

$$\varepsilon_{CE} = \frac{q_1q_2e^2}{R} \tag{29}$$

where R is the separation of the two ions at the point of ionization. In almost all cases, the observed Coulomb explosion energy of an exploding diatomic or other small molecule is less than that expected of an explosion from the molecules equilibrium distance (which is, for example, 1.4 a_B for H_2).[145] This arises because of pre-expansion of the nuclear separation from bond softening and Coulomb repulsion of lower charge states before final ionization. A good rule of thumb is that ε_{CE}

upon strong field ionization will be about 45 to 55 percent of the energy calculated from equilibrium distances.[138] For example, Coulomb explosion of H_2 usually leads to the ejection of protons with energy between 3 and 5 eV.[146] ε_{CE} is largely independent of pulse duration and wavelength.[147]

Molecular Tunnel Ionization and the Critical Ionization Distance

The ionization rate for the first electrons of diatomic molecules in a strong laser field for low charge states in the tunneling regime (i.e., $\gamma << 1$) frequently follows standard atomic tunnel ionization rates, such as the ADK rate of Eq. (19), with the appropriate molecular ionization potential inserted into the formula.[134] Nonsequential recollision double ionization of diatomics also occurs in a manner similar to that of atoms.[148,149] There are, however, some subtleties which manifest in the tunnel ionization rate of certain diatomic species; these deviations from standard tunneling formulas are thought to arise from destructive interference between electrons liberated from the two nuclear centers.[150]

The production of higher charge states in a molecule under higher intensity irradiation and the subsequent Coulomb explosion of the highly charged fragments deviates significantly from the predictions of tunnel ionization of single atoms. In particular, charge states from field ionization of molecular nuclei tend to occur at an intensity much lower than that of the same charge state in an isolated ion. This occurs because of the presence of what is known as the critical ionization radius in the molecule.[151–155] This effect can be explained simply in the quasi-classical tunneling/barrier suppression ionization model described above. It arises because the field-induced tunneling of an electron from the molecule can be aided by the presence of the second charged nucleus of the molecule near the first. This effect is illustrated for a diatomic molecule in Fig. 14, in which a diatomic molecule

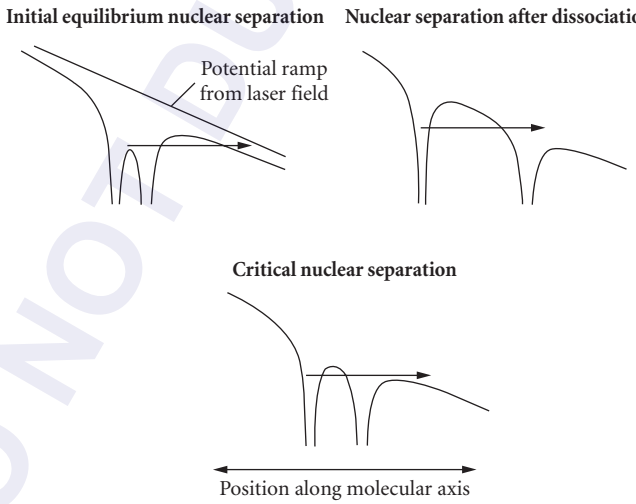

FIGURE 14 Drawing of the electron potential energy curves for a diatomic molecule immersed in a strong slowly varying field for three nuclear spacings. At the initial equilibrium position, pictured in the upper left, ionization by tunneling occurs when the electron tunnels out of the combined Coulomb well into the continuum. On the other hand, if the molecular nuclear have become greatly separated by dissociation, ionization must occur by tunneling from the potential of an isolated ion. However, at an intermediate separation, the electrons from the left-most ion need only tunnel through a narrow barrier formed from the combination of both Coulomb fields. This results in a greatly enhanced ionization rate at this nuclear separation.

is aligned along the axis of the laser electric field. When the nuclei are close together, the electrons are confined in the combined potential of the two nuclei; an applied field then requires an electron to tunnel from the combined potential. At very large nuclear separation, the electron is effectively localized at one of the nuclei and the tunneling rate is just that of an electron tunneling from an isolated Coulomb potential well. However, as the spacing of the diatomic nuclei begins to expand from the close initial position, the outer barrier (on the right in the figure) begins to drop and the central barrier begins to rise. There will occur an optimum distance in which an electron confined to the "uphill" potential need only tunnel through the relatively thin central potential barrier (see Fig. 14 bottom). This separation is the critical ionization distance. A simple analysis of the shape of the potential surrounding two ions each with charge q, indicates that this critical ionization distance will occur roughly at

$$R_c \approx \frac{4qe^2}{I_p} \tag{30}$$

If we make the approximation that the binding potential of charged ions in a diatomic are roughly given by the unionized molecular ionization potential divided by q, we find that the critical distance is independent of charge state. For a diatomic such as H_2, the ionization potential of 15.4 eV suggests a critical ionization distance of about 3.7 Å (about 7 atomic units or 5 times the equilibrium separation). A similar calculation for I_2 suggests a critical ionization distance of 10 a.u. for all of the iodine charge states.[145]

This ionization enhancement at the critical distance explains the appearance of higher charge states in molecular strong field ionization at lower intensity than might be expected.[35] The multiple ionization dynamics follow a multistep process. After some initial ionization of a high Z molecule, the ions begin to separate. If they come apart to the critical distance on a time scale faster than the laser pulse passes [predicted by Eq. (28) for most small molecules], the nuclei will be rapidly ionized to higher charge states at the critical distance, leading to an energetic Coulomb explosion of the higher charged ions from R_c separation. This process is described in Fig. 15[156] in which the barrier suppression ionization thresholds are plotted for various charge states of iodine as a function of I_2 separation along with the trajectory of an iodine molecule in a strong field.

There is some theoretical evidence for the presence of a second, more closely spaced critical ionization distance in molecule strong field ionization.[157] This effect, often called charge-resonance enhanced ionization (CREI), is a quantum mechanical effect and results from a localization of part of the electron wavepacket in the upper well at an internuclear separation smaller than R_C described above. There is presently no experimental evidence for this second critical distance.

Triatomic and Larger Molecules in Strong Fields

The fragmentation of molecules larger than a diatomic quickly becomes more difficult to describe, though the principles described in the last two subsections apply, particularly if the molecule is linear. However, the ionization dynamics are complicated and many fragmentation channels are usually observed at intensity $>10^{14}$ W/cm^2.[138] For example, even in a molecule as simple as CO_2 multiple channels such as $O^+ + CO^+ + 4.7$ eV and $O^{2+} + CO^+ + 8.5$ eV are observed with about equal probability when irradiated in near-IR pulses of intensity $\sim 10^{15}$ W/cm^2.[138] Many fragmentation channels occur not as a sequence of two independent bond fragmentations but occur as one, nonsequential rupture of both bonds.

Tunnel ionization rates for multinuclear molecules which are linear can often be found by treating the molecule as a single elongated well potential from which the electron can tunnel in the laser field.[158] These so-called structural tunnel ionization models have been employed successfully to explain ionization of more complex molecules, such as benzene,[159] though multielectron effects play a much larger role, and the single active electron approximation implicit in tunnel ionization theory is inaccurate.

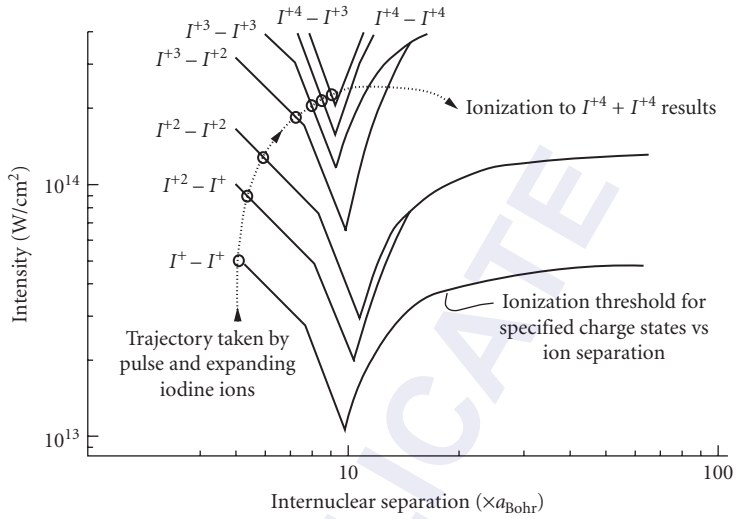

FIGURE 15 The solid lines in this plot show the BSI ionization threshold for various iodine ion pairs aligned along the laser field as a function of nuclear separation. The large dip in ionization threshold at around $10a_{Bohr}$ for all charge state pairs is a consequence of the critical ionization distance described in Fig. 14. The dashed line shows the trajectory in terms of laser intensity and nuclear separation that an iodine molecule undergoes when it is irradiated by a 150-fs pulse at an intensity of 2.5×10^{14}W/cm^2 showing the various charge states created by BSI ionization in the pulse as the I_2 molecule Coulomb explodes. The presence of the critical ionization dip results in higher charge state (+4 for both ions) than would be achieved at this intensity by irradiation of a single iodine atom. *(Plot adapted from that of Ref. 156.)*

21.7 STRONG FIELD NONLINEAR OPTICS IN GASES

High Order Harmonic Generation

When a strong field pulse of light propagates through an extended gas a number of new phenomena occur. These occur when the gas density is high enough that coherent optical and nonlinear optical effects become important, a point that occurs in a practical sense in gases with density above about 10^{17} cm^{-3}. The single atom or single molecule interactions described above come into play and often are the seeds to the initiation of other physical effects, the most common of which is strong field ionization leading to plasma formation. However, another important strong field effect which manifests itself at intensity just at or slightly below the intensity threshold for ionization is the generation of radiation at harmonics of the laser field.[7,24,38,160,161] This process, termed high order harmonic generation (HHG), is described in greater detail in other chapters of this volume so only a rudimentary over view is given here.

Harmonic generation in gases subject to strong laser fields arises from the nonlinear oscillations of the bound electrons in the gas's atoms. This is generally performed in gases of rare gas atoms, though HHG from molecular[162] and clustering[163] gases is also possible. At modest intensity ($<10^{14}$ W/cm^2), HHG can be thought of as a multiphoton process, illustrated in the upper left of Fig. 16. In this picture an atom simultaneously absorbs q photons from the intense light field and then re-emits a photon with energy $q\hbar\omega_0$. Since free atoms in a gas exhibit a centro-symmetric potential, angular momentum must be conserved. This constraint, combined with the fact that the absorption and emission of a

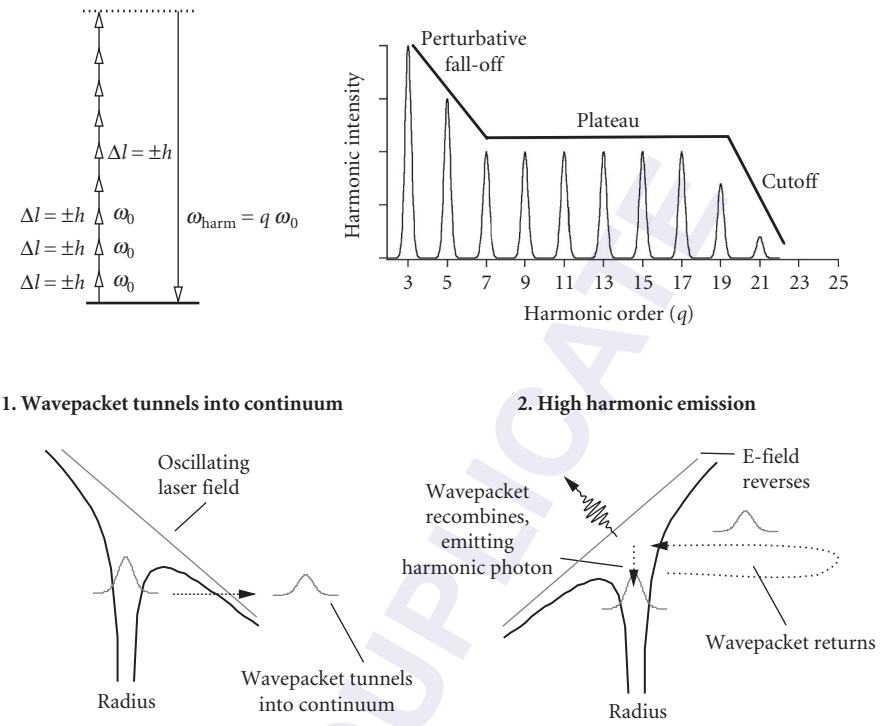

FIGURE 16 Simple view of the various aspects of high order harmonic generation physics. In the upper left, the multiphoton view of HHG is illustrated showing why only odd harmonics are possible given the need to conserve momentum by the interaction with atoms in a gas. The plot in the upper right is a generalized illustration of the character of a usual HHG spectrum at nonperturbative intensities ($>10^{14}$ W/cm^2) showing the presence of an initial fall-off of yield with harmonic order at low orders followed by a long plateau of harmonics at roughly constant yield terminated by a cutoff. The bottom pictures illustrate the quasi-classical picture of HHG in which the generation of harmonic photons can be thought of as a result of a tunnel ionized electron recombining with its parent ion upon return to the nucleus in the field.

photon is accompanied by the change in angular momentum of $\pm h$, indicates that only odd harmonics of the light field can be emitted. (It also indicates that harmonics cannot be produced in a gas with circularly or elliptically polarized light.[164,165]) Because all of the atoms in a gas are driven in this way harmonically, their emitted radiation will add coherently and the emitted harmonic radiation will propagate in the same direction as the drive laser and will retain many of the temporal and coherence properties[166] of the driving laser field. More accurately, HHG can be thought of as arising from the nonlinear polarization induced in a medium of density n_g such that $\mathbf{P}(t)=n_g\mathbf{d}(t)$, where $\mathbf{d}(t)$ is the induced atomic dipole. In the single active electron approximation, $\mathbf{d}(t)=\langle\psi(t)|e\mathbf{r}|\psi(t)\rangle$, where $\psi(t)$ is the time-dependent wave function of the laser-driven atom.

This dipole, when driven very nonlinearly by a strong light field, will have Fourier components, $\mathbf{d}(q\omega_0)$, at frequencies $q\omega_0$ out to rather high harmonic orders (where q is an odd integer). In the weak field regime, where perturbation theory is appropriate, $\mathbf{d}(q\omega_0)$ varies as the qth power of the electric field, resulting in a harmonic yields which increase as the qth power of the incident intensity. Such behavior is indeed observed at intensity below about 10^{13} W/cm^2 in gases of noble gas atoms at moderate harmonic number (say $q=3$ to 9). However, in a strong field, at intensity of 10^{14} to 10^{15} W/cm^2 the nonperturbative behavior of the laser driven atom leads to an atomic dipole of the qth harmonic

that will vary with a power law, I^p, that is usually well below the harmonic order ($p < q$).[167] In most strong field interactions in near-IR pulses at orders of $q = 11$ to 101, p will typically rest in the range of 5 to 8.[7]

Harmonic generation in this nonperturbative regime leads to a dramatic spectrum of harmonics that differs markedly from that expected from simple, multiphoton arguments. The emitted harmonic spectrum in this nonperturbative regime usually exhibits behavior illustrated in Fig. 16. The yield of the low order harmonics, out to perhaps the 5th or 7th order, falls exponentially, as expected under perturbation theory. However, the yield of harmonics at higher orders will then remain roughly constant, out to rather high order, a feature usually termed the HHG plateau. This plateau is then followed by an abrupt cutoff in harmonic production. Extremely high orders of harmonics from near-IR lasers have been demonstrated, with $q > 101$ achievable with sub-100 fs laser pulses. When extremely short (<20 fs) pulses are used, the gas atoms can survive to an even higher intensity resulting in extremely high order harmonic production. Orders well over $q \sim 201$ can be produced with such pulses in high ionization potential atoms such as helium,[6,168] though the spectrum loses its distinct harmonic character at these very high orders. Obviously, conversion of a near-IR laser to such high-order results in light with wavelengths in the XUV and soft x-ray region (2 to 30 nm), and as such represents an attractive means for generation coherent pulses in this soft wavelength region.

Quasi-Classical Model of High Harmonic Generation In the strong field regime, it is possible to describe HHG with a quasi-classical model, much as strong field ionization and ATI can be described in this regime.[10,11] Again, such a model is appropriate when the light field meets the condition that $\gamma_K < 1$. The mechanism for producing harmonic radiation by this model is illustrated in Fig. 16 at the bottom. The strong laser field can induce tunneling of the bound electron wavepacket; this freed electron wavepacket oscillates in the laser electric field. Electrons freed at certain phases of the laser oscillation can return to the vicinity of the nucleus and recombine back down to its initial ground state, emitting a photon of energy $I_p + \varepsilon_{osc}$. The periodic return of many wavepackets leads to emission of radiation at well-defined harmonics of the light field.[169]

The energy of the emitted photon depends on the electron's energy upon return to the nucleus. As Eq. (24) illustrates, if the electron is born by tunneling at a phase ϕ_0, then the electron can return to the nucleus to produce a harmonic photon with energy

$$\hbar\omega_{\text{Harm}} = \frac{1}{2} m_e v_{\text{osc}}^2 (\sin\phi - \sin\phi_0)^2 + I_p \tag{31}$$

As mentioned in Sec. 21.5, analysis of Eqs. (24) and (31) indicates that the electron will return with maximum energy at $\phi_0 = 17°$ and 197° and does so, in that case, with energy $3.17U_p$. This analysis leads to a well-known formula for the *maximum* photon energy of the high harmonic spectrum, known commonly as the cutoff harmonic

$$q_{\text{cutoff}} \hbar\omega_0 \approx I_p + 3.2U_p \tag{32}$$

In most experimental situations, U_p is usually evaluated at the intensity at which ionization starts to saturate. Above this intensity, there are no further atoms to participate in the harmonic generation process so further increase in intensity does not lead to a higher order cutoff harmonic. This cutoff formula was first discovered via numerical simulations[170] and has been well confirmed in many experiments.[6,7,168]

This quasi-classical model for HHG predicts some important features of HHG. Because some time must elapse between the freeing of the electron by tunneling and its return to the nucleus to emit a photon, the emitted harmonic will pick up a phase shift with respect to the laser field.[169,171] This model indicates that this phase shift is intensity dependent and, therefore, has a consequence on the macroscopic phase matching of the harmonics.[172] Also note that Eqs. (24) and (31) indicate that most return energies can be generated by two different electron trajectories, resulting from liberation at two distinct phases in the laser field. The two trajectories, a short and a long trajectory, can

destructively interfere in the harmonic generation because of their differing phases resulting from their different times spent in the continuum before recombining with the parent nucleus.[173,174]

Harmonic Yield and Phase-Matching Considerations Because HHG is a parametric process that results from the coherent addition of radiation produced from the nonlinear oscillations of electrons from many atoms in the gas, the harmonic intensity is strongly affected not only by the single atom physics of the atomic dipole, but also by phase-matching processes. As in standard nonlinear optics and usual harmonic generation, the harmonic field will continue to grow along with the propagating laser as long as the HHG field is in phase and newly generated harmonic light can add coherently.[175] If this condition is preserved, the harmonic yield will increase as the square of propagation distance. However, phase shifts associated with differences in refractive index between the fundamental and the harmonic as well as phases intrinsic to a focused laser beam will lead to mismatches that will clamp the harmonic generation.

While there are a number of ways to generate harmonics, one of the most common ways is to focus a Gaussian-shaped beam into a gas medium of length L with density n_0. Calculating the harmonic yield is a very difficult problem, however, estimates can be simply made with a few assumptions. A simple model for the harmonic conversion yield can be delineated for a focused Gaussian beam with confocal parameter b (defined by usual Gaussian optics as $b = 2\pi w_0^2/\lambda$, where w_0 is the usual $1/e^2$ focal radius) and with the induced single atom dipole at the qth harmonic that varies as $|d(q\omega)| = \xi_p |E_1|$. The integrated energy yield of the qth harmonic generated by a square top pulse of duration t_p then is given by[167]

$$\text{Energy}_q = \frac{\pi^2 q^2 \omega_0 n_0^2 b \tau_p |d(q\omega)|^2 L^2}{p} \left[\frac{\sin\{(\Delta k + 2q/b - 2q/pb)L/2\}}{\{(\Delta k + 2q/b - 2q/pb)L/2\}} \right]^2 \tag{33}$$

where Δk is a phase mismatch induced by the medium itself. The final sinc^2 factor is a strong field generalization of the phase-matching factor found in standard nonlinear optics and determines the coherence length

$$L_c = [\pi(\Delta k/2 + q/b - q/pb)]^{-1} \tag{34}$$

over which harmonic generation can build up. A medium length, longer than this coherence length will result in destructive interference and a clamp on the harmonic conversion.

The harmonic yield is determined by a complicated interplay of the laser propagation, the medium density, the atomic response, and loss of media through ionization. As a result, the harmonic conversion efficiency of high harmonics in the plateaus varies broadly and can range from 10^{-8} times the input laser energy for very high harmonics (q ~ 31 to 101) in tightly bound atoms (such as He or Ne)[176] up to as high as $\sim 10^{-5}$ for moderate order harmonics (q ~ 23 to 31).[177] The phase mismatch Δk usually arises at low intensity from the intrinsic dispersion of the gas itself between the fundamental and the harmonic. At higher intensity, as ionization becomes important, Δk will be determined by the dispersion of the plasma itself. In this regime when a plasma density of n_e is created by ionization

$$\Delta k_{\text{plasma}} \cong \frac{2\pi n_e e^2}{qc\omega_0 m_e}(q^2 - 1) \tag{35}$$

At higher intensity in weakly focused beams (i.e., when $b >> L$) this plasma-induced phase mismatch dominates the high harmonic production process. For example, at a plasma density of 10^{18} cm^{-3}, the coherence length of the 31st harmonic implied by Eq. (35) is only ~10 μm. Therefore, harmonics are produced only over this length, even if the medium is substantially longer (as is usually the case).

Attosecond Pulse Generation

The harmonic spectrum schematically illustrated in Fig. 16 in fact has a very broad bandwidth if the entire spectrum is considered as having a coherent phase relationship over the entire spectral window. This implies that such a broad spectrum, when Fourier transformed, results in a pulse, or a train of pulses, with duration well under 1 fs, that is, in the attosecond regime. This situation can indeed be achieved experimentally leading to the production of attosecond pulses with duration approaching 100 as.[9,31,178–180] The physical origin of this can be easily seen within the context of the quasi-classical model. The return of an electron during its HHG generating recollision can be thought of as producing a short burst of bremsstrahlung radiation with duration comparable to the return encounter of the electron. If a laser pulse is short enough, such a bright burst can be made to occur for only one laser cycle and, therefore, produce a single isolated burst of attosecond radiation. This process is described at length in another chapter in this volume.

21.8 STRONG FIELD INTERACTIONS WITH CLUSTERS

When a strong laser field interacts with a cluster of atoms, collective effects not present in the interaction of strong field pulses with ions or small molecules come into play.[19,39,181–183] Here clusters refer to assemblages of greater than ~100 atoms on one hand, but assemblages whose spatial dimension is still well below the laser wavelength, that is, particles with diameter <100 nm or < 10^6 atoms. Such clusters are usually van der Waals bonded assemblies of atoms or small molecules. Large, easily polarizable atoms such as Xe or Kr form clusters most easily, though even small atoms or molecules, such as H_2 can be made to cluster under the right circumstances.

Ionization Mechanisms in Clusters

Clusters will ionize in strong laser fields at intensities in which single atoms begin to ionize. In the cluster, however, there are two aspects of the ionization that must be considered, the inner ionization of the constituent atoms and ions and the outer ionization, resulting from the removal of free electrons within the cluster out, away from the cluster.[39] Ionization of the cluster is shaped by the fact that the laser field penetrates completely through the cluster, even when many free electrons are retained in the cluster and act as a plasma. This can be seen by noting that the plasma skin depth $\lambda_p = c/(\omega_p{}^2 - \omega_0{}^2)^{1/2}$ is almost always much smaller than the cluster diameter, even at solid electron density n_e (note that $\lambda_p \sim 20$ nm at solid density). Here $\omega_p = (4\pi e^2 n_e/m_e)^{1/2}$ is the plasma frequency (the resonant frequency at which electron waves in a plasma oscillate.[184])

Inner Ionization Processes in the Cluster When a strong field light pulse begins to interact with the initially unionized cluster the constituent atoms in the cluster undergo ionization. This process is usually termed inner ionization because the electrons liberated from the atoms within the cluster do not necessarily exit the cluster as a whole. If these electrons linger in the cluster, they produce a nanoplasma which has unique collective properties.[181] Inner ionization in the early stages of the laser interaction is usually dominated by quasi-classical tunnel ionization. The tunnel ionization of atoms within the cluster can be enhanced in a manner similar to the enhancement of ionization in diatomic molecules resulting from the suppression of the binding potential from neighboring ions in the molecule (discussed in Sec. 21.6).[185] The presence of nearby ions in the cluster can succeed in lowering the Coulomb binding potential (as illustrated in Fig. 17), and tunnel ionization can be greatly enhanced. This process has been termed "ionization ignition."[186] A second process can also increase the rate of inner ionization in the cluster. This ionization occurs by collisional ionization by free electrons in the cluster, driven in an oscillatory motion by

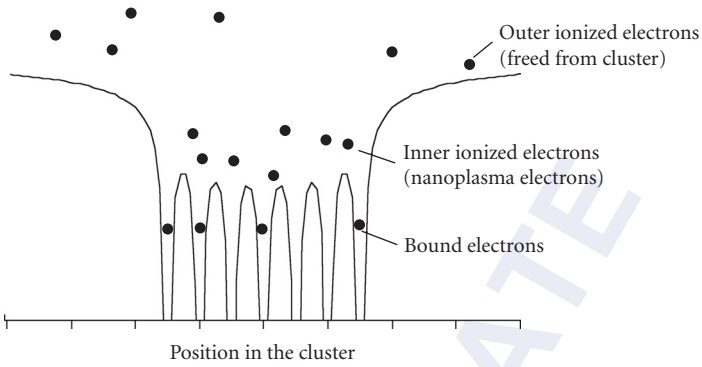

FIGURE 17 Plot of the Coulomb potential of ions arrayed in a cluster. The close proximity of many ions can suppress the barrier of the binding potentials, enhaning the tunnel ionization rate in the cluster. Some ionized electrons, however, will be confined to the cluster potential as a whole, resulting in the formation of a nanoplasma.

the strong laser field. The rate of this laser-driven collisional ionization can be calculated by using the well-known Lotz formula for ionization[187]

$$W_{\text{las}} = n_e \frac{a_i Q_i}{\pi I_p} \sqrt{\frac{1}{m_e U_p}} \int_{I_p}^{2U_p} \frac{\ln(K_e/I_p)}{2K_e} \frac{1}{\sqrt{1-K_e/2U_p}} dK_e \tag{36}$$

Here $a_i \approx 1.1 \times 10^{-37}$ cm^2 – erg^2, and Q_i is the number of electrons in the outer shell of the ion. This laser driven collisional ionization rate tends to dominate the ionization in the cluster, usually being higher than the tunneling rate for most solid density cluster plasmas.[181] This laser driven collisional ionization in the cluster leads to the production of charges states well above those which are observed in strong field ionization of single atoms at similar intensity.[188–190] For example, Eq. (36) predicts that the ionization rate for $Ar^{+15} \rightarrow Ar^{+16}$ is about 0.001 fs^{-1} at an intensity of 5×10^{17} W/cm^2 in a 1-μm laser pulse. This would yield approximately 10 percent ionization to He-like Ar during a 100-fs pulse. On the other hand, the BSI theory indicates that an intensity of 2×10^{21} W/cm^2 would be needed to achieve significant ionization to Ar^{+16} by direct field ionization. This laser driven collisional ionization can lead to the production of very high charge states in clusters, even at modest laser intensity.[189,190]

Outer Ionization of the Cluster If space charge forces retain the inner ionized electrons in the body of the cluster, the removal of electrons from the cluster sphere, outer ionization, may take much longer than the initial inner ionization (see Fig. 17). There are two regimes for outer ionization in the strong field irradiation of the cluster. First, the laser field itself can extract the electrons from the cluster. In a very strong field (i.e., $E_0 >> Q_{\text{clust}} e/R_0^2$, where Q_{clust} is the number of electrons removed by outer ionization from the cluster, and R_0 is the radius of the cluster), outer ionization occurs almost instantaneously and the cluster enters the Coulomb explosion regime. For laser fields comparable to or smaller than the binding field of the laser, it can be shown that the number of electrons outer ionized by the laser field is[191]

$$Q_{\text{clust}} \approx 12\pi \frac{n_e R_0^2 e E_0}{m_e \omega_p^2} \tag{37}$$

which is proportional to the square root of intensity. Alternatively, outer ionization can occur by electrons that have been heated sufficiently to escape the binding potential of the cluster. In this case, the rate of outer ionization by "free streaming" can be estimated assuming a Maxwellian electron energy distribution with temperature, T_e[181]

$$W_{fs} = n_e \frac{2\sqrt{2\pi}}{m_e^{1/2}(kT_e)^{1/2}}(K_{esc}+kT_e)\exp\left[-\frac{K_{esc}}{kT_e}\right]\times\begin{cases}\dfrac{\lambda_e}{4r}(12r^2-\lambda_e^2) & \lambda_e < 2r \\ 4r^2 & \lambda_e > 2r\end{cases} \tag{38}$$

where $K_{esc} = Q_{clust}e^2/R_0$ is the energy needed to escape, $\lambda_e = (k_B T_e)^2/4\pi n_e (Z+1)e^4 \ln\Lambda$ is the electron mean free path in the cluster and $\ln\Lambda$ is the well-known plasma Coulomb logarithm.

Coulomb Explosion of Small Clusters

If a cluster is stripped of most of its electrons via the outer ionization process very quickly, much faster than the cluster can expand, the cluster will disassemble by a Coulomb explosion. For the cluster to evolve in this limit, two conditions must be met (1) the intensity of the light field must be high enough and (2) the laser pulse must ramp up to the intensity needed for complete outer ionization must faster than the cluster expands.

The first condition is difficult to determine as the intensity needed for complete outer ionization is not easily calculated analytically; it depends on the dynamics of the driven electron cloud in the cluster. This can be estimated by requiring that the laser ponderomotive energy dominates the electron dynamics over the confining potential energy of the cluster,

$$U_p > \frac{Q_{clust}e^2}{R_0} \tag{39}$$

Here Q_{clust} is the total charge on the cluster sphere from electrons that have previously exited the cluster. The second condition mandates that the rise time of the laser pulse to the stripping ponderomotive potential be faster than the explosion time of the cluster. This characteristic explosion time can be estimated by calculating the time required for a charged cluster to expand from its initial radius, *a*, to twice its initial radius. Integration of the motion of a charged deuterium cluster yields for this characteristic explosion time:

$$\tau_{Coul} \approx \sqrt{\frac{m_i}{n_i Z^2 e^2}} \tag{40}$$

where m_i is the mass of the ions and n_i is the density of atoms in the cluster. Note that τ_{Coul} is independent of cluster radius and equals about 15 fs for fully stripped hydrogen clusters. Equation (40) indicates that the Coulomb explosion limit can usually be accessed in clusters only with intense, sub-100-fs laser pulses.[192]

If a Coulomb explosion is driven and it can be assumed that all electrons are removed prior to any ion movement, the ion energy spectrum from a single exploding cluster, denoted $f_{sc}(\varepsilon)$, can be stated as[193]

$$\begin{aligned} f_{sc}(\varepsilon) &= \frac{3}{2}\,\varepsilon_{max}^{-3/2}\varepsilon^{1/2} \qquad \varepsilon \le \varepsilon_{max} \\ &= 0 \qquad\qquad\qquad\quad \varepsilon > \varepsilon_{max} \end{aligned} \tag{41}$$

where ε_{max} is the maximum energy of ions ejected and corresponds to those ions at the surface of the cluster, $\varepsilon_{max} = 4\pi e^2 n_i R_0^2/3$. In hydrogen clusters, for example, ε_{max} is about 2.5 keV for 5 nm

clusters. This ion spectrum is peaked near ε_{max}. In most experiments, however, the clusters irradiated are composed of a broad size distribution. This tends to broaden the ion energy distribution observed.

Nanoplasma Description of Large Clusters

In the limit of a Coulomb explosion, the principal absorption mechanism for laser light is in the deposition of the energy needed to expel the electrons from the charged cluster. The other limit of strong field laser cluster interactions occurs when there is little or no outer ionization subsequent to significant inner ionization in the cluster. This tends to occur in larger clusters and clusters composed of higher Z atoms which can become more highly charged. When outer ionization lags inner ionization, a nanoplasma is formed in the cluster.[181] In this case, the laser interactions with the cluster can be dominated by collective oscillations of the electron cloud.

Cluster Electron Heating Because the electrons are confined to the cluster by space charge forces, they can acquire energy from the intense laser field. Because of the collective oscillation of the electron cloud, the electric field inside the cluster will be[72]

$$E = \frac{3}{|\varepsilon_D + 2|} E_0 \tag{42}$$

where the dielectric constant can usually be taken to be a that from a simple Drude model for a plasma $\varepsilon_D = 1 - \omega_p^2/\omega_0(\omega_0 + i\nu)$. ν is the electron-ion collision frequency (discussed below). Equation (42) indicates that the field is enhanced in the cluster when the laser frequency is $3^{1/2}$ times the plasma frequency, that is, when $n_e/n_{crit} = 3$. ($n_{crit} = m_e\omega_0^2/4\pi e^2$ is the plasma critical density, at which the laser oscillates at the plasma resonance frequency.) This resonance condition corresponds to a state in which the laser frequency matches the natural collective oscillation frequency of the electron cloud in the spherical cluster. This resonance condition is accompanied not only by an increase of the field in the cluster but also an increase in the electron heating rate and cluster absorption of energy from the laser. The heating rate of electrons in the cluster is then[194]

$$\frac{\partial U}{\partial t} = \frac{9\omega_0^2\omega_p^2\nu}{8\pi} \frac{1}{9\omega_0^2(\omega_0^2 + \nu^2) + \omega_p^2(\omega_p^2 - 6\omega_0^2)} |E_0|^2 \tag{43}$$

The choice of collision frequency in this equation is complicated by various aspects of strongly coupled plasma physics, but for most interactions in which the electrons in the cluster are dominated by the driven motion of the laser electric field, we can say that the collision frequency most relevant for strong field cluster interactions is[195]

$$\nu_E = \frac{16Z^2 e n_i m_e \omega_0^3}{E_0^3} \left(\ln\left[\frac{eE_0}{2m_e\omega_0 v_e} \right] + 1 \right) \ln\Lambda \tag{44}$$

where Z is the average charge state of ions in the cluster and $v_e = (k_B T_e/m_e)^{1/2}$. The principal consequence of this resonance occurs after the cluster has been initially inner ionized to an electron density near that of a solid ($\sim 10^{23}$ cm^{-3}). As the cluster expands, its resonance frequency falls and, if the laser pulse is long enough, will come into resonance with the laser. This is accompanied by a violent driving of the cluster nanoplasma cloud with rapid energy deposition in the cluster. Electron temperatures of many tens of keV are possible, even with modest ($<10^{16}$ W/cm^2) drive intensities. When such cluster nanoplasmas are irradiated in a dense gas jet, very high (near 100 percent) absorption of the laser occurs[196] and bright x-ray emission, high ion temperatures, and even nuclear fusion can be observed.[182,197–200] Because of this dynamic plasma resonance, there is often an optimum pulse

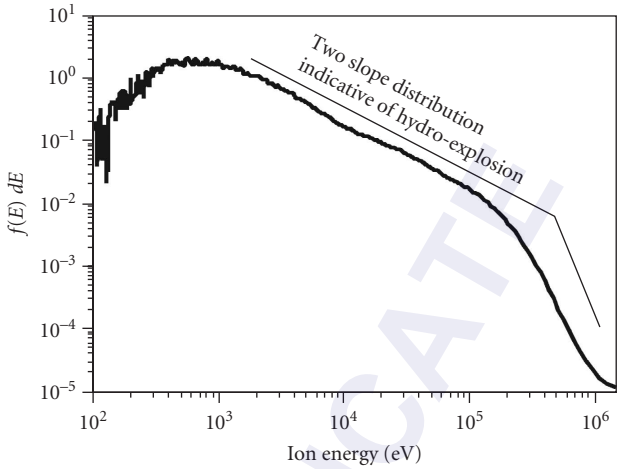

FIGURE 18 Example of the ion spectrum resulting from the irradiation of Xe clusters in the nanoplasma regime. These ~2500 atom Xe clusters were irradiated by a 100-fs pulse at an intensity of $\sim 2 \times 10^{16}$ W/cm^2. This illustrates how ions with energies (~1 MeV in these data) much higher than U_p (~1.2 keV here) can be generated during the interaction with clusters. *(Figure adapted from Ref. 189.)*

duration for heating clusters in this manner.[201] For example, small Ar clusters can expand into resonance on a 100-fs timescale, while large (>10 nm) Xe clusters can take 1 to 5 ps to reach resonance with a near-IR laser.[202]

Cluster Expansion Mechanisms In the nanoplasma regime, the cluster will expand, though not by Coulomb repulsion forces between ions, as it does in the Coulomb explosion regime. Instead, it will expand by the ambipolar potential created by the thermal pressure of the hot electrons in the nanoplasma, $p_e = n_e k T_e$. This pressure will lead the cluster to explode on a time scale of $t_{expl} \approx R_0 (m_e/ZkT_e)^{1/2}$. The resulting ion spectrum will be characteristic of that from a hydrodynamicailly exploding plasma, as illustrated in Fig. 18. The hot tail that results from such an expansion can lead to the production of ions with hundreds of keV to MeV of energy, even in laser pulses with ponderomotive energies of only ~1 keV (an intensity of about 10^{16} W/cm^2 in a near-IR field).

It should be noted that the simple model used here to describe the clusters in the nanoplasma regime rely on the assumption that the cluster remains more or less uniform density. During the expansion of the cluster, it will devolve from a uniform density to a plasma with a radial plasma gradient. In this case, the absorption is likely dominated by resonance absorption (described in Sec. 21.10) at the critical density surface around the cluster circumference.[203] In addition to the absorption processes described, various plasma processes can occur, such as electron ion equilibration and electron recombination, affecting the cluster dynamics.

Intense Laser Pulse Interactions with Clusters in the Nonneutral Regime

The description of the dynamics of a cluster in a strong laser field in a regime intermediate to the Coulomb explosion and the nanoplasma regimes, when outer ionization is only partial, is complicated. Simple electrostatic theory tells us that if some of the electrons have been outer ionized, then

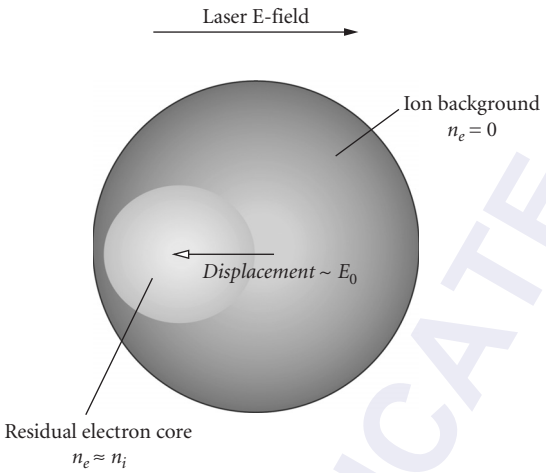

FIGURE 19 Schematic showing the geometry of the electron cloud within the ion sphere of a partially charged cluster. The electron cloud contracts to create a quasi-neutral core which can be driven from side to side by the strong laser field. When the oscillations are large enough that some of the electron cloud is pulled out away from the ion sphere, outer ionization of these electrons occurs.

the cluster, no longer quasi-neutral will evolve so that the remaining electrons will collapse into an inner, neutral cloud within the cluster, a situation illustrated in Fig. 19.[191] The laser field will then pull the electron cloud over by a distance $d_0 = 3eE_0/m_e\omega_p^2$. This extracts electrons through laser field acceleration.

Electron Stochastic Heating In the intermediate regime of cluster ionization, there will be a population of electrons that will be driven by the laser in the vacuum surrounding the cluster sphere. These electrons can pass in and out of the cluster a number of times, picking up energy from the laser at each pass, in a manner similar to the vacuum heating described in Sec. 21.10. This heating is called stochastic heating and leads to the generation of a population of very high energy electrons. It can be shown that the maximum energy that can be reached by electrons in this manner is $\varepsilon_{max} \sim m_e R_0{}^2\omega^2$, an energy which can be well in excess of the ponderomotive energy if the cluster is much larger than a quiver amplitude.[191]

21.9 STRONG FIELD PHYSICS IN UNDERDENSE PLASMAS

In this section, we will discuss the physics involved in the interaction of strong field electromagnetic pulses with underdense plasma, namely, plasma in which the plasma frequency $\omega_p = \sqrt{4\pi e^2 n_e/m_e}$ is smaller than the laser frequency, ω_0. In this situation, the refractive index of the plasma $n = \sqrt{1-\omega_p^2/\omega_0^2}$, is real and the laser field can propagate through the plasma. At high intensity, various field driven coupling mechanisms occur which deposit energy into the plasma fluid through interactions with charged particles individually or through interactions with plasma waves. These interactions tend to heat the plasma electrons as a whole or they directly couple laser energy into a small population of fast electrons.

Strong Field Inverse Bremsstrahlung Heating

Perhaps the most basic mechanism for an intense light pulse to heat underdense plasma is through inverse bremsstrahlung: collisional heating. In the strong field regime with IR or optical wavelength pulses, the process can be accurately described classically. The nature of the heating is illustrated in Fig. 20. When an oscillating electron in the laser field collides with an ion and scatters from the Coulomb field of the ion, its adiabaticity is broken, acquiring some random, thermal energy from the laser field. The heating rate of electrons is then some appropriate electron-ion collision frequency times the amount of energy gained per collision, which can usually be taken to be the ponderomotive energy. So the heating rate per electron is $dU/dt|_{IB} \approx \nu_{ei} U_p$.[184]

At low intensities, the electron-ion collision frequency can be taken to be the usual temperature-dependent plasma electron-ion collision rate.[204] In the strong field regime the picture is a little different. When $U_p > k_B T_e$ the electron motion is dominated not by thermal motion but instead by the ponderomotive motion of the laser, which means that the standard collision frequencies utilized in normal plasma physics cannot be used. There have been various models published to describe the electron heating and dynamics in this strong field limit.[195,205] A good model for heating of electrons in a strong field leads to a heating rate of[206]

$$\left.\frac{\partial U}{\partial t}\right|_{\text{las}} = \frac{16 Z^2 n_i e^3 m_e \omega_0}{3E_0} \ln\left[\frac{eE_0}{m_e^{1/2}\omega_0 (kT_e)^{1/2}}\right] \ln\Lambda \tag{45}$$

Again, $\ln\Lambda$ is the usual plasma Coulomb logarithm, which can be taken for the underdense plasmas treated here to be $\Lambda = (kT_e)^{3/2}/4\pi^{1/2} Z e^3 n_i^{1/2}$.

Notice that in this high-intensity regime, the heating rate actually decreases with increasing intensity (as $I^{-1/2}$), which results from the strong decrease of the Coulomb scattering cross section with increasing electron velocity. (The heating rate also decreases with increasing wavelength for the same reason.) It is interesting to note that, when the full kinetic evolution of the electron energy distribution function is solved in the high-field limit, the electron distribution approaches that naturally of a Maxwellian, independent of any electron equilibration.[206]

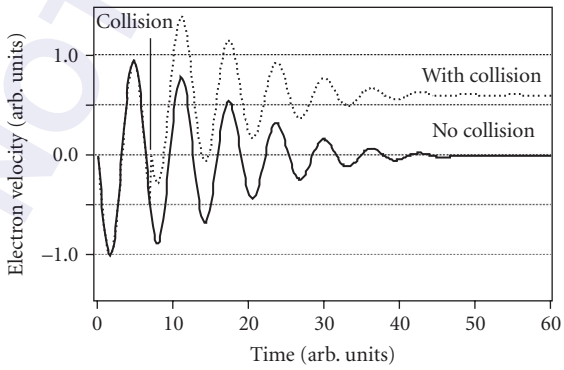

FIGURE 20 Calculation of the classical trajectory of an electron in a laser pulse which decays in time adiabatically to zero. The electron velocity falls to zero with the laser field and acquires no net energy when no collision takes place. If, however, an instantaneous 90° collision occurs, this breaks the adiabaticity of the electron's oscillation leaving it with some residual velocity after the pulse field has fallen to zero. This is the origin of inverse bremsstrahlung heating.

Plasma Instabilities Driven by Intense Laser Pulses

A salient feature of high-intensity laser interactions with plasmas is that plasmas can support collective motion, including coherent waves, which couple to the electromagnetic field of the laser. These plasma waves manifest themselves in various ways, such as in ion acoustic waves, (which are essentially sound waves in the plasma gas[184]). Because a plasma is composed of a positively charged ion fluid and a negatively charged, light electron fluid, it can also support electrostatic and propagating electromagnetic waves, often called Langmuir waves, composed of an oscillating electron density fluctuation.

Because the laser field is an electromagnetic wave, it can couple energy to these plasma waves as the pulse propagates through the plasma. For example, if the pulse drives ion acoustic waves, the process is termed Brillouin scattering. This process is usually not significant in ultrashort pulse, high-intensity interactions because the mass of the ions are so large that the growth rate of such instabilities is too slow for the laser pulse duration. Of greater importance to intense ultrashort laser pulses (with $I > \sim 10^{16}$ W/cm^2) is the coupling of laser energy to electron plasma waves. This coupling can occur through a panoply of mechanisms, such as the so-called $2\omega_p$ mechanism,[207] but the most important process in the strong field regime is electron Raman scattering.[208] The energetics of this process are described in Fig. 21. In Raman scattering, one laser photon is coupled to an electron plasma wave (which naturally oscillates at the plasma frequency) and results in the production (or destruction) of one quanta of the plasma wave with the simultaneous production of a photon at a shifted wavelength. The scattered light has frequency downshifted if energy added to the plasma wave (the Stokes process) or upshifted if energy is absorbed from the plasma (the anti-Stokes process).

In an intense laser pulse this process can undergo positive feedback, resulting in an exponentially growing instability, coupling a significant amount of light energy into the electron plasma wave (which is usually a longitudinal electron density fluctuation). How this happens can be seen if one considers what happens if a Stokes photon is produced in a Raman scattering event at a frequency of $\omega_s = \omega_0 - \omega_p$. This new field can add to the fundamental laser oscillation creating a beat frequency of $\omega_b = \omega_0 - \omega_s = \omega_p$ which can then, in turn, drive the plasma wave resonantly, increasing its amplitude and further driving the production of more Stokes photons. This feedback process leads to exponential growth of the Stokes field and the plasma wave, and is usually referred to as stimulated Raman scattering (or SRS).

The growth rate, defined by noting that the scattered wave amplitude and scattered light field grow as $\sim e\Gamma^t$, can be found from the coupled nonlinear equations describing the Stokes field (which is the one which will be resonant, growing the fastest) and the plasma wave. In the nonrelativistic limit, this growth rate is[184]

$$\Gamma_{\mathrm{SRS}} = \frac{k_e}{2}\sqrt{\frac{U_p}{m_e}\frac{\omega_p^2}{\omega_{\mathrm{BG}}(\omega_0 - \omega_{\mathrm{BG}})}} \tag{46}$$

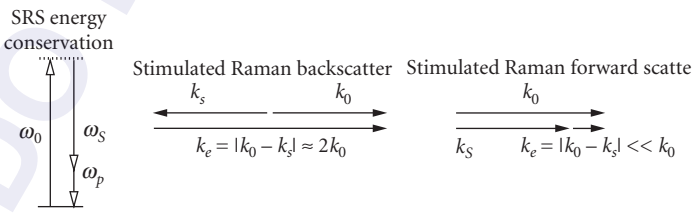

FIGURE 21 On the left, the energetics of Raman scattering in a plasma are demonstrated for the Stokes process in which a laser photon is scattered by a plasma wave creating a lower energy Stokes photon and depositing $\hbar\omega_p$ of energy into the plasma wave. The right-hand drawing illustrates the conservation of momentum for SRS backscatter and forward scatter, showing that the electron wave k-vector, and hence the growth rate, are maximum for the backscatter case.

here ω_{BG} is the Bohm-Gross plasma frequency $\omega_{BG} = \sqrt{\omega_p^2 + 3k_e^2(k_B T_e)^2/m_e}$, which is simply equal to the plasma frequency for a cold (T_e = 0) plasma, and $k_e = |\mathbf{k}_e|$ is the magnitude of the wavenumber of the plasma wave, defined by conservation of momentum by $\mathbf{k}_e = \mathbf{k}_0 + \mathbf{k}_s$. Equation (46) illustrates that the growth rate of this instability increases as the square root of the light intensity. In underdense plasma such that $\omega_0 >> \omega_p$, ω_{BG} the growth rate also scales with the square root of laser drive wavelength. Consequently, high intensity, long wavelength light pulses are much more susceptible to the SRS instability. In practice, an intense light pulse will cause the instability to grow from density fluctuations arising from thermal noise present in any plasma. When the laser pulse has passed, the plasma waves will tend to damp either by collisional processes in the plasma or by noncollisional processes such as Landau damping.[184]

The growth of SRS has two significant consequences: (1) it acts to absorb energy from the intense laser pulse coupling its energy to the plasma electrons and (2) it can drive plasma waves to large amplitude, which, in turn generate high energy, nonthermal electrons. Often the hot electrons generated can have energy many times that of the ponderomotive energy, which means electrons of tens to hundreds of keV even at modest intensity (say ~10^{16} to 10^{17} W/cm^2). There are two important regimes of SRS.

Stimulated Raman Backscatter In a low density plasma ($\omega_0 >> \omega_p$) $|\mathbf{k}_0| \approx |\mathbf{k}_s|$. From Eq. (46) it can be seen that for a given plasma density and laser intensity the growth rate is maximum when k_e is maximum. As Fig. 21 illustrates this occurs when the generated Stokes light is directly backscattered. In this case, when the plasma is cold, the growth rate in the nonrelativistic limit is $\Gamma_{SRS\text{-}bs} \approx \sqrt{\omega_p \omega_0 U_p/m_e c^2}$. The growth time in this case is just the temporal pulse duration of the main pulse, since the Stokes field propagates backward through the main pulse. If the laser pulse spatial length is comparable to the length of the medium of interaction, a condition satisfied, for example, when an intense picosecond pulse propagates through a gas jet of a few mm in length, SRS backscatter will be the dominant plasma instability.[209] Practically speaking, SRS backscatter will be important—resulting is a significant amount of laser energy backscattered (>1 percent) and significant plasma heating—when $\Gamma_{SRS}\tau_{pulse}$ ~6 to 7. Equation (46) indicates that this will occur in a 100-fs pulse with wavelength near 1 μm propagating through a plasma of $n_e \sim 10^{18}$ W/cm^2 when the pulse intensity exceeds ~2×10^{17} W/cm^2.

Stimulated Raman Forward Scatter When the laser pulse is very intense, and the duration is short, so that SRS backscatter has little time to grow, the situation is different. In this case, SRS forward scattering is possible, with geometry illustrated in Fig. 21.[210] Now, though k_e is small the Stokes or anti-Stokes radiation copropagate with the intense drive laser, (and, in fact, both Stokes and anti-Stokes can be nearly resonant and grow at about the same rate[211]). The scattered radiation growth factor is now determined by the length of the pulse propagation in the plasma. This effect tends to be particularly important for pulses at relativistic intensity (i.e., >10^{18} W/cm^2) so relativistic effects must be included in deriving a growth rate. In this case, the growth rate, in terms of the normalized vector potential a_0, is[66]

$$\Gamma_{SRS\text{-}fs} = \frac{\omega_p^2 a_0}{\sqrt{8}\omega_0(1 + a_0^2/2)} \tag{47}$$

SRS forward scattering becomes important when $\Gamma_{SRS\text{-}fs}\, L/c \sim 6$, where L is the propagation length through the plasma. Equation (47) yields the surprising result that at strongly relativistic intensity $\Gamma \sim 1/a_0 \sim 1/I^{1/2}$ so the growth rate actually decreases with increasing intensity. This is a consequence of the increase of the effective mass of the electrons when they are driven at relativistic oscillation velocities. Equation (47) indicates that a 1-μm wavelength pulse traversing 5 mm of plasma at density 10^{18} W/cm^2 will exhibit significant forward scattering when $a_0 \approx 0.8$, an intensity of ~1×10^{19} W/cm^2.

Wakefield Generation and Electron Acceleration

The plasma instabilities discussed in the section "Plasma Instabilities Driven by Intense Laser Pulses" essentially arise from the fact that electron plasma oscillations can be driven to large amplitude by

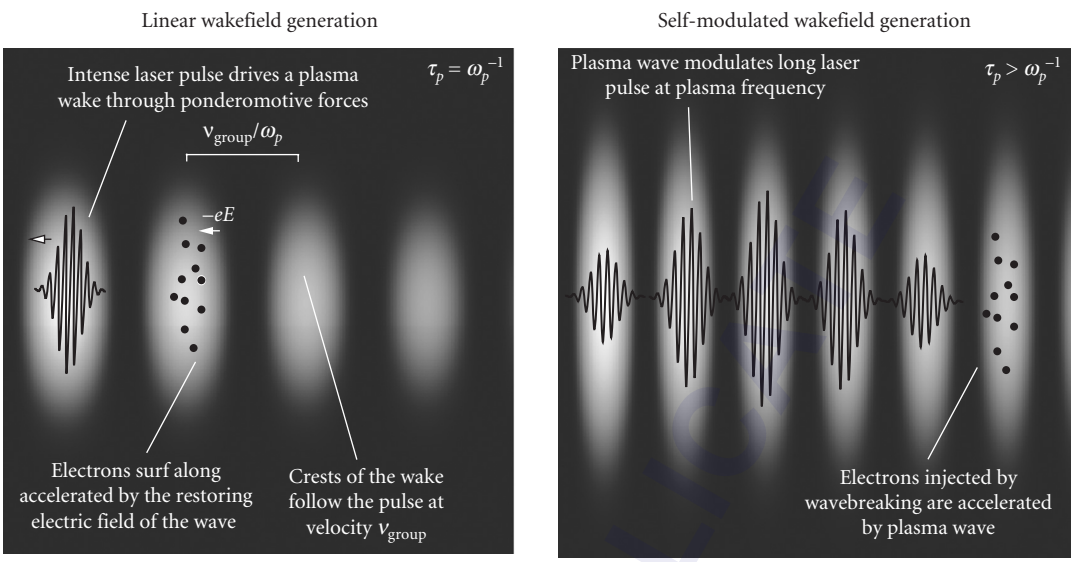

FIGURE 22 Schematic illustration of how wakefield acceleration works in two situations. On the left, the plasma wave is excited by the ponderomotive force of a laser pulse with duration comparable to the plasma oscillation time. On the right is illustrated the case in which the driving laser is longer than a plasma period, but through Raman forward scattering has become modulated at the plasma frequency.

the oscillating ponderomotive force of the strong light field. These plasma oscillations are longitudinal waves, with longitudinal electric fields acting as restoring forces on the oscillating electron density fluctuations. This situation is shown schematically in Fig. 22. The presence of these strong, oscillating electric fields has been investigated for a number of years as a means to accelerate electrons.[14,15,32,212–217] Electrons to be accelerated are either injected externally or get accelerated from the free electrons in the plasma itself, often through a process known as wave breaking (discussed below). Since the acceleration is accomplished through the creation of a plasma wave left in the wake of the ponderomotive force of the laser, this idea is termed plasma wakefield acceleration.

In a general sense, the idea is to expel electrons from a region in the essentially immobile background ions through the ponderomotive force of the laser. The phase velocity of this plasma wave, then, is just that of the group velocity of the laser pulse traveling through the plasma, $v_g = c\sqrt{1-\omega_p^2/\omega_0^2}$. Electrons injected at the right phase of the plasma wave, if traveling at a velocity near this group velocity (i.e. ~c) can surf along with the wave, acquiring energy from it. The laser intensity required is set by the scheme in which the plasma wave is produced (detailed below) but in general the ponderomotive force, $-\nabla U_p$ at the peak of the pulse should be sufficient to expel a sizable number of electrons from their background neutralizing ions. Practically this means that the required intensity is 10^{16} to 10^{18} W/cm^2 for ~1-μm wavelength pulses in moderate density (~10^{18} cm^{-3}) plasmas. The longitudinal electric field that is produced in such an oscillating plasma wake, E_{WF}, can be easily estimated using Poisson's equation and the fact that the wave moves at nearly c with an oscillation frequency of ω_p[32]

$$E_{WF} = \eta\sqrt{4\pi m_e c^2 n_e} \tag{48}$$

where η is the fractional plasma wave amplitude of the wakefield ($\Delta n/n$). Equation (48) indicates that very large acceleration gradients are possible with plasmas. In a plasma of density 10^{18} cm^{-3} nearly 1 GeV/cm acceleration can be achieved if the laser pulse is intense enough to approach $\eta \sim 1$.

The accelerating field is limited by the fact that, as one pushes to higher fields, eventually the plasma wave becomes nonlinear. This means that the electron fluid velocity begins to exceed the wave phase velocity and the wave loses its coherence, a situation called wave breaking.[184] This nonlinear behavior can serve to inject electrons out of the coherent wave oscillation into the accelerating gradient of the wakefield.[213] It does, however, set a limit on the maximum electric field attainable. In general this maximum field is very difficult to predict, but a rough estimate can be made using the "cold wave-breaking" limit, which says that the maximum wakefield strength occurs when $\eta \sim 1$, that is when $E_{\max} \approx m_e c\omega_p/e$.[66]

The limit of acceleration with such laser driven plasma waves, at least in a single plasma stage, arises from the fact that there is a slight mismatch between the electron velocity and phase velocity of the plasma wave, so that electrons eventually move out of the accelerating phase of the wave and catch up to the electric field in the other direction, decelerating the electrons. This dephasing length can be found by assuming that the electrons are relativistic with velocity very near c, but that the plasma wave has velocity given by that of the laser pulse group velocity. Then the maximum length over which an electron can be accelerated before dephasing is $L_{\text{depahse}} \approx 2\pi\omega_0^2 c/\omega_p^3$. For the example just cited, this implies a maximum per-stage acceleration length of 3 cm. Because the acceleration field scales as $n_e^{1/2}$, while the dephasing length scales as $n_e^{-3/2}$ there tends to be an advantage in using lower plasma density (subject to the constraint that it becomes more difficult to propagate an intense focused pulse over longer distances). In general, there are three methods of optical wakefield generation.

1. *Linear wakefield generation*. This method relies on nearly resonantly driving a wakefield in the plasma by matching the laser pulse duration to the plasma oscillation period, such that $\tau_{\text{pulse}} \approx 2\pi/\omega_p$.[14,212] This situation is schematically illustrated in Fig. 22 on the left. For the conditions cited in the above examples, the optimum plasma wave amplitude is achieved with a pulse of ~100-fs duration.
2. *Self-modulated wakefield generation.* When the laser pulse is much longer than the plasma oscillation period, it cannot resonantly drive the plasma wave. However, as described in the section "Plasma Instabilities Driven by Intense Laser Pulses," plasma instabilities can lead to the creation of radiation with frequency shifted by the plasma frequency.[210] This copropagating light, stimulated Raman forward scattering, modulates the laser pulse at the plasma period (illustrated in Fig. 22, right). Consequently, the self-modulated wakefield requires some period of propagation for instability growth and, therefore, typically requires higher intensities than the linear wakefield. In both linear and self-modulated wakefield experiments, the fast electrons that emerge from the plasma typically have a very broad energy spectrum, essentially arising from the fact that if electrons are not externally injected, wavebreaking will tend to inject electrons at ALL phases of the wakefield, leading to a range of accelerated energies.[213,214,216]
3. *Plasma beat wave acceleration.* The third approach to wakefield generation involves copropagating two pulses at slightly different frequencies such that their difference "beat" frequency is resonant with the plasma frequency. This approach usually requires difficult laser technology and is not commonly pursued in the strong field laser regime.[215]

Bubble Acceleration A somewhat different regime exists in the plasma when the driving laser pulse is very intense ($>10^{19}$ W/cm^2), the pulse duration is shorter than the characteristic plasma oscillation time (about half an oscillation time has been found optimal in simulations[28]), and the pulse is focused to a spot comparable to a plasma oscillation wavelength. In this regime the plasma electron density is driven strongly nonlinearly to an amplitude in which wave breaking occurs over a fraction of a plasma cycle.[218–221] The plasma structure changes and cannot be described as a simple harmonic plasma oscillation like that pictured in Fig. 22. Instead, the plasma electrons are completely expelled by the three-dimensional ponderomotive force of the pulse, leading to a cavity depleted of electrons in the region immediately behind the laser pulse. This "bubble" of electrons filled with the ion background, depicted in Fig. 23, can then accelerate electrons which get trapped in a region just ahead of the closing rear wall of the bubble. The interesting aspect of such a structure is not that the accelerating

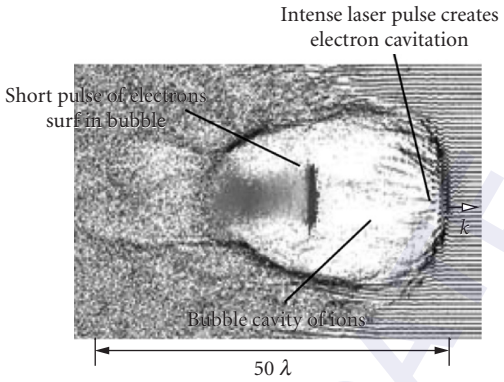

FIGURE 23 Illustration of how a plasma responds and electrons are accelerated when irradiated in the bubble regime. *(This figure was adapted from Ref. 28.)*

gradient is substantially different than the strongly driven linear wakefield case, but that self-injected electrons tend to get accelerated at one spot in the bubble, leading to electrons accelerated with gradients >1 GeV/cm with a quasi-monoenergetic spectrum, often with energy spread of only a few percent.[219]

Ponderomotive Channel Formation

The strong ponderomotive forces which lead to the bubble formation described above can also lead to a Coulomb explosion of the ions due to their space charge repulsion while the electron expulsion exists.[222] If the laser pulse is substantially longer than a plasma period (a situation different than the bubble regime just discussed) the laser pulse will ponderomotively expel the plasma electrons in a more or less adiabatic manner from the focal region. This electron cavitation is nearly 100 percent if the following cavitation condition is met: $a_0 > w\omega_p/c$,[66] where w is the spot size radius of the focused laser beam. This ponderomotive cavitation, held during the duration of the laser pulse can then result in an ion radial explosion which will persist even after the pulse has departed because of the inertia imparted to the ions. This ponderomotive channel formation has been observed in experiments with picosecond duration laser pulses (which are long enough to initiate the ion expansion), leading to a channel formed on the laser axis.[223] The radial Coulomb explosion of ions in the channel can lead to the production of radially directed ions with many MeV of kinetic energy.

Direct Laser Acceleration and Betatron Resonance

The expulsion of electrons by the strong ponderomotive force of a relativistic pulse propagating in an underdense plasma can have other consequences. On a timescale prior to the Coulomb explosion of the heavy ions (often taking many picosecond) the ions do not move significantly, producing a transient radial electric field that will confine a small number of electrons to the pondermotively cleared core, acting as potential well in which electrons can oscillate. As illustrated in Sec. 21.4, electrons in a relativistic intensity laser pulse are actually driven in a forward motion by the combination of the electric and magnetic fields of the laser; this laser driven current in turn creates a toroidal magnetic field. Trapped electrons in the ponderomotive channel will oscillate in this potential well. A relativistic electron trapped in the channel will oscillate at the betatron frequency, which is roughly $\omega_B = \omega_p/2\gamma^{1/2}$. If the electron is propagating at relativistic speed along with the laser, the betatron frequency can be in resonance with the oscillations of the laser field. This leads to significant

acceleration of the electron while it remains in resonance with the laser field, a situation termed "direct laser acceleration" (DLA).[224]

This situation is, in a sense, the inverse to the free electron laser situation. In an FEL energy is coupled from relativistic electrons to an electromagnetic wave in an undulator; in DLA the reverse occurs with the betatron oscillations of the ion channel playing the role of the undulator. The oscillating relativistic electrons will also produce soft x-ray radiation through their interactions with the quasi-static toroidal magnetic field,[28] a situation similar to electrons in a synchrotron.

Ionization-Induced Defocusing

As an intense focused laser pulse propagates into a gas it will ionize the atoms by tunnel and multiphoton ionization, initiating the creation of a plasma. As this ionization occurs, the electron density of the plasma increases, affecting the propagation of the laser in a process known as plasma-induced defocusing.[225,226] Because the spatial profile of any focused laser pulse is inevitably peaked with higher intensity near the center of the propagation axis, ionization tends to occur in the center of the beam earlier in the pulse, resulting in a higher density plasma on axis than at the edges of the beam. The situation that arises is illustrated in Fig. 24. A plasma has a refractive index less than 1, meaning that the denser plasma yields a *faster* phase velocity. Because of this, the pulse's phase fronts will advance in the center of the beam, where the ionized plasma has higher electron density, causing a net *defocusing* of the beam. This has the practical experimental consequence of clamping the maximum intensity that can be achieved by a focused laser in a gas target.[226]

The magnitude and specifics of the defocusing effects are difficult to quantify, as they depend on the kind of gas irradiated, the intensity of the laser and the spatial profile of the light beam near the focus (not to mention that the electron density radial profile is transient evolving during the laser pulse itself). However, an estimate for the maximum electron density that can be reached before defocusing clamps the laser intensity can be made by noting that the refractive index near the focus acquires a radially (and time) dependent profile:

$$n(r,\,t)=\sqrt{1-\frac{n_e(r,\,t)}{n_{\text{crit}}}}\approx 1-\frac{1}{2}\,\frac{n_e(r)}{n_{\text{crit}}} \tag{49}$$

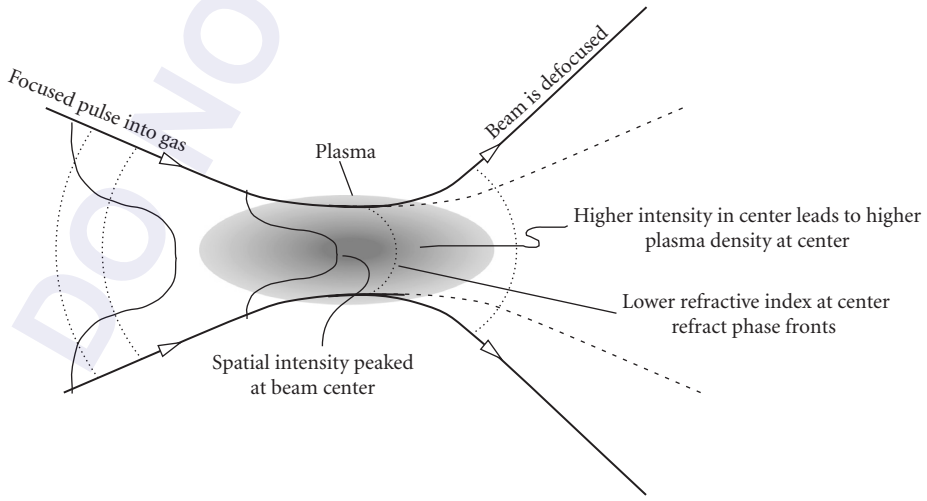

FIGURE 24 Description of how plasma formation at the focus of a laser can induce defocusing.

(Assuming that the electron density is well below the critical electron density, $n_{crit} = me\,\omega_0^2/4\pi e^2$ which is about 10^{21} cm^{-3} for 1-μm wavelength light.) Noting that the higher electron density acts as a negative lens, we can find the focal length of this negative lens by assuming that the laser propagates through the plasma over a length equal to its focused Rayleigh length $z_R = \pi w^2/\lambda$. In this case, ionization-induced defocusing will dominate the propagation of the focused pulse when

$$n_e(r=0) \approx \frac{\lambda}{\pi z_R} n_{crit} \tag{50}$$

When the on-axis electron density reaches this level, the pulse focusing will be clamped and will begin to defocus. For example, a 1-μm wavelength laser focused to a 10-μm spot will defocus when the on-axis electron density reaches about 10^{18} cm^{-3}. Creating any greater electron density will be difficult unless the gas geometry is fashioned so that the beam is focused to its tightest spot outside of the gas.

Relativistic Interactions in Plasma: Self-Channeling and Self-Phase Modulation

When the light pulse intensity is relativistic ($a_0 > 1$) the electrons oscillating in the strong field of the laser, acquire relativistic velocity during a single cycle. This means that the electron mass changes during the course of the light period affecting the optical properties of the plasma.[25] This can be seen by noting that the refractive index of a plasma, $n = \sqrt{1-\omega_p^2/\omega_0^2}$, depends on the plasma frequency, which in turn depends on the square root of the electron mass. An increase in the effective mass of the electrons in the plasma through their relativistic oscillation will decrease the instantaneous value of the plasma frequency and, therefore, *increase* the value of the refractive index. Because the relativistic mass increase in the field depends on field amplitude (and hence intensity), the refractive index of the plasma in the relativistic regime is now intensity dependent.

Recalling the field-induced oscillatory gamma $\gamma_{osc} = \sqrt{1+a_0^2/2}$ the refractive index in the plasma is now

$$n = \sqrt{1 - \frac{\omega_p^2}{\gamma_{osc}\omega_0^2}} \tag{51}$$

Many of the results of standard nonlinear optics can now be applied to this relativistic underdense plasma. In low-density plasma ($n_e << n_{crit}$) at modest a_0 (<1) Taylor expansion of refractive index allows us to retrieve the refractive index in a standard nonlinear optics format in which $n = n_0 - n_2 I$,[175] where n_0 is the usual, nonrelativistic linear refractive index of the plasma, $n = \sqrt{1-\omega_p^2/\omega_0^2}$ and the nonlinear refractive index is

$$n_2 = \frac{\pi e^2}{m_e^2 \omega_0^2 c^3} \frac{n_e}{n_c} \tag{52}$$

The intensity dependence of the plasma refractive index has two significant consequences, both with analogues in traditional nonlinear optics.

Relativistic Self-Focusing and Self-Channeling When a relativistically intense pulse, with a radially dependent intensity profile propagates through the plasma, relativistic effects can cause an increase in the refractive index on the center of the propagation axis, as illustrated in Fig. 25. This causes the phase fronts near the axis to be retarded with respect to those at the pulse's outer edges, resulting in self-focusing of the pulse as it passes through the plasma.[20,227–230] Focusing will occur if the focusing power of the nonlinear refractive index is stronger than the natural defocusing of a pulse from diffraction of the wave (or any ionization-induced defocusing). Because both of these competing

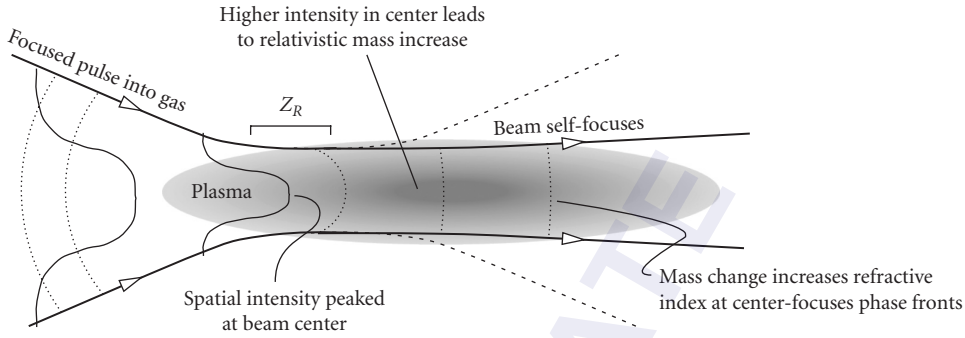

FIGURE 25 Description of relativistic induced self-focusing and channeling in an underdense plasma.

effects depend on the spot size (a larger spot means lower intensity and less relativistic self-focusing but, at the same time, a larger spot means less defocusing from diffraction). It can be shown that the threshold for self-focusing to occur is independent of intensity and depends only on the power of the light pulse. This critical power is[217]

$$P_c = \frac{2c^5 m_e^2}{e^2}\left(\frac{\omega_0}{\omega_p}\right)^2 \tag{53}$$

or in practical units, (and in a form often quoted in the literature) $P_c = 17\ (\omega_0/\omega_p)^2$ in GW. This means that if a 1-μm wavelength pulse propagates through a plasma at an electron density of 10^{18} cm^{-3}, the critical power for the pulse to undergo relativistic self-focusing is ~20 TW.

If this power is achieved in the plasma, the pulse can potentially (though not necessarily) undergo relativistic channeling. The power of the laser must exceed P_c, but, in addition, the self-focal length must be fast enough to force a collapse of the pulse spatially within the experimental extent of the plasma (see Fig. 25). When these conditions are fulfilled, self-channeling occurs, permitting the intense pulse to propagate through the plasma at its focused diameter over a length which is many times that which would be allowed by simple diffraction (i.e., $\sim z_R$). Self-channeling in underdense plasma of distances up to 100 Rayleigh ranges has been observed.[230] Using these criteria, and Eq. (52) the intensity required for self-channeling in a plasma of length l_p is $I > w^2/n_2 l_p^2$. This relationship implies that a 1-μm wavelength pulse, focused to a radius of 10 μm in a plasma of $n_e \sim 10^{18}$ cm^{-3} with length of 1 mm, will require a peak intensity of about 10^{18} W/cm^2 to undergo self-channeling.

Relativistic Self-Phase Modulation The second nonlinear optical consequence of the relativistic refractive index results from the temporal variation of the intensity of the pulse. This temporal variation leads to a time-dependent refractive index which, in turn, induces a time-varying phase on the pulse, a process known as relativistic self-phase modulation (SPM).[36,231] As in the analogue of SPM in traditional nonlinear optical materials, the relativistic SPM can significantly broaden the spectrum of the pulse. The effects of SPM on a pulse are well treated in the optics literature and the relativistic case is essentially similar to these treatments utilizing Eq. (52). The spectrum of the pulse will be broadened by the SPM through the frequency shift acquired over a propagation distance dx

$$d\omega = -\frac{\omega_0}{c} n_2 \frac{\partial I}{\partial t} dx \tag{54}$$

This relationship shows that a strongly phase modulated pulse (initially transform limited) in a plasma of length, L will have its initial spectrum broadened significantly when $I > c/\omega_0 n_2 L$. This will

be a significant effect, for example, on a 1-μm wavelength pulse in a 1-mm-long plasma of 10^{18} cm^{-3} at an intensity of $> 2 \times 10^{18}$ W/cm^2 (independent of pulse duration).

21.10 STRONG FIELD PHYSICS AT SURFACES OF OVERDENSE PLASMAS

Structure of a Solid Target Plasma Irradiated at High Intensity

The irradiation of a solid target with a strong field laser pulse leads to an enormous plethora of effects, far too numerous to detail in this chapter. However, a common aspect of such interactions is that the intense laser pulse deposits energy very quickly into the solid, creating an overdense plasma ($n_e > n_{crit}$). This plasma expands and, depending on the pulse duration and the temporal structure of the laser pulse, can create an underdense region through which the intense pulse must propagate before reaching the critical density surface (where $n_e = n_{crit}$) and being reflected. The morphology of such interactions is illustrated in Fig. 26. Solid target interactions are accompanied by a range of mechanisms which serve to absorb laser energy, many of which result in the production of hot electrons. These hot electrons can often have energies in the relativistic range if $I\,\lambda^2$ of the laser is greater than ~10^{17} W/cm^2-μm^2 (an a_0 of about 0.3).

It is usually convenient to think of strong field laser interactions with solid target plasmas in two regimes.

1. When the laser pulse has very little "prepulse" (i.e., laser energy which precedes the primary, typically Gaussian-shaped pulse, by many picoseconds or nanoseconds), *and* is very fast, the solid target retains a sharp density profile with electron density rising from vacuum to an over critical value within much less than a laser wavelength. This condition can be achieved if the plasma expands much less than a wavelength within the laser pulse duration, a condition which can be estimated by noting that the plasma expands like an ideal gas so a sharp plasma interface is retained if $\tau_p\,(k_B T_e/m_i)^{1/2} << \lambda$.
2. If the intense laser pulse is longer or is preceded by significant prepulse (intense enough to preionize the solid before the main pulse arrives), the solid plasma will expand, creating a lower density plasma scale length (as pictured in Fig. 26). In this case, the incoming laser must interact with some region of underdense plasma many wavelengths long, in which effects such as SRS or

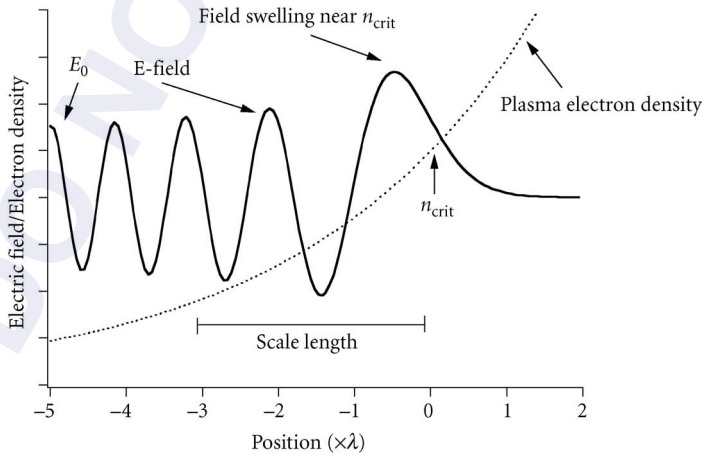

FIGURE 26 Illustration of the laser field as it propagates into a plasma density scale length up to the critical density at the surface of an overdense plasma.

self-channeling as discussed in Sec. 21.9 can take place. The specific profile of the plasma, and the shape of the incoming light field will be complicated, but it is useful to examine the solution when the plasma density profile is linear with position characterized by density scale length ℓ, (the length over which the electron density ramps up from 0 to n_{crit}). In this case, the incoming electric field of the laser is of the form[184]

$$E(z) = 2\pi^{1/2}(\omega_0 \ell/c)^{1/6} E_0 \,\mathrm{Ai}[(\omega_0{}^2/c^2\ell)^{1/3}(z-\ell)] \tag{55}$$

where E_0 is the strength of the incident field in vacuum and Ai[x] is the well-known Airy function. The field swells near the critical density reflection point, which has a consequence on many strong field aspects of longer pulse interactions. The extent of this swelling is approximately given as $E_{MAX} \approx 1.9(\omega\ell/c)^{1/6} E_0$.

Resonance Absorption and Vacuum Heating

When an intense laser creates conditions like those shown in Fig. 26, various absorption mechanisms, almost all of them coupling laser light into plasma electron energy, rise up. Typically, all of these absorption mechanisms will conspire to create a situation in which the absorption of the laser by the solid is in the vicinity of 20 to 60 percent, depending on laser intensity and focal geometry.[232,233] One particularly important absorption mechanism arises when the laser is obliquely incident on the target surface with *p*-polarization, a situation with a nonzero component of the laser field oscillating in and out of the target surface, as illustrated in Fig. 27. The component of the laser field perpendicular to the surface of the target $E_\perp$ leads to electrons being driven across a density gradient, depositing energy into those electrons near the critical density surface. The nature of the laser coupling of energy to these electrons depends on whether the plasma interface has a long scale length or is sharp.

Resonance Absorption When a plasma scale length greater than the incident laser wavelength exists, $E_\perp$ of the laser can drive resonant plasma oscillations at the critical density surface (where the

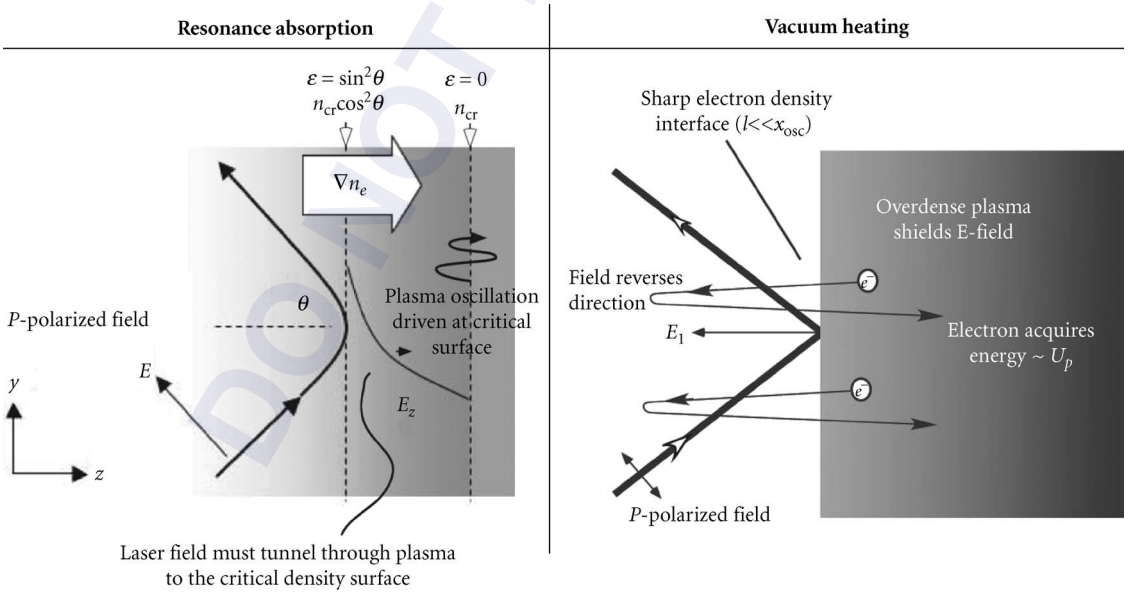

FIGURE 27 Illustration of resonance absorption on the left and vacuum heating on the right.

laser frequency is equal to the plasma oscillation frequency) along a direction parallel to the plasma gradient. These driven plasma oscillations lead to what is known as resonance absorption.[184,234] This process, illustrated on the left in Fig. 26, leads to deposition of laser energy into an electron wave which can be damped by collisions or by other collisionless effects, such as Landau damping or wave breaking, in turn leading to the production of supra-thermal electrons.[235] Because the driving field $E_\perp$ determined two competing effects with incidence angle there is an optimum incidence angle for maximum resonant absorption. Greater incidence angle θ produces greater perpendicular component of E-field, however, the laser field reflects further away from the critical density surface at higher incidence angle[184] requiring the field to tunnel further to the resonant electron density at n_{crit}. Consequently, the efficiency of resonance absorption peaks at an angle given approximately by

$$\theta_{MAX} \approx \sin^{-1}\left[\left(\frac{c}{2\omega_0 \ell}\right)^{1/3}\right] \tag{56}$$

Energy deposited by resonance absorption per unit time in the plasma is linear with laser intensity, and the fraction of laser power absorbed in this manner, f_{RA}, can be shown to be equal to[22] $f_{RA} \cong 2.6q^2 e^{-4q^3/3}$, where $q=(\omega\ell/c)^{1/3}\sin\theta$. This absorption mechanism tends to produce a component of hot electrons which travel into the target in a direction normal to the target surface. The electrons usually exhibit an energy distribution much like that of a Maxwellian. Particle-in-cell (PIC) simulations and experiments have shown that, in the strong field, ultrashort pulse regime, temperature of this hot Maxwellian from resonance absorption is roughly, (in terms of indicated units), $T_{hot}[\text{keV}] \approx 2\times 10^{-4}\,(T_0[\text{keV}]\, I[\text{W/cm}^2]\, \lambda[\mu\text{m}]^2)^{1/3}$,[236] where T_0 is the background plasma temperature. So a 1-μm laser at an intensity of 10^{18} W/cm^2 incident on a 1 × keV plasma typically produces a distribution of hot electrons with temperature in the vicinity of 200 keV.

Vacuum Heating When the plasma density gradient is much smaller than a wavelength (or more accurately, when the plasma density gradient is smaller than the oscillation amplitude of electrons in $E_\perp$) a different description of the resonant heating is required. Instead, a situation like that shown on the right side of Fig. 27 exists. Here, an obliquely incident intense laser can pull electrons from the overdense plasma, accelerate them in vacuum and, once the oscillating electric field reverses direction, accelerate them back toward the overdense plasma interface. Once the electrons are propelled back into the overdense plasma, the laser field is shielded and the electrons retain a large fraction of the energy they acquired in their vacuum excursion. This process is commonly called vacuum heating or "Brunel absorption."[237–239] Like resonance absorption, this process requires *p*-polarized light so that $E_\perp \neq 0$, and results in fast electrons being accelerated in a direction perpendicular to the target surface. The electrons' average energy will, naturally be roughly equal to U_p since this is about the energy they gain in their vacuum half-cycle oscillation. When the laser intensity is nonrelativistic, the absorbed power varies as the 3/2 power of intensity (unlike resonance absorption where the power deposition is linear with intensity). The fraction of absorbed laser power in vacuum heating in this case is

$$f_{VH} = \frac{4eE_0}{\pi m_e \omega_0 c}\left(\frac{\sin^3\theta}{\cos\theta}\right) \tag{57}$$

where, again, θ is the incidence angle of the laser. This absorption is maximum at the highest angles and increases with the square root of the intensity. Note, however, that the *hottest electrons* are created when $E_\perp$ is maximum, a condition which occurs at 55° if we assume nearly 100 percent reflection from the plasma surface. Note that the absorption fraction predicted in Eq. (57) can be >1 at high-intensity and incidence angle. This is because 100 percent reflection was assumed and no relativistic effects are included. Therefore, Eq. (57) is only appropriate for the low-absorption regime. In the strongly relativistic limit (when a_0>>1) the dynamics of vacuum heating become

more complicated. It can be shown that in this regime the absorption approaches 100 percent at an optimum angle of 73° and that the fractional absorption is[66]

$$f_{\mathrm{VH}}^{\mathrm{rel}} \approx \frac{4\pi(\sin^2\theta/\cos\theta)}{(\pi+\sin^2\theta/\cos\theta)^2} \tag{58}$$

Other Collisionless Absorption Mechanisms: $j \times B$ Heating and Anomalous Skin Effect

Resonance absorption or vacuum heating are usually the most important absorption mechanisms for an intense laser pulse incident on a solid-density plasma (though at near normal incidence, or with *s*-polarization, simple collisional absorption is most important when $\ell >> \lambda$). However, there are other mechanisms which can lead to absorption of an intense light pulse on the surface of an overdense plasma (and the potential for producing hot electrons). In almost all cases these mechanisms rely on the presence of a steep density gradient, just as one finds in the vacuum heating regime discussed above. At modest intensity, defined as the regime in which $U_p < k_B T_e$, a phenomena known as the anomalous skin effect takes place.[240] Absorption through this effect essentially results when electrons in the plasma have a large mean free path when compared to the skin depth (c/ω_p) in the plasma. Electrons migrate via their thermal motion into this skin depth region and acquire energy from the electric field's evanescent wave in the plasma. This absorption effect is found to play a minor role in short-pulse laser-plasma interactions (with absorption typically less than 5 percent) and, because of the requirement of low U_p, is usually not important for laser intensity above about 10^{15} W/cm^2. Unlike RA or vacuum heating, this absorption mechanism does not require oblique incidence, and therefore, can play a nonnegligible role for moderate intensity, normal incidence situations.

A much more important absorption mechanism at a sharp dense plasma interface occurs in the relativistic intensity regime. In this regime, the magnetic field of the light pulse begins to play a significant role in the trajectory of the driven plasma electrons. Plasma electrons at the surface of the plasma, driven transversely by the E-field with velocity approaching *c*, feel an oscillating force in the direction of the laser's **k** vector from the now significant $\mathbf{V}_{\mathrm{osc}} \times \mathbf{B}$ force.[241,242] The electrons acquire energy in a manner similar to vacuum heating except now the oscillatory driving force is the $\mathbf{j} \times \mathbf{B}$ term, oscillating at a frequency of $2\omega_0$. Oblique incidence is not necessary for this $\mathbf{j} \times \mathbf{B}$ heating to occur; the heating, in fact, is maximum at normal incidence (where E-field driven vacuum heating vanishes). As a consequence, at relativistic intensity, the relative importance of vacuum heating and $\mathbf{j} \times \mathbf{B}$ heating depends on incidence angle, polarization (*s*- or *p*-) and intensity. In general, $\mathbf{j} \times \mathbf{B}$ heating will dominate when $v_{\mathrm{osc}} B > 2E_0 \sin\theta$, even with *p*-polarized light, which is equivalent to $a_0 > 2^{1/2}$ or an intensity greater than $\sim 4 \times 10^{18}$ W/cm^2 in a 1-μm wavelength field at $\theta = 45°$. There are situations when both vacuum heating and $\mathbf{j} \times \mathbf{B}$ occur, with vacuum heating producing hot electrons normal to the target and $\mathbf{j} \times \mathbf{B}$ producing electrons parallel to the laser direction. Again, the energy of the accelerated electrons from $\mathbf{j} \times \mathbf{B}$ heating will roughly equal the relativistic ponderomotive potential, $(\gamma_{\mathrm{osc}} - 1)\, m_e c^2$.[22]

Ponderomotive Steepening and Hole Boring

An intense pulse incident on a solid density plasma surface will exert a force on that plasma. Because the pulse will have some temporal rise, there is naturally a gradient in the ponderomotive energy $-\nabla U_p$, which will drive the plasma inward, as illustrated in Fig. 28.[242] This ponderomotive gradient is really nothing other than the manifestation of the pressure associated with the light pulse *I*/*c*, which can be very high. The light pressure of a pulse at an intensity of 10^{18} W/cm^2 is ~330 Mbar, equivalent to the thermal pressure of a plasma at solid density of $n_e \sim 10^{23}$ cm^{-3} when the electron temperature is 2 keV, well above the thermal temperatures of most laser plasmas. At modest intensities, the ponderomotive gradient will simply slow the expansion of the plasma outward. However, when $I/c > n_e k_B T_e$, the laser pulse will push the plasma back toward higher density, decreasing the plasma density

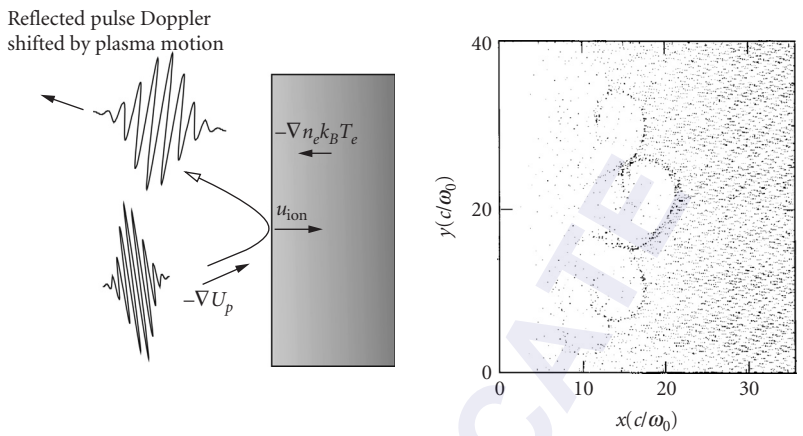

FIGURE 28 On the left is an illustration of how ponderomotive steepening leads to hole boring when intense pulse is focused on a solid target plasma. On the right, a PIC simulation from Ref. 242 is reproduced showing the bubblelike structure that develops in the plasma ions at the surface of a plasma as a result of hole boring by a picosecond duration intense laser.

gradient, a process referred to as ponderomotive steepening. This reversal of the plasma velocity will manifest itself as a red shift in the spectrum of the reflected laser pulse or its harmonics.[243,244]

At very high intensities, such as 10^{19} W/cm^2 or greater, the light pressure can be sufficient to push the plasma, even over the short timescales of laser pulses usually employed, back into the target. The high-intensity limit of ponderomotive steepening is commonly called hole boring, a process pictured in the PIC simulations of Fig. 28. Hole boring drives ions into the plasma at high velocity. This ion velocity can be estimated by balancing the inward ion momentum flux with the light pressure. Accounting for some incidence angle θ and some potential fractional absorption, f_{abs}, the inward ion velocity is

$$u_{\text{ion}} = \sqrt{\frac{(2-f_{\text{abs}})I\cos\theta}{2n_i m_i c}} \tag{59}$$

Equation (59) predicts, for example, that a solid aluminum plasma irradiated at 10^{19} W/cm^2 can acquire ion velocities during hole boring of ~4×10^7 cm/s. It is possible that the high energy ions driven inward at ultrahigh intensities (>10^{20} W/cm^2) can produce a collisionless shock in the underlying overdense plasma.[245] The amount of laser energy absorbed from the laser into these fast ions can be easily estimated and is (for small absorption) $f_{\text{hole boring}} \approx 2u_{\text{ion}}/c$. This relation suggests that a few percent of the incident laser energy can be transferred to ions though ponderomotive acceleration.

High Harmonic Generation from Solid Plasmas

The light reflected from the surface of an overdense plasma at modest intensity will typically retain with good fidelity the spectrum of the incident laser light, though at higher intensity this spectrum can be Doppler shifted from ponderomotive steepening or hole boring. At these high intensities, however, nonlinear interactions can occur at the reflection surface, in such a way that harmonics of the light field are generated.[246–249] At very high intensity (> ~10^{19} W/cm^2) quite high orders can be generated at the plasma surface, up to orders of $q \sim 50$ to 100.[248]

The origin of these harmonics can be seen by noting that the ponderomotive pressure at the surface of the plasma is ~$\nabla a^2/2$, which not only has a time averaged term (the force which gives

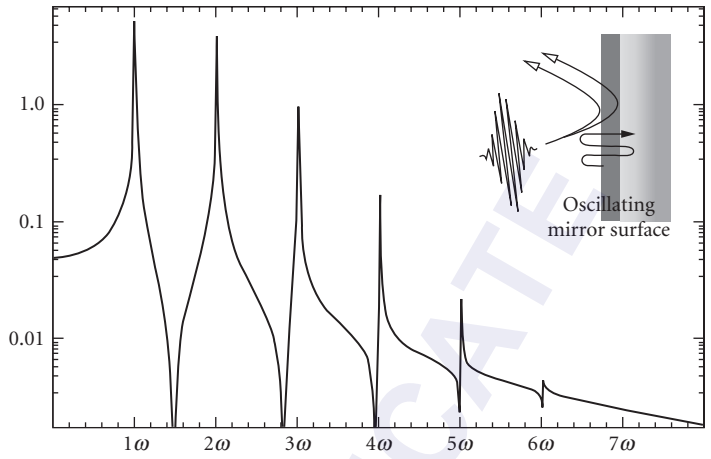

FIGURE 29 Plot of the Fourier transform of Eq. (61) with $kA_{mirror} = 1$, showing how harmonics can arise from the oscillating mirror model. The inset shows the geometry of the oscillating mirror.

rise to the hole boring discussed above) but also has a fast time varying component which varies as $p_{osc} \sim a_0^2 \sin 2\omega_0 t$. This rapidly oscillating force will drive the plasma electrons collectively in and out of the plasma. A similar situation occurs for *p*-polarized light incident on a solid plasma at an angle, though now the plasma electrons are driven at the laser frequency by the laser's electric field (see the inset to Fig. 29). If the intense light pulse is incident on a sharp-density gradient these driving forces effectively act to create an oscillating critical density surface, or, in other words, an oscillating mirror.[246,247] It is the oscillation of the reflection point in the plasma which yields the nonlinearity leading to high harmonic generation at the plasma surface.

The theory describing this situation is complex, particularly in the relativistic limit, however, a simple analysis of the oscillating mirror amplitude, A_{mirror}, in the nonrelativistic limit, shows that[66]

$$A_{mirror} \cong \frac{\lambda_0}{\pi}\left(\frac{\omega_0}{\omega_p}\right)^3 a_0^2 \tag{60}$$

This equation illustrates that the efficiency of creating these surface high harmonics increases with increasing intensity and with lower surface plasma density (because a lower density plasma is easier to drive by the ponderomotive forces of the laser). Simulations have shown that high harmonic generation from dense plasma surfaces is maximized with the target density in the vicinity of $4n_{crit}$,[247] a consequence of an interaction between the second harmonic of the laser and the target surface, leading to violent resonant driving of the plasma surface. Equation (60) also shows that the mirror amplitude begins to approach the scale of one laser wavelength when $a_0 \to (n_e/n_{crit})^{3/4}$. In the nonrelativistic limit when the mirror oscillates with the laser frequency (the case for obliquely incident *p*-polarized light), the reflected light will have an electric field at the plasma surface ($z = 0$) such that

$$E_{refl}(t) \cong \frac{\omega_p}{2\omega_0} a_0 \sin(\omega_0 t + kA_{mirror} \sin\omega_0 t) \tag{61}$$

A Fourier transform of this field when $kA_{mirror} = 1$ is illustrated in Fig. 29, showing how the nonlinearity introduced by the oscillating mirror amplitude gives rise to numerous harmonics (at both even and odd harmonics of the laser in this case).

In the strongly relativistic limit, the theory becomes much more difficult. PIC simulations have shown, however, that the efficiency of the high orders ($q >> 1$) can be estimated with the empirical relation $\eta_q \sim I\,\lambda^2\,(1/q)^5$.[249] As this indicates the high harmonic spectrum from solids does not exhibit a plateau and cutoff, but instead, harmonics are created in a spectrum which simply falls off with order as a power law. The yield of the harmonic becomes nearly linear with intensity.

Relativistic Effects and Induced Transparency

As in underdense plasmas, relativistic effects can affect the optical properties of overdense plasmas as well. Self-induced relativistic transparency is one such effect.[250] At relativistic intensity, the mass change of the electrons leads to an effective shift in the plasma frequency, such that

$$\omega_p^{\text{rel}} = \omega_p/\gamma_{\text{osc}}^{1/2} = \sqrt{\frac{4\pi e^2}{m_e}}\,\frac{1}{(1+a_0^2/2)^{1/4}} \tag{62}$$

Since ω_p^{rel} drops with the square root of intensity, an overdense, reflecting plasma can be shifted by the relativistic factor in Eq. (62) to one which becomes effectively underdense, with $\omega_p^{\text{rel}} < \omega_0$, allowing the high-intensity light to propagate through the plasma. The critical intensity for this to occur, in the strong relativistic limit ($a_0 >> 1$) is

$$a_0^{\text{trans}} = \sqrt{2}\,\frac{n_e}{n_{\text{crit}}} \tag{63}$$

Consequently, a solid density plasma, with $n_e \sim 10^{23}$ cm^{-3}, will become transparent to 1-μm laser light at an a_0 of ~140. This is an intensity near 3×10^{22} W/cm^2, just within reach of the highest intensity lasers now available. That this relativistically induced transparency can occur in a plasma was mentioned in the literature many years ago, however, to date there has yet to be a direct experimental observation of this effect.

21.11 APPLICATIONS OF STRONG FIELD INTERACTIONS WITH PLASMAS

Modern strong field research now focuses on a range of effects that arise from the basic phenomena that we have described in this chapter. It is impossible to summarize all of these research avenues here, but we conclude in this section with a very brief sampling of some of the applications of high-field research that are among the most active at this writing.

Femtosecond X-Ray Production

Many of the strong field effects discussed in previous sections result in the production of energetic electrons (through, e.g., plasma or free wave acceleration via wakefield, SRS, resonant absorption, or vacuum and $\mathbf{j} \times \mathbf{B}$ heating). When electrons are accelerated by these mechanisms at the surface of a cold, solid target, the penetration of these hot electrons will lead to x-ray production. If the laser generating these fast electrons is short, it is possible to produce bright sources of x-rays with femtosecond time duration, which, can, in turn, be used for various pump-probe applications.[38] There are generally three principal ways in which x-rays are generated in these experiments: (1) through the direct interaction with the laser field or other strong fields in and around a plasma; (2) through the ejection of inner shell electrons in the underlying cold solid leading to K_a line emission; or

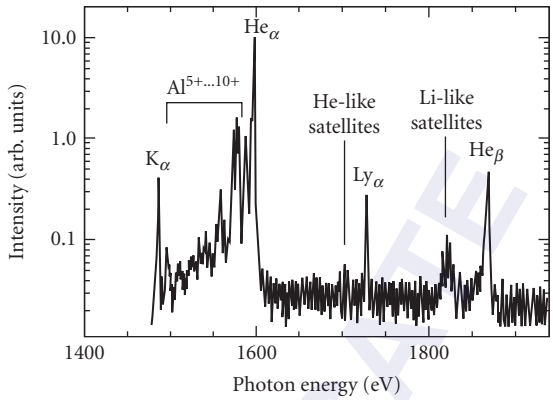

FIGURE 30 An example of an x-ray spectrum produced by irradiation of a solid Al target at intensity of $\sim 10^{18}$ W/cm^2. This spectrum shows that not only are H-like and He-like lines emitted from the hot plasma, but also that K_a x-rays are emitted when the hot electrons produced by the laser penetrate the cold target and knock out K-shell holes in the unionized Al atoms. This x-ray pulse is usually very fast, <1 ps in duration. *(Adapted from Ref. 252.)*

(3) through free-free transitions of the electrons as they pass by highly charged nuclei of the solid, yielding bremsstrahlung radiation. The later process has been shown to yield x-rays with energies well above 1 MeV when intensities of $>10^{18}$ W/cm^2 are used to irradiate a solid target.[251] A characteristic x-ray spectrum resulting from an example experiment is shown in Fig. 30.

Fusion Neutron Production

The production of fast ions in strong field interactions, through processes such as ponderomotive acceleration of ions at the surface of a target or through the ejection of ions from the Coulomb explosion of irradiated clusters, can be harnessed to drive nuclear fusion. The production of bursts of 2.45 MeV neutrons when various targets contain deuterium (solid or cluster targets) has been well studied by experiment.[199,253]

High Magnetic Field Production

In addition to the very strong magnetic fields associated with high intensity EM waves, the intense irradiation of solid target plasmas can produce strong transient DC magnetic fields. These fields essentially arise from two sources: (1) Thermo-electric magnetic field generation. In the high temperatures and steep density gradients found in intense ultrafast laser irradiation of solids, magnetic fields can be generated by thermal transport effects. In this case the magnetic field is proportional to $\nabla T_e \times \nabla n_e$ which favors high B-field production in the steep density gradients found in femtosecond laser plasma interactions.[254] (2) Fast electron magnetic field generation. The fast electrons produced by the panoply of mechanisms discussed in previous sections, frequently lead to the production of high peak currents, perhaps exceeding a MA. This leads to enormous B-fields. Fields of upto many 100s of MG are possible with this mechanism.[255]

MeV Proton Acceleration

When fast electrons are generated at the surface of a solid target plasma by an intense laser and the target is sufficiently thin such that the electron mean free path is greater than the target thickness, the fast electrons can exit the back surface and set up a strong ambipolar field. This situation is illustrated in Fig. 31. These electrons will set up an electric field which ionizes ions on the back surface (often covered with water and hydrocarbon contamination in vacuum) and accelerate them to high velocity.[256–258] The field created will be of the order of $eE_{sheath} \approx k_B T_{hot}/\lambda_{Debeye}^{hot}$, where $\lambda_{Debye}^{hot} = \sqrt{k_B T_{hot}/4\pi n_{hot} e^2}$ is the hot electron Debye radius and T_{hot} and n_{hot} are the temperature and density of the hot electrons. The sheath field can often be of the order of a few MeV/μm, so protons can easily acquire many MeV of energy during their acceleration in the direction of the target back surface normal. This ion acceleration mechanism is termed "target normal sheath acceleration" (TNSA). Ion temperatures of a few MeV are often observed when sub-picosecond (200 to 1000 fs) pulses are focused at intensity in the vicinity of 10^{20} W/cm^2. It has been found that this TNSA mechanism is most effective for higher energy pulses (>1 J) in the >500 fs range since such pulses tend to produce a greater *number* of hot electrons than sub-100 fs pulses at similar intensities.

Fast Ignition

The production of fast electrons by an intense short pulse laser has been proposed as a means to ignite a fusion capsule imploded by a large scale laser or Z-pinch, in the so-called inertial confinement approach to fusion (ICF).[259] One variant of ICF, known as fast ignition, is described in Fig. 32. The basic idea is that a separate, high energy driver will assemble at high density (>200 g/cm^3) a deuterium/tritium fusion fuel, and the short pulse laser will be focused from the side, onto the edge of the fusion fuel, generating a beam of hot electrons with temperature in the range of 1 to 10 MeV which penetrate

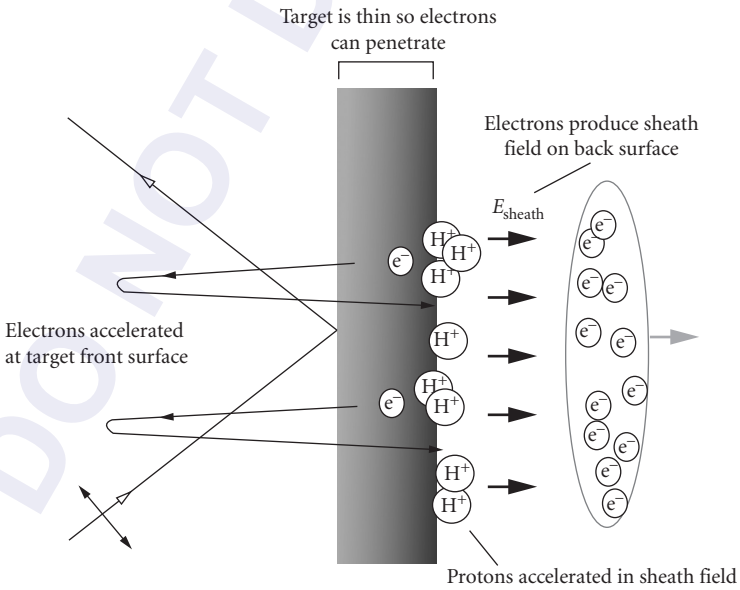

FIGURE 31 Illustration of how protons can be accelerated from the back surface of an intensely irradiated target by the target normal sheath acceleration phenomenon.

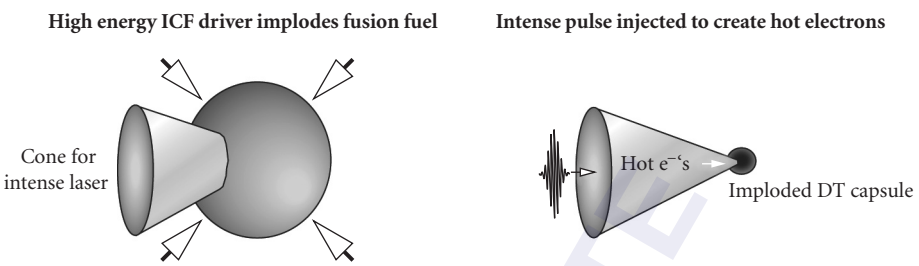

FIGURE 32 Illustration of how fast ignition would utilize an intense pulse to ignite an imploded inertial confinement fusion capsule.

the fuel and heat it to fusion ignition temperature. At present, the most promising method of doing this is to embed a cone in the fusion fuel prior to its compression (see Fig. 32) to permit effective injection of the intense laser at the peak of the fuel's compression. There remain many technical challenges to the ultimate implementation of this idea, with numerous physics issues remaining unsolved (such as understanding how such high peak currents of electrons transport into such a dense plasma or what fraction of short pulse laser energy converts to hot electrons). Nonetheless, there have been experimental studies conducted in Japan in recent years which have yielded promising results on the fast ignition approach at modest laser compression and short pulse laser drive energy.[260]

Raman Amplification

It has been recently demonstrated that it is possible to amplify ultrashort pulses in a plasma by counterpropagating a long pulse laser with an intense short pulse laser of lower frequency.[261] This superradiant amplification essentially occurs through a parametric process in the plasma closely akin to stimulated Raman scattering. With this high-intensity technique, it may be possible using kJ-class nanosecond lasers to amplify kJ-energy sub-100 fs pulses in a plasma.

SLOW LIGHT PROPAGATION IN ATOMIC AND PHOTONIC MEDIA

Jacob B. Khurgin

Department of Electrical and Computer Engineering
Johns Hopkins University
Baltimore, Maryland

22.1 GLOSSARY

ω	field frequency
ω_{12}	resonant frequency of an atomic transition
f_{12}	oscillator strength of an atomic transition
γ_{12}	damping coefficient (dephasing rate) of the transition
$\varepsilon(\omega)$	dielectric constant
$n(\omega)$	refractive index
e	electron charge
m	free electron mass
Ω_p	plasma frequency
Ω	Rabi frequency
c	speed of light in vacuum
η_0	impedance of vacuum
$\alpha(\omega)$	absorption coefficient
$k(\omega)$	wave vector
λ	wavelength
v_g	group velocity
$S(\omega)$	slow down factor
$\beta_n(\omega)$	nth order dispersion
B	bit rate
N_{st}	number of bits stored (delayed) in an optical buffer
Λ	period of Bragg grating or other periodic photonic structure
δn	refractive index modulation
ω_B	Bragg frequency
$\Delta\omega_{gap}$	Photonic bandgap width

κ	coupling coefficient
τ	one half of the resonator round trip time
$\Delta\nu_{\text{pass}}$	width of passband of the photonic structure
$g(\omega)$	gain per unit length of optical amplifier
ΔT_d	delay time

22.2 INTRODUCTION

While the subject of slow light had become immensely popular in the last decade, the physics of the phenomenon of light propagation in media and structures with reduced group velocity, for which the term "slow light" had been coined, can be traced to the 19th century when the classical theory of dispersion of electromagnetic waves had been first formulated in works of Lorentz[1] and others. Slow wave propagation has also been observed and widely used in the microwave range since as early as the 1940s.[2] Building on this history and following the pioneering works of Refs. 3 and 4, the science and technology of slow light had been transformed from a scientific curiosity to a rapidly evolving field with many potential applications. Slow light propagation had been observed in a wide variety of media and structures ranging from Bose-Einstein condensates and low-pressure metal vapors on one hand, to optical fibers and photonic bandgap structures on the other hand. This makes slow light a truly interdisciplinary field that is not easy to describe in a short review. There exists a body of review work on slow light, starting in 2002 with reviews by Boyd and Gauthier[5] and Milloni[6] who also published a book in 2005 including chapters on slow, fast, and left-handed light.[7] The first comprehensive treatment of diverse slow light, schemes has been given in the recent book,[8] which contains contributions from 18 groups that have been actively involved in the slow-light field and have all made significant contributions in recent years.

With all the seeming diversity of slow light schemes, they can be all characterized by a single common feature—the existence of sharp single or multiple resonances. The resonance can be defined by a simple atomic transition, by a Bragg grating or other resonant photonic structure, or by an external laser as in the schemes involving various nonlinear processes—resonant scattering, spectral hole burning, or four-wave mixing. In this chapter, we try to emphasize the commonality of all slow light approaches as well as their distinctive features.

22.3 ATOMIC RESONANCE

Let us consider a simple atomic resonance characterized by the resonant frequency ω_{12} and the oscillator strength f_{12} as shown in Fig. 1*a*. The dielectric constant in the vicinity of the resonance has a familiar expression

$$\varepsilon(\omega)=\bar{\varepsilon}+\frac{\Omega_p^2}{\omega_{12}^2-\omega^2-j\omega\gamma_{12}} \tag{1}$$

where $\bar{\varepsilon}=\bar{n}^2$ is the nonresonant part or "background" part of the dielectric constant, and γ_{12} is the dephasing rate of the polarization. The expression in the numerator Ω_p is the "plasma frequency" that can be found as

$$\Omega_p^2=\frac{N_a e^2}{\varepsilon_0 m_0} f_{12} \tag{2}$$

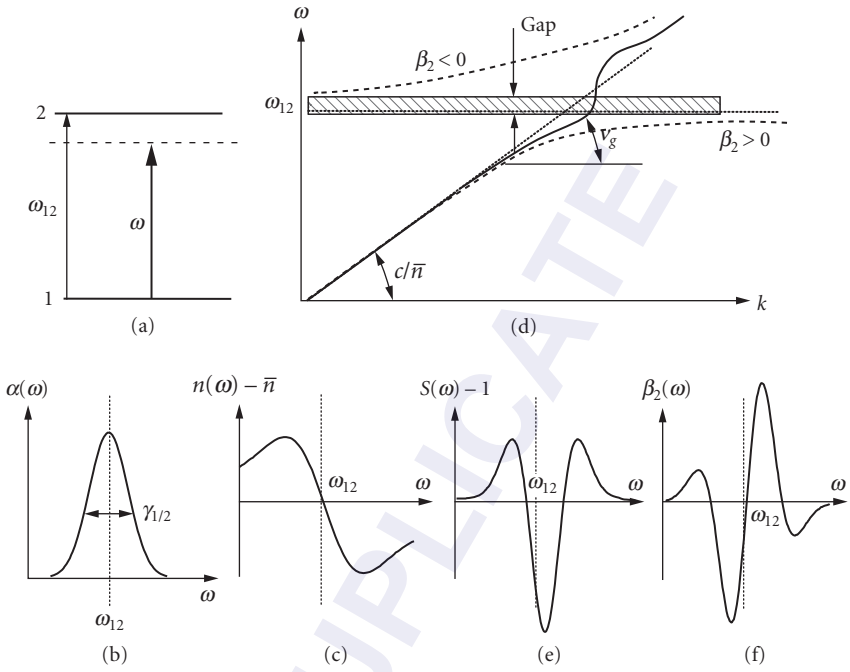

FIGURE 1 (*a*) Two-level atomic resonance; (*b*) spectrum of absorption coefficient; (*c*) spectrum of refractive index; (*d*) dispersion diagram and group velocity in the vicinity of a resonance; (*e*) spectrum of slowdown factor; and (*f*) spectrum of group velocity dispersion.

where e is an electron charge, ε_0 is the dielectric permittivity of vacuum, m_0 is a free electron mass, and N_a is the concentration of active atoms. From real and imaginary parts of Eq. (1) one immediately obtains the expressions for the absorption coefficient shown in Fig. 1*b*

$$\alpha(\omega)=\frac{2\omega}{c}\mathrm{Im}(\varepsilon^{1/2})\approx\frac{1}{4\bar{n}c}\frac{\Omega_p^2\gamma_{12}}{(\omega_{12}-\omega)^2+\gamma_{12}^2/4} \tag{3}$$

and refractive index (Fig. 1*c*)

$$n(\omega)=\mathrm{Re}(\varepsilon^{1/2})\approx\bar{n}+\frac{1}{4\bar{n}\omega}\frac{\Omega_p^2(\omega_{12}-\omega)}{(\omega_{12}-\omega)^2+\gamma_{12}^2/4}=\bar{n}+\frac{c}{\omega}\alpha(\omega)\frac{\omega_{12}-\omega}{\gamma_{12}} \tag{4}$$

the last relation being a particular form of more general Kramer-Kronig relation. In the vicinity of the resonance the refractive index first increases, then rapidly decreases to the point where $n(\omega)<\bar{n}$, and then increases once again to the value of background index. Introducing the wave vector as

$$k(\omega)=n(\omega)\cdot\omega/c \tag{5}$$

One can obtain the dispersion relation between the frequency and wave vector shown in Fig. 1*d* (solid line) and then introduce group velocity as

$$v_g=\partial\omega/\partial k \tag{6}$$

and slow down factor defined as a relative reduction of group velocity due to resonance

$$S(\omega)=\frac{c}{\bar{n}v_g(\omega)}=1+\frac{\Omega_p^2}{4\bar{\varepsilon}}\frac{(\omega_{12}-\omega)^2-\gamma_{12}^2/4}{[(\omega_{12}-\omega)^2+\gamma_{12}^2/4]^2}=1+\frac{c\alpha(\omega)}{\bar{n}\gamma_{12}}\frac{(\omega_{12}-\omega)^2-\gamma_{12}^2/4}{(\omega_{12}-\omega)^2+\gamma_{12}^2/4} \tag{7}$$

shown in Fig. 1*e*. One can now see that there are two regions in which $S > 0$, that is, slow light regime, and one region where $S < 1$, which can be either the fast light regime ($0 < S < 1$) or negative group velocity regime ($S < 0$) indicating that the light gets reflected. One can get better intuitive picture of the physical phenomena governing slow and fast light propagation by plotting the dispersion curve in the absence of loss (i.e., $\gamma_{12} = 0$) as dashed line in Fig. 1*d*. This curve corresponds to a well-known coupled modes model, also known as polariton dispersion curve in solid state physics. The first mode is a photon which in the absence of atomic transition is described by linear dispersion curve $\omega_p = ck/\bar{n}$. The second mode is the atomic polarization characterized by a resonance frequency ω_{12}. The dispersion curve of atomic polarization is a horizontal line $\omega_a = \omega_{12}$ indicating the obvious fact that it has zero group velocity as atoms do not move, at least not on the scale of the speed of light. In the vicinity of the resonance, two modes couple into each other and the modified dispersion curve is split into two branches separated by the gap in which the light cannot propagate. Notice that for each wave vector there are two coupled solutions characterized by two different group velocities. The one further away from the resonance has higher group velocity and is usually referred to as a "photonlike," while the one closer to the resonance has lower group velocity and is usually referred to as "atomlike." One can then interpret the slow light propagation phenomenon in the following way: The energy gets constantly coupled from the electromagnetic field to the atomic polarization and back. The longer is the time the energy spends in the form of atomic excitation, the slower the coupled mode propagates. Thus the slow light propagation in atomic system can be understood as constant excitation and de-excitation of atoms in which coherence is preserved.

One important implication is related to the strength of the electric field in the electromagnetic wave propagating in a slow light regime caused by an atomic resonance. Since the group velocity is the velocity with which the energy propagates, the local energy density of light beam with power density P is

$$U = P/v_g = (P\bar{n}/c)S \tag{8}$$

and it gets enhanced by a slowdown factor in the slow light medium. But since the energy density is related to electric field as

$$U=\frac{1}{4}\varepsilon_0\frac{\partial(\omega\varepsilon)}{\partial\omega}E^2+\frac{1}{4}\mu_0H^2=S\frac{1}{2}\varepsilon_0\bar{\varepsilon}E^2 \tag{9}$$

where the first term corresponds to electric energy and the second term to the magnetic energy. It follows from Eqs. (8) and (9) that $E^2 = 2\eta_0 P/\bar{n}$, where $\eta_0 = \sqrt{\mu_0/\varepsilon_0} = 377\Omega$ is the vacuum impedance. Thus the electric field does not get enhanced in the atomic slow light medium. In our intuitive picture this simply means that all the additional energy *compressed* into the medium gets stored in the atomic polarization. This fact has important implications in the nonlinear optics. Also, one can see that without absorption the region of fast light ($0 < S < 1$) is absent in Fig. 1*d*—and it is important that fast light is associated with the absorption peak, while the slow light is associated only with the off-resonant absorption—hence significant delays of the signal in the slow light are quite possible, while significant advances are difficult to observe due to absorption.

When it comes to practical applications of the slow light, it is important to achieve large delays over significant bandwidth and in a compact device. The obstacles on the way to this goal include the aforementioned loss and the dispersion of group velocity and dispersion of absorption.[9–11] To ascertain the importance of the group velocity dispersion (GVD), one only needs to use the Taylor

series expansion of the dispersion relation $k(\omega)$ near the signal frequency ω_0 to obtain the expression for the group velocity

$$v_g^{-1}(\omega)=v_g^{-1}(\omega_0)+\beta_2(\omega_0)\cdot(\omega-\omega_0)+\frac{1}{2}\beta_3(\omega_0)\cdot(\omega-\omega_0)^2+\cdots \tag{10}$$

where $\beta_n(\omega)=\partial^n k(\omega)/\partial\omega^n$. One can estimate the limitations imposed by GVD by noticing that the time delay of the signal can be written as

$$T_d(\omega)=v_g^{-1}(\omega)L=v_g^{-1}(\omega_0)L+\beta_2(\omega-\omega_0)L+\frac{1}{2}\beta_3(\omega-\omega_0)^2L+\cdots \tag{11}$$

and then introducing a criterion for the on-off keyed gaussian signal of bit rate B the difference between the delay times of spectral components at the edges of the signal bandwidth, that is, at $\omega_0\pm\Delta\omega_{\text{sig},0}/2$, should be less than one-half of the bit interval, that is

$$\Delta T_d(L)\approx\beta_2\Delta\omega_{\text{sig}}L<1/2B \tag{12}$$

which leads to the condition relating the maximum allowable length and bit rate

$$|\beta_2|B^2L<\frac{1}{16\ln 2} \tag{13}$$

This condition shows the severe limitations imposed by the second order GVD term β_2 whose spectrum is plotted in Fig. 1*f*. In addition to GVD, the signal bandwidth is also limited by the dispersion of absorption—the fact that different frequency components of the signal experience different attenuation causes signal distortion, but it is usually GVD that is the main reason that limits slow light scheme performance. Hence, while slow light had been observed in single-atomic resonance schemes as early as 1960s and 1970s[12–16] it was only in 1990s when a double resonance schemes with complete cancellation of β_2 had been discovered[17] that the slow light research had really taken off.

Double Atomic Resonance

Although the first practical slow light results were achieved using phenomenon of electromagnetic transparency (EIT),[17,18] where the double resonance is created by strong pump beam, the main features of the double-resonant atomic schemes can be understood easier if one considers closely spaced narrow resonances do occur naturally in metal vapors, such as, for instance, in Rb^{85} Ref. 19 where two D^2 resonances near 780 nm separated by $\nu_{32}=3$ GHz have been used most successfully to this date in SL experiments in atomic medium. The rational for using double resonance can be seen from Fig. 1*d* and *f,* which show that the lowest order GVD term β_2 has opposite signs below and above resonance. Then, if one can combine two resonances as in Fig. 2*a*, only the third-order GVD β_3 will be a factor for signals centered at frequency ω_0 in the middle between two transitions where the absorption (Fig. 2*b*) is low, as evident from the dispersion curves Fig. 2*c* and *d*.

A closer look at the dispersion curve Fig. 2*c* reveals the basic trade-off inherent in every slow light scheme—the dispersion curve is split into three branches of which the central one, "squeezed" between two atomic resonances, is the one with a slow group velocity. Clearly, the group velocity, being a slope of the curve is inversely proportional to the splitting between two resonances ν_{32}, that is, to the maximum theoretical bandwidth of the scheme. In reality, the

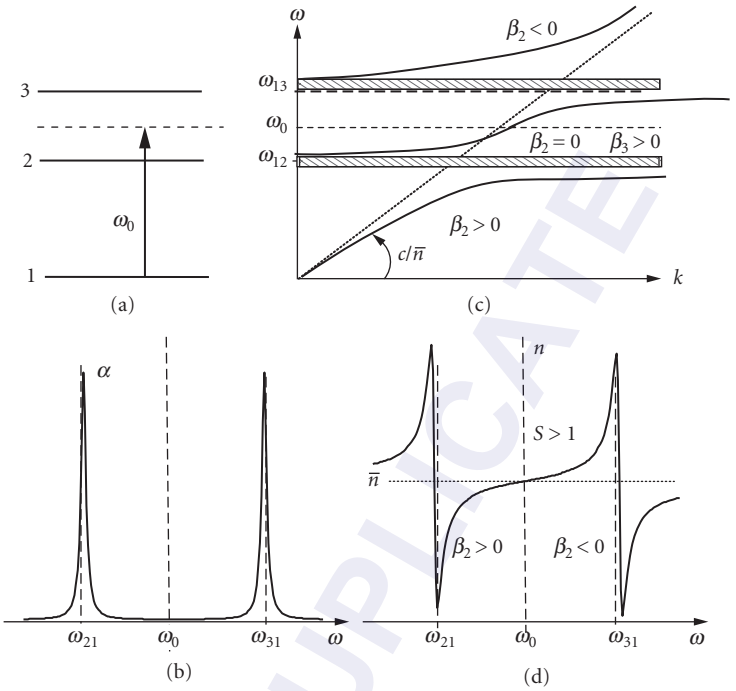

FIGURE 2 (*a*) Double atomic resonance and its (*b*) dispersion and group velocity near it; (*c*) absorption spectrum; and (*d*) refractive index spectrum.

practical bandwidth (or bit rate for digital signals) is even smaller than that and is mostly limited by the third-order dispersion[11,20]

$$|\beta_3| B^3 L < 1/16(\ln 2)^2 \tag{14}$$

In the works[19] group delays in excess of 100 ns with 2-ns pulses at 780 nm had been obtained—that correspond to about 50-bit tunable optical buffers. The delay could be tuned by changing concentration of Rb vapor as shown in Fig. 3.

Tunable Double Resonance—Electromagnetically-Induced Transparency

The double atomic resonant scheme described cannot be adapted to variable bandwidth because the width of passband cannot be changed. To change the passband width, one can consider an alternative of spectral hole burning in the inhomogeneously broadened transition.[21,22] As shown in Fig. 4, a strong pump pulse creates a situation at which the absorption in the frequency range $\Delta\omega$ becomes depleted. The profile of the absorption spectrum shown in Fig. 4*b* looks remarkably like the double-resonant profile of Fig. 2. With the refractive index profile shown in Fig. 4*c*, one can see that a strong reduction of group velocity can be expected near the center of the spectral hole.

By changing the spectrum of the pump, for instance, using intensity or frequency modulation, one can change $\Delta\omega$ to achieve the maximum delay without distortion for a given bit rate. Delays of 2-bit intervals were achieved in Ref. 23 for a moderate bandwidth of 100 MHz but only in a

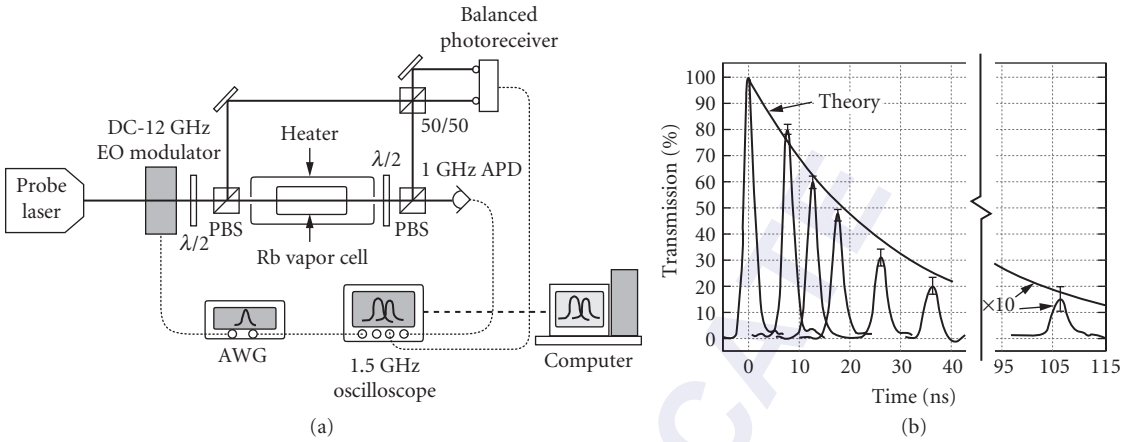

FIGURE 3 Experimental apparatus (*a*) used in Ref. 19 to obtain variable pulse delays at various optical depths using double resonance in Rb vapor (*b*).

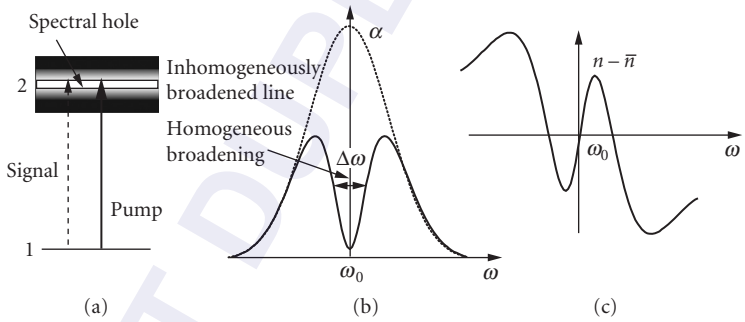

FIGURE 4 (*a*) Slow light scheme based on spectral hole burning; (*b*) absorption spectrum; and (*c*) refractive index spectrum.

40-cm-long Rb vapor delay line. Since the background absorption in the hole burning is always high, it is the dispersion of loss α_2 that causes the signal distortion and is in fact a limitation in this scheme. The scheme also suffers from the large energy dissipation as the pump gets absorbed.

To avoid large background absorption and to achieve wide passband tunability one uses an entirely different SL scheme based on electromagnetic transparency (EIT), first considered by Harris.[24–26] Without trying to explain all the intricacies of EIT, one can understand the rationale of using it. Since finding two closely spaced atomic resonances is not trivial, one should consider the means for their creation artificially.

Now, the atomic oscillator in the absence of external modulation has just one resonant frequency ω_{12} in its response spectrum, just like any harmonic wave whose spectrum contains just one frequency component ω_{12}. But if the wave is amplitude modulated with some frequency Ω, there will appear two sidebands at frequencies $\omega_{12} \pm \Omega$ in its spectrum, and when the modulation depth reaches 100 percent the carrier frequency ω_0, would get entirely suppressed and the spectrum shows just two sidebands separated by 2Ω. Now, according to this analogy, if one strongly modulates the strength of atomic oscillator with some external frequency Ω, one should expect the absorption spectrum to behave in fashion similar to the spectrum of amplitude modulated wave, that is, it should show two absorption lines separated by 2Ω. The material should then become more transparent at the resonance frequency ω_0—hence the term "EIT."

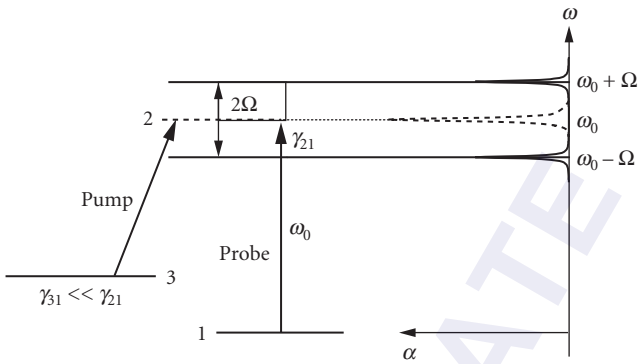

FIGURE 5 Principle of electromagnetic transparency in atomic "Λ" scheme.

To accomplish the EIT transmission modulation there exist numerous schemes, but we shall consider only one—the most widely used three-level "Λ" scheme[1] shown in Fig. 5 in which the ground-to-excited state transition ω_{12} is resonant with the frequency of the optical signal carrier ω_0 and has a dephasing rate of γ_{21}. In the absence of pump, the absorption spectrum (dashed line in Fig. 5) is a normal lorentzian line. There also exists a strong transition that couples the excited level 2 with the third level 3, but notably, the transition between levels 1 and 3 is forbidden. When a strong resonant pump with intensity I_{pump} at frequency ω_{23} is turned on, the mixing of states 2 and 3 causes modulation of the absorption of signal. As expected, the Lorentzian peak in the absorption spectrum splits into two smaller peaks at frequencies $\omega_0 \pm \Omega$, where the Rabi frequency is

$$\Omega = \left(f_{23} \frac{12\pi\alpha_f I_{\text{pump}}}{m\bar{n}\omega_{23}} \right)^{\frac{1}{2}} \tag{15}$$

where $\alpha_f = 1/137$ is a fine structure constant. Thus changing pump intensity allows one to achieve full tunability of the group velocity and to achieve very small group velocities.[3,4] But aside from being a convenient technique of implementing the tunable double resonant scheme, EIT has a significant advantage over other schemes because the residual absorption rate at the resonant frequency

$$\alpha(\omega_0) = \frac{1}{\bar{n}c} \frac{\Omega_p^2}{8\Omega^2} \gamma_{31} \tag{16}$$

is proportional to the dephasing rate of the intra-atomic excitation 31, which is not coupled to outside world. Thus typically $\gamma_{31} << \gamma_{21}$ and the residual absorption is much weaker in the EIT than in the case of two independent resonances. It indicates that EIT is a coherent effect and the reduction of absorption occurs because of the destructive interference of the absorption by two sidebands. This effect has a rather simple physical interpretation. While in the simple single, or double-resonant slow light scheme, the energy transferred from the electromagnetic wave to the atomic excitation and back in the EIT scheme the process involves more steps. First, as the signal photon propagates in the EIT medium, it transfers its energy to the excitation of atomic transition between levels 1 and 2. Due to the presence of strong pump wave coupling between levels 2 and 3, the excitation is almost instantly transferred to the long-lived excitation between the levels 1 and 3 and then the process occurs in reverse until the energy is transferred back into the photon. Then the process repeats itself. Overall, most of the time the energy gets stored in the form of 1-3 excitations and thus it propagates with a very slow group velocity. Furthermore, the actual absorption event occurs only when

the excitation 1-3 loses coherence and the energy cannot get back to the photon. Naturally, it is the dephasing rate of this excitation, that is, $\gamma_{31} << \gamma_{21}$, which determines the residual absorption loss in Eq. (16). We stress here once again that since the energy gets stored in the form of atomic excitation, one cannot expect enhancement in the strength of the optical field.

22.4 BANDWIDTH LIMITATIONS IN ATOMIC SCHEMES

The most spectacular results were achieved in slow light experiments of EIT in which the light velocity was slowed down to the pedestrian speed[3] and then even stopped[4] first in metal vapors and then in solid state medium containing rare earth ions.[27] These achievements are of great importance for physics when it comes to manipulating single photons[28] and coherent control.[29] Also important are imaging applications of slow light where indeed impressive results were observed by a number of groups,[30,31] extra high resolution interferometers,[32,33] and rotation sensors.[34] There has also been significant progress on using electrically pumped semiconductor medium to achieve slow light in EIT configuration or using coherent population oscillations.[35–37] But overall the best results in term of the delay-bit rate product were achieved in metal vapors[19,24] at relatively narrow bandwidths. The delays were usually limited by the third-order dispersion. These results follow the basic properties of the lorentzian dispersion—according to Eq. (7) the slowdown factor S is proportional to $(\omega_{12}-\omega)^{-2}$—hence the total delay can be very large in the narrow frequency band near the resonance, but then it changes and becomes much smaller. A number of publications have been devoted to the limits of delay-bit rate product.[9–11,38,39] In fact, it was shown in Ref. 11 and then in Ref. 39 that the most relevant figure of merit for slow light delay line is the minimum length of the delay line L required to store a number of bits N_{st} at a given bit rate B. The required length was found in Ref. 11 to be

$$L \sim cBN_{st}^2[\Omega_P/2\pi]^{-2} \tag{17}$$

indicating that the performance suffers at higher bit rate and also that the required length increases nonlinearly with storage capacity. Indeed, most of the demonstrated and proposed slow light schemes based on atomic transitions do not show spectacular results at bit rates above 1 Gbit/s and for this reason a different class of resonances shall be considered.

22.5 PHOTONIC RESONANCE

As we have already mentioned, in case of atomic resonance the apparent slow down of light is caused by the resonant energy transfer to and from the excitation of atomic polarization. An entirely different resonance is the photonic resonance in which the energy is resonantly transferred between two or more modes of electromagnetic radiation. When the transfer takes place between forward and backward propagating wave slow light, the group velocity gets reduced and we are once again faced with the slow light phenomenon, albeit of entirely different nature from the slow light in atomic medium.

The most common photonic resonance is the Bragg grating (Fig. 6*a*)—a structure in which the refractive index is periodically modulated with period Λ,

$$n = \bar{n} + \delta n \cos\left(\frac{2\pi}{\Lambda^z}\right) \tag{18}$$

As a result, a photonic bandgap opens in the vicinity of Bragg frequency[40]

$$\omega_B = \frac{\pi c}{\Lambda \bar{n}} \tag{19}$$

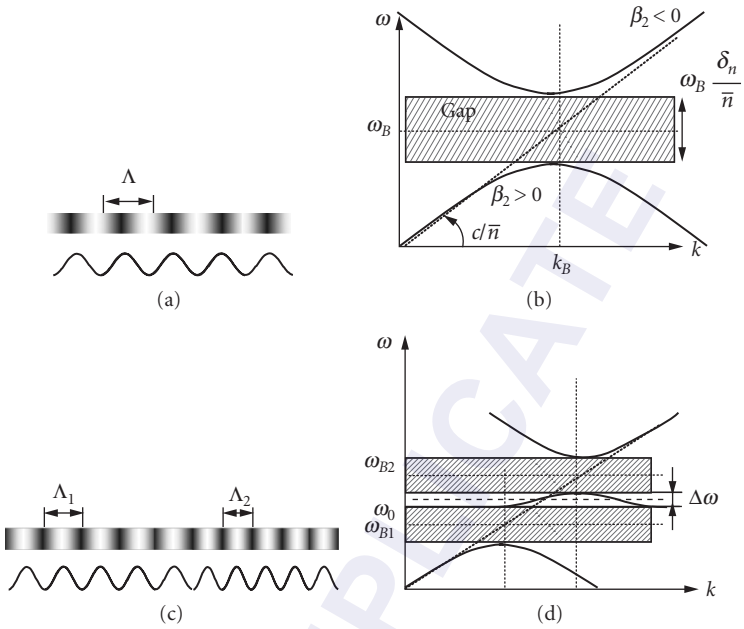

FIGURE 6 (*a*) Bragg grating and its index profile; (*b*) dispersion of Bragg grating; (*c*) cascaded Bragg grating; and (*d*) dispersion curve of cascaded grating.

and the dispersion law becomes modified as

$$\frac{k-k_B}{k_B}=\sqrt{\left(\frac{\omega-\omega_B}{\omega_B}\right)^2-\left(\frac{\delta n}{2\bar{n}}\right)^2} \tag{20}$$

This dispersion law is plotted in Fig. 6*b*. One can see the similarities between it and the dispersion of a single atomic resonance (Fig. 1*d*), especially the presence of the gap near the resonance frequency indicating that the light gets reflected from the grating just as it gets reflected from the atomic medium at resonance. Close to the gap, the group velocity indeed gets reduced with the slowdown factor being

$$S=\frac{\left|\dfrac{\omega-\omega_B}{\omega_B}\right|}{\sqrt{\left(\dfrac{\omega-\omega_B}{\omega_B}\right)^2-\left(\dfrac{\delta n}{2\bar{n}}\right)^2}} \tag{21}$$

Furthermore, the width of forbidden gap is $\Delta\omega_{\text{gap}}=\omega_B(\delta n/\bar{n})$, and hence the index contrast $\delta n/\bar{n}$ can be called the "strength" of the grating. This "grating strength" plays a role equivalent to that played by the oscillator strength of the atomic resonance. But the physics is quite different—the slow down effect in a photonic structure is the result of the transfer of energy between the forward and backward propagating waves—no energy is transferred to the medium. Hence the strength of the electric field in photonic SL structures gets greatly enhanced with important implications for nonlinear optics. One can also use simple photonic crystals[41,42] whose dispersion curves are similar to

Bragg gratings but the problem of structures with a single photonic resonance is identical to the single atomic resonance—strong second-order dispersion β_2. Clearly, in order to compensate it one should consider structures with more than one photonic resonance.

Double Resonant Photonic Structures

Since any atomic SL scheme requires operation near a particular narrow linewidth absorption resonance, finding such a resonance near a particular wavelength is not an easy task, and, in fact, only a very few absorption lines have been employed in practice, Rb vapors being a "workhorse." Finding two closely spaced narrow lines is even more difficult, and even if such two lines can be found, the splitting between them ν_{32} is fixed—hence the SL delay will be optimized for one particular combination of storage capacity and bit rate.

In contrast, the photonic double resonant can be easily implemented by simply combining two Bragg gratings with slightly different periods Λ_1 and Λ_2 as shown in Fig. 6*c*. Such combination was first suggested for dispersion compensation[43,44] and then considered for application in electro-optic modulators.[45] As long as one deals with linear devices, such as delay lines, one can simply cascade two Bragg gratings sequentially and the resulting dispersion curve will be simply the mean of the individual dispersion curves. For the nonlinear and electro-optic devices one can alternate the short segments of Bragg gratings with periods Λ_1 and Λ_2. The dispersion curve of Fig. 6*d* is remarkably similar to the dispersion curve of the atomic double resonance in Fig. 2*b*. Two gratings engender two photonic bandgaps, centered at $\omega_{B,i} = \pi c/\Lambda_i \bar{n}$ of almost equal widths $\Delta\omega_{\text{gap},i} = \omega_{B,i}(\delta n/\bar{n}) \approx \omega_0(\delta n/\bar{n})$ with a narrow passband $\Delta\omega$ between them. By choosing the periods Λ_1 and Λ_2 for a given index modulation δn one can design $\Delta\omega$ to be arbitrarily narrow or wide. This fact gives the designer true flexibility. In fact, one can show the slowdown factor in this scheme is

$$S(\omega_0) \approx \left[1 + \frac{\Delta\omega_{\text{gap}}}{2\Delta\omega}\right]^{1/2} \tag{22}$$

Thus, as one can see, the dispersion curve gets *squeezed* between two gaps and the group velocity decreases with the passband, but the dependence is not as strong as in the case of atomic resonance, thus the photonic structures in general should have far superior performance at large bandwidth when compared to atomic medium. A similar approach can be cascaded photonic crystal waveguides as demonstrated in Refs. 46 to 50.

However, cascaded Bragg gratings have also a number of disadvantages, the first of which is a relatively small index contrast available, and the second is difficulty in fabricating two gratings with a prescribed value of the frequency offset. Furthermore, the cascaded geometry is applicable only to the linear devices that do not incorporate any nonlinear or electro-optic component. For this reason it is preferable to use alternating short segments of gratings with different periods. But a periodic sequence of short Bragg grating segments can be considered a new grating with periodically modulated properties, or Moiré grating (Fig. 7*a*). In a Moiré grating the segments are not independent but interact coherently—hence its properties are somewhat different from the cascaded grating as shown in Ref. 51, with the main distinction being the fact that the dispersion curve of Moiré grating with period d is also periodic in wave-vector space with a period $2\pi/d$. The ability of a Moire grating to slow down the light was first predicted in Ref. 51 and demonstrated in Ref. 52. It was also noted that the Moiré grating is only example of periodically structured photonic media in which slow light can be observed. In the periodically structured media, the light energy density is distributed periodically and the periodically spaced regions of high intensity can be thought of as the resonators coupled to each other. Thus we shall refer to them as coupled resonator structures (CRS).[53] Aside from using Moiré gratings, CRS can be fabricated by coupling Fabry-Perot resonators (Fig. 7*b*), ring resonators (Fig. 7*c*),[54] or so-called "defect modes" in the photonic crystal (Fig. 7*d*).[55,56] These and other CRS implementations are discussed at length in the literature[41,57–61] and here we shall only give a short description of their properties and compare them with the EIT-like photonic structures.

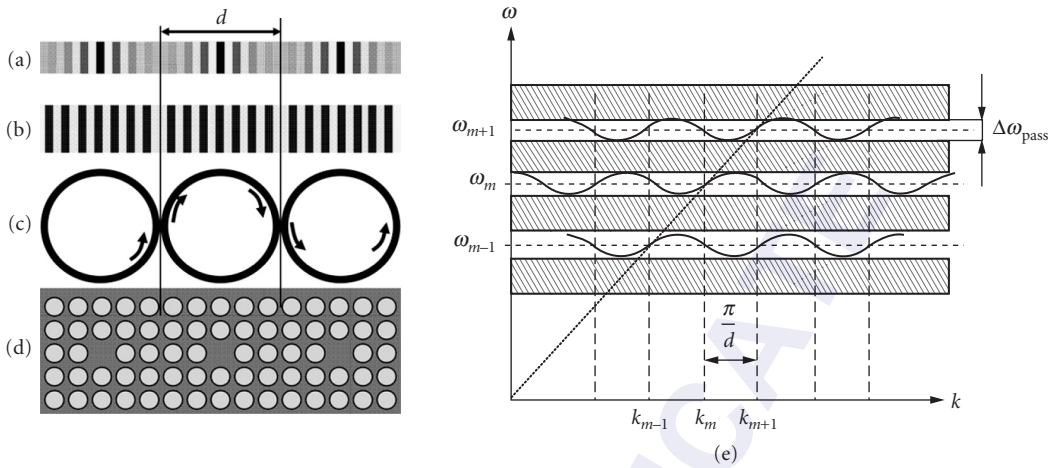

FIGURE 7 Photonic SL structures based on coupled resonators (CRS): (*a*) Moiré grating; (*b*) coupled Fabry-Perot resonators; (*c*) coupled ring resonators; (*d*) coupled defect modes in photonic crystal; and (*e*) dispersion in a typical CRS.

A periodic chain of coupled resonators is characterized by three parameters: period d, the time of one way pass through each resonator τ, and the coupling (or transmission) coefficient κ. The dispersion relation in this chain can be written as

$$\sin\omega\tau = \kappa \sin kd \tag{23}$$

The dispersion curves are shown in Fig. 7*e* and consist of the series of passbands around resonant frequencies $\nu_m = m/2\tau$ separated by the wide gaps. Presence of multiple resonances indicates that the light propagating through CRS can be considered a superposition of more than one forward and more than one backward propagating wave. Alternatively, one can also think about the resonators as "photonic atoms" analogous to real atoms in EIT. At any rate, the dispersion curve is quite similar to the EIT dispersion curve in sense that it gets *squeezed* into a narrow passband of width

$$\Delta\nu_{\text{pass}} = (\pi\tau)^{-1} \sin^{-1}(\kappa) \tag{24}$$

The three parameters d, τ, and κ are not independent of each other. First of all d and τ are obviously related to each other. This relation can be obtained from taking a limit of Eq. (23) at $\kappa = 1$

$$\frac{d}{\tau} = \frac{\omega}{k} = \frac{c}{\bar{n}} \tag{25}$$

which simply indicates that with 100 percent coupling the light simply propagates through medium without reflections. Also related are the size of resonator, that is, d and the coupling coefficient κ; to achieve small κ, one needs to confine the light tightly within the resonators which requires large spacing between them. If the index contrast $\delta n/\bar{n}$ is large, a high degree of confinement can be achieved within a relatively small resonator; otherwise the light will leak from one resonator to another. This issue has been addressed in detail in Ref. 11, but here we simply assume that one uses the smallest resonator size that can be fabricated using a technology with a given index contrast.

Using Taylor expansion of the dispersion relation [Eq. (24)], one obtains the group velocity

$$v_g^{-1} = \frac{\tau}{d\kappa} = \frac{\bar{n}}{c}\kappa^{-1} \tag{26}$$

Hence the slowdown factor is simply

$$S=\kappa^{-1} \tag{27}$$

At the same time the third-order dispersion is

$$\beta_3=v_g^{-1}\left(\frac{\tau}{\kappa}\right)^2(1-\kappa^2) \tag{28}$$

indicating that one can always optimize the performance of CRS delay line by choosing proper coupling coefficient to strike the balance between sufficient delay and low distortion caused by dispersion. As a result one can achieve the following relation between the storage capacity N_{st} and the required delay line length

$$L\sim cN_{st}^{3/2}\left(\omega\frac{\delta n}{\bar{n}}\right)^{-1} \tag{29}$$

Comparing Eq. (29) with the results for atomic delay line Eq. (17), one can first notice that the required length of the buffer (essentially the number of coupled resonators) does not increase with the bit rate. Thus the CRS should have much better performance at high bit rates compared to EIT delay lines. This result (and the fact that required length increase only as a power 3/2 of storage capacity) follows the fact that the slowdown factor is not as strong function of passband width in CRS as in EIT. Furthermore, the expression inside the parenthesis can become commensurate with the optical frequency when large index contrast is used. This contrast can be as high as a factor of 2 in Si on SOI ring resonators[61,62] or photonic crystal,[41] which means that one can ultimately store N_{st} bits of optically encoded information in roughly $L\sim N_{st}^{3/2}\lambda$ length.[63]

The limitations imposed by high order dispersion can be mitigated by using a combination of CRS with β_3's of different sign as shown in.[64] Alternatively, one can use the so-called dynamic slow light scheme[65–67] in which the properties of the CRS are adiabatically tuned when the light enters it allowing the compression of spectrum and thus reducing the deleterious effect of dispersion. Similar results can be in principle achieved using semiconductor devices[68,69] combining Bragg grating with quantum wells that are resonant near the Bragg frequency. It should be noted, however, that even dynamic structures have limited storage capacity due to dispersion occurring before the spectral compression, that is, when the light enters the delay line.[70,71]

22.6 SLOW LIGHT IN OPTICAL FIBERS

In the prior subsections, we have described the slow light in the vicinity of atomic and photonic resonances that are always associated with loss. In case of atomic resonance, the loss is inherent and can be traced to dephasing of atomic polarization. In case of photonic resonance, the loss occurs simply because the light spends more time inside the delay line (or, in one case, it takes longer effective path by bouncing back and forth or making circles). But it is well known that strong dispersion also takes place in the spectral vicinity of the resonant gain. The advantages of using gain are manyfold—first of all one is not faced with attenuation, and second the gain can be changed at will by changing the pump strength and spectrum—hence the delay and the bandwidth can be made tunable.

Consider a gain profile $g(\omega)$ shown in Fig. 8*a* and characterized by its peak value $g_0=g(\omega_0)$ and the FWHM linewidth $\delta\omega_{1/2}$. Usually the peak gain is inversely proportional to the linewidth and therefore it makes sense to introduce the integrated optical gain that is proportional to the total pump power $\gamma\sim g_0\delta\omega_{1/2}$. Applying Kramers-Kronig transform to the gain profile, one can obtain

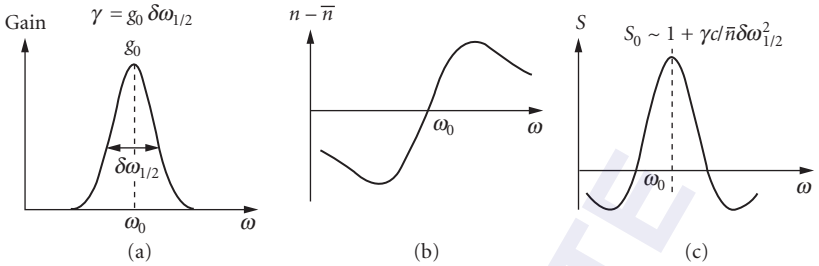

FIGURE 8 Slow light in an optical amplifier: (*a*) gain; (*b*) index; and (*c*) slowdown factor.

the refractive index spectrum shown in Fig. 8*b*. There is a positive slope at the center of the gain and this leads to slowdown factor of

$$S(\omega_0) \sim 1 + g_0 c/\overline{n}\delta\omega_{1/2} \sim 1 + \gamma c/\overline{n}\delta\omega_{1/2}^2 \tag{30}$$

shown in Fig. 8*c*. To achieve tunable gain, most often one uses stimulated Brillouin or stimulated Raman scattering. One unique advantage of these processes is that it can be observed in many media including the ubiquitous silica optical fiber which allows the slow light devices to be easily integrated into communication systems.

In the stimulated Brillouin scattering (SBS) process, a high-frequency acoustic wave is induced in the material via electrostriction for which the density of a material increases in regions of high optical intensity. The process of SBS can be described classically as a nonlinear interaction between the pump (at angular frequency ω_p) and a probe (or Stokes) field ω_s through the induced acoustic wave of frequency Ω_A.[72] The acoustic wave in turn modulates the refractive index of the medium and scatters pump light into the probe wave when its frequency is downshifted by the acoustic frequency. This process leads to a strong coupling between the three waves when this resonance condition is satisfied, which results in exponential amplification (absorption) of the probe wave. Efficient SBS occurs when both energy and momentum are conserved, which is satisfied when the pump and probe waves counterpropagate. This leads to atypically very narrow gain bandwidth of typically about 30 MHz. With the peak values of Brillouin gain of about $g_0 \sim 0.02\,\mathrm{m}^{-1}$ one can then expect the slowdown factor to be on the order of only a few percent different from unity—hence the value of this scheme is not in the absolute delay time but in adjustable additional delay

$$\Delta T_d \sim g_0 L/\delta\omega_{1/2} \tag{31}$$

Since the large value of total gain $g_0 L$ can lead to Brillouin lasing, it is usually limited to about 10 to 15 meaning that maximum pulse delay of about 2 pulse lengths.[73] It is important that the main limitation for the achievable delay in amplifiers is the dispersion of gain rather than dispersion of group velocity.[73] While this delay of a few pulse lengths is relatively small, it is tunable and as such may be sufficient for many applications.

Tunable slow-light delay via SBS in an optical fiber was first demonstrated independently by Song et al.[74] and Okawachi et al.[75] In the experiment preformed in Ref. 74 delay could be tuned continuously by as much as 25 ns by adjusting the intensity of the pump field and the technique can be applied to pulses as short as 15 ns. A fractional slow-light delay of 1.3 was achieved for the 15-ns-long input pulse with a pulse broadening of 1.4.

Following the first demonstrations of SBS slow light in optical fibers, there has been considerable interest in exploiting the method for telecommunication applications. One line of research

has focused on reducing pulse distortion by reducing the distortion caused by the gain dispersion performance[76–81] by essentially trying to shape the Brillouin gain with multiple pumps. In numerous experimental demonstrations of multiple closely spaced SBS gain lines generated by a multifrequency pump, significant increases in slow-light pulse delay were achieved as compared with the optimum single-SBS-line delay.

Another line of research has focused on broadband SBS slow light.[82–86] The width of the resonance which enables the slow-light effect limits the minimum duration of the optical pulse that can be effectively delayed without much distortion, and therefore limits the maximum data rate of the optical system. Herraez et al.[82] were the first to increase the SBS slow-light bandwidth and achieved a bandwidth of about 325 MHz by broadening the spectrum of the SBS pump field. Zhu et al. extended this work to achieve an SBS slow-light bandwidth as large as 12.6 GHz, thereby supporting a data rate of over 10 Gb/s.[83] The latest results on expanding bandwidth are summarized in the review article.[87]

An alternative way to achieve tunable delays in optical fibers is via stimulated Raman scattering (SRS) can also be achieved in optical fibers. The SBS arises from exciting vibrations in individual molecules also known as optical phonons—as opposed to exciting sound waves (acoustic phonons) as in the SBS process. The optical phonons, unlike acoustic phonons, are localized and have very short lifetimes, measured in picoseconds or fractions of picoseconds. Furthermore, in amorphous materials, such as glass, the frequencies of optical phonons are spread over the large interval (measured in THz)—hence the Raman gain is much broader than Brillouin gain, but is also much smaller in absolute value. Integrated gain $\gamma \sim g_0 \delta\omega_{1/2}$ is similar for SBS and SRS but in SRS it is spread out over much wider $\delta\omega_{1/2}$.

Sharping et al. demonstrated an ultrafast all-optical controllable delay in a fiber Raman amplifier.[88] In this experiment a 430-fs pulse is delayed by 85 percent of its pulse width using SRS in 1-km-long high nonlinearity fiber. The ability to accommodate the bandwidth of pulses shorter than 1 ps in a fiber-based system makes SRS slow light useful for producing controllable delays in ultrahigh bandwidth telecommunication systems.

In addition to optical fibers, SRS slow light has also been demonstrated in a silicon-on-insulator planar waveguide.[89] Since silicon is a single-crystalline material, the Raman gain is concentrated into the narrower bandwidth than in glass, but this bandwidth is still sufficient for delaying short optical pulses of 3 to 4 ps in a very short (8 mm) waveguide. This scheme represents an important step in the development of chip-scale photonics devices for telecommunication and optical signal processing.

Slow light propagation was also demonstrated in erbium-doped fibers[90,91] using coherent population oscillations, but the bandwidth, related to the relaxation time in erbium ion was only on the order of kHz. Other methods included using the parametric gain[92] in the optical fiber as well as taking advantage of EIT in hollow optical fibers.[93]

22.7 CONCLUSION

In this chapter, we have only given a very brief overview of the physics involved in the phenomenon of slow (and fast) light propagation. We have shown that while the underlying mechanisms are diverse, they all are characterized by a relatively narrow resonance, whether it is due to an atomic transition, resonance in the photonic structure, or is determined by a pump in an optical amplifier. As a result, the delay bandwidth and physical dimensions of all slow-light media are interdependent and must be optimized for a given set of objectives that depends on application. The applications of slow light, in both linear and nonlinear optics, are so diverse that it is impossible to cover them all even briefly in this chapter. They involve optical communications, optical signal processing, microwave photonics, precise interferometric instruments, and many others, and many new ones appear every year. The multidisciplinary field of slow light experiences rapid growth and this brief survey of the current state of affairs is nothing more than a snapshot intended to provide sufficient background to the newcomers into this field and to suggest a number of sources from which a deeper knowledge can be gained.

23.1 INTRODUCTION

The newly emergent fields of quantum sensing and imaging utilize quantum entanglement—the same subtle effects exploited in quantum information processing—to push the capability of precision measurements and image construction using interferometers to the ultimate quantum limit of resolution.[1,2] Alan Migdall at the U.S. National Institute of Standards and Technology, for example, has proposed and implemented a quantum optical technique for calibrating the efficiency of photodetectors using the temporal correlations of entangled photon pairs.[3] It was one of the first practical applications of quantum optics to optical metrology, and has produced a technique to calibrate detectors without the need for an absolute standard.

These quantum effects can also be applied to increase the signal-to-noise ratio in an array of sensors from Laser Interferometer Gravitational Wave Observatory (LIGO) to Laser Light Detection and Ranging (LIDAR) systems, and to synchronized atomic clocks. Quantum imaging exploits similar quantum ideas to beat the Rayleigh diffraction limit in resolution of an imaging system, such as used in optical lithography. We present an introduction to these exciting fields and their recent development.

Entanglement is the most profound property of quantum mechanical systems.[4,5] First we need to define entanglement. For simplicity, let us consider a system of two modes A and B only. Modes A and B may describe the two spatial paths of a Mach-Zehnder interferometer or two different polarization modes in an optical cavity. We can put a photon in either of the modes or let them remain empty. Let us suppose a general state of mode A which is a superposition of the two possible states, therefore we obtain $\alpha|0\rangle_A+\beta|1\rangle_A$, where α and β may be complex and $|\alpha|^2+|\beta|^2=1$ is required for proper normalization of the state. We also write a superposition for a general state for mode B, that is, $\gamma|0\rangle_B+\delta|1\rangle_B$ and $|\gamma|^2+|\delta|^2=1$. Now consider the combined two-mode state $|\Psi\rangle=(|1\rangle_A|0\rangle_B+|0\rangle_A|1\rangle_B)/\sqrt{2}$, where either a photon is in mode A or B. It is easy to see that this state cannot be decomposed into a product state for mode A and mode B only, that is, we *cannot* find any coefficients α, β, γ, δ such that the equation $(\alpha|0\rangle_A+\beta|1\rangle_A)(\gamma|0\rangle_B+\delta|1\rangle_B)=(|1\rangle_A|0\rangle_B+|0\rangle_A|1\rangle_B)/\sqrt{2}$ is satisfied. The state $|\Psi\rangle$ is an example for a nonseparable state. In general, any nonseparable state of two or more systems is called entangled. Erwin Schrödinger was the first who coined the term entanglement,[6] although he is by far more prominent for his Schrödinger cat. Now we have a proper definition for entangled

pure states. But what is the definition for entangled mixed states? Let us suppose two systems A and B that can be in n different mixed states ρ_i^A and ρ_i^B with $i=1,\ldots,n$. A separable mixed state may be written as $\rho=\sum_i p_i \rho_i^A \otimes \rho_i^B$, where the p_i are probabilities. Mathematicians call this particular sum a convex combination of product states. Now we can define entanglement for mixed states in excluding just these separable states. We say, if the bipartite system *cannot* be written in the above way, we call it entangled.[7]

Entanglement is not necessarily a useful physical quantity. Entanglement is usually discussed together with nonlocal correlations. These nonlocal correlations can be verified by Bell experiments.[8] For a nice review of the current status of Bell experiments see, for example, Ref. 9. The violation of a Bell inequality[10,11] by a specific quantum state is an indication that the state is able to exhibit nonlocal correlations. It is known that for any entangled *pure* state of any number of quantum systems one may violate a generalized Bell inequality.[12,13] An extension of this statement for mixed entangled states has not been found. Furthermore Werner provided in 1989 an example of nonseparable mixed states that do not violate a Bell inequality.[7] This demonstrated that the class of entangled mixed states decomposes into states that are entangled but do not show nonlocal correlations and those that are entangled and are nonlocal. The state $|\Psi\rangle$ is clearly entangled but only until very recently it has been proven in several experiments that this state violates a Bell inequality.[14–17] Generalizations of this state where the single photon is replaced by N photons will play an important role in applications described later in this chapter. That also this generalization for N photons in either of the modes violates a Bell inequality has been proven in Ref. 18 very recently. This shows that the connection of entanglement and nonlocal correlations is still a very hot research topic. Now let us come back to a very practical application, an optical interferometer.

In order to see the role of quantum mechanics in optical interferometers, we first consider a prototype Mach-Zehnder interferometer (MZI).[19] The task is to measure the path-length difference between the two arms of the interferometer. In the standard approach, as shown in Fig. 1, an input laser beam is launched into the first 50-50 beam splitter (BS) on the left in port A, bounced off of the two mirrors in the middle, and recombined at the second 50-50 BS on the right. Light then emerges from the top and bottom ports, C and D, of the second BS, and is then made incident on two photodetectors $\mathcal{C}$ and $\mathcal{D}$, as shown. Typically, the intensities in each port, I_C and I_D, are measured at each detector and the result is combined to yield the difference intensity, $I = I_D - I_C$, which

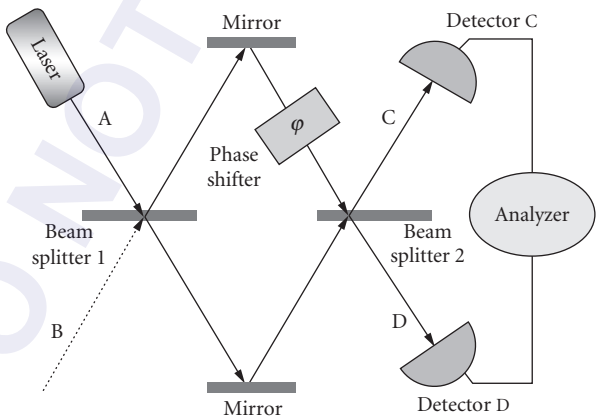

FIGURE 1 Schematic of a Mach-Zehnder interferometer. Laser light in port A is split by the first 50-50 beam splitter, aquires a phase difference, and recombines at the second beam splitter and emerges in ports C and D. We take a convention such that, for a balanced interferometer, port C is the dark port. Hence, any light emergent here is indicative of an arm displacement and can be detected by the two detectors and the analyzer.

we shall call the signal. To indicate the phase induced by the path difference between the upper and lower arms, we place an icon for a phase shift φ, which in this example has the value $\varphi = kx$. Here x is the path-length difference between the two arms. The wave number, $k = 2\pi/\lambda$, is a predetermined constant, given the optical wavelength λ.

We adopt the convention that the light field always picks up a $\pi/2$ phase shift upon reflection off of a mirror or off of a BS, and also no phase shift upon transmission through a BS. Then, the two light fields emerging from the second BS out the upper port C are precisely π out of phase with each other, and hence completely cancel out due to destructive interference (the dark port). Consequently, the two light fields recombine completely in phase as they emerge from the lower port D and add up due to constructive interference (the bright port). Hence for a balanced MZI all of the energy that comes in port A emerges out of port D and none out of port C. Clearly, any change in the path difference x away from the $x = 0$ balanced condition will cause light to appear in the formerly dark port, and in this way we can measure x by simply measuring intensities at the detectors.

The question is: How precise a measurement of the path difference x can we make? If the light intensity incident on port A is I_A, then in terms of the phase shift φ the output-port intensities can be written as

$$I_C = I_A \sin^2(\varphi/2) \tag{1a}$$

$$I_D = I_A \cos^2(\varphi/2) \tag{1b}$$

It is typical for the analyzer in Fig. 1 to compute the difference intensity $M = I_D - I_C$ (where M stands for "minus") such that

$$M(\varphi) \equiv I_D - I_C = I_A \cos(\varphi) \tag{2}$$

Since $\varphi/2 = kx/2 = \pi x/\lambda$, we have that $I_C = 0$ and $I_D = I_A$ whenever $x/\lambda = 0, 1, 2, 3, \ldots$ Hence, our ruler is the light wave itself and the tick marks are spaced the wavelength λ apart. We may start with a balanced interferometer with equal arm lengths, $x = 0$ (and $M = I_A$), and then slowly move the upper mirror upward increasing x. As we do we will break the balance and begin to see light emerging from the formally dark port C (M decreases in the plot).

At the point $\varphi = \pi/2$, when $I_C = I_D$, then $M = 0$. Eventually, we will see port C attain maximum brightness and port D will go dark ($M = -I_A$). As we continue the mirror displacement, this process will reverse, as sine and cosine are periodic, and finally port C will go dark again (M is maximum again with $M = I_A$). At this point, we can stop moving the upper mirror and we are assured that now the path difference x has gone from 0 to λ. If we take $\lambda = 1.0$ μm, then it would seem we have a machine capable of measuring distances to an accuracy of about $\lambda = 1.0$ μm. This is consistent with the Rayleigh diffraction limit, typically invoked in classical optics.

Let us now balance the interferometer such that we start at the point $\varphi = \pi/2$, when $I_C = I_D$, and hence $M = 0$ in Fig. 2. Note this is where the curve crosses the horizontal axis and the slope of the M-curve is steepest. If we call the horizontal displacement change $\Delta\varphi$, then we can see this is related to the vertical intensity change ΔM. For small changes, we may approximate this relation using differentials, that is, $\Delta M = I_A \Delta\varphi$ or

$$\frac{\Delta M}{\Delta\varphi} = \frac{\partial M}{\partial\varphi} = I_A \sin(\varphi) \tag{3}$$

which may be written as

$$\Delta\varphi = \frac{\Delta M}{\partial M/\partial\varphi} = \frac{\Delta M}{I_A \sin(\varphi)} \tag{4}$$

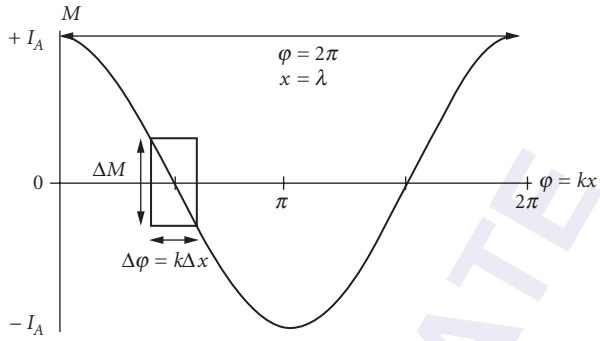

FIGURE 2 Typical Mach-Zehnder analyzer. The difference intensity M is plotted as a function of the phase shift $\varphi = kx$, where x is the arm displacement to be measured. The minimal detectable displacement, Δx, is limited by the fluctuations in the optical intensity, ΔM. These fluctuations are quantum mechanical in nature.

The quantity $\partial M/\partial\varphi$ is the slope of the curve, which is largest at the crossing point, implying our minimum detectable phase $\Delta\varphi$ is smallest there, via Eq. (4). At the crossing point $\varphi = \pi/2$ and $\sin(\pi/2) = 1$, and so this relation would seem to indicate that *if* we can measure the intensity displacement ΔM with infinite precision ($\Delta M = 0$), we can measure the phase (and hence distance) with infinite precision ($\Delta\varphi = 0$). In practice, various technical imperfections tend to set the limit for the finite precision ΔM.[20] However, as far as classical electromagnetic waves are concerned, nothing "fundamentally" prevents ΔM being zero. Hence, it would appear that *if* we try hard, we could detect any amount of phase shift no matter how small it is.

23.2 SHOT-NOISE LIMIT

The problem is that the simple classical arguments we used above do not take into account the effects of quantum mechanics. Specifically it does not take into account the fact that the intensity of the light field is not a constant, which can be measured with infinite precision, but that it fluctuates about some average value, and those fluctuations have their origin in the vacuum fluctuations of the quantized electromagnetic field.[21,22] According to quantum mechanics, optical intensity can never be measured with infinite precision. Hence the uncertainty, in the curve of Fig. 2, always has some finite value, indicated by the box of height ΔM. The intensity displacement M can never be measured with infinite precision and has a fundamental uncertainty ΔM, and therefore the consequent phase φ will always have its related uncertainty $\Delta\varphi$, which is the width of the box. These fundamental quantum intensity fluctuations suggest that there is a Heisenberg uncertainty principle at work, which in our example implies that the intensity I and the phase φ cannot both simultaneously be measured with infinite precision.

For a quantum analysis of this phenomenon, we introduce the mean number of photons in the laser field as the dimensionless quantity n, and note that the intensity I is then proportional to n for a steady-state system. If we denote the fluctuation in the phase as $\Delta\varphi$ and that in the intensity as Δn, we can then write down the Heisenberg number-phase uncertainty relation as[23–25]

$$\Delta n \Delta\varphi \geq 1 \tag{5}$$

This is closely related to the better know energy-time uncertainty principle $\Delta E \Delta t \geq \hbar$, where ΔE is the uncertainty in the energy, Δt is the uncertainty in the time, and $\hbar$ is Dirac's constant (Planck's constant

divided by 2π). For a standing, monochromatic, electromagnetic wave we have $E=\hbar n\omega$, where ω is the frequency. This is just the energy per photon multiplied by the average number of photons. Since there is no propagation for a standing wave we have $\varphi = \omega t$ as the accumulated phase at any point. Approximating both of these expressions with differentials gives $\Delta E=\hbar\Delta n\omega$ and $\Delta\varphi = \omega\Delta t$. Inserting these two expressions into the energy-time uncertainty relation yields the number-phase relation, Eq. (5).

For a laser beam, the quantum light field is well approximated by a coherent state, denoted as $|\alpha\rangle$, where the complex number $\alpha=|\alpha|e^{i\varphi}$ is proportional to the electric field amplitude E such that $|\alpha|^2=n$, the latter of which we recall is the dimensionless field intensity.[21] This is the dimensionless quantum version of the classical relation $|E|^2=I=I_0n$. The full dimensional form is $E=E_0\sqrt{n}$, where $I_0=|E_0|^2=\hbar\omega/(\varepsilon_0V)$, which in SI units, $\hbar$ is Dirac's constant, ε_0 is the free-space permittivity, and V is the mode volume for the electromagnetic field. Hence I_0 is the intensity of a single photon. The fluctuations are typically represented in a phasor diagram, as shown in Fig. 3. Here the phase is the polar angle φ measured counterclockwise off the horizontal axis. The radius from the origin to the center of the coherent-state disk is $R=|\alpha|^2=n$. The diameter of the disk d is on the order of $d=\Delta n=\sqrt{n}$. From simple geometry, we can then approximate $d = R\,\Delta\varphi$, where $\Delta\varphi$ is the uncertainty or fluctuation in the angular φ direction.

Combining all this we arrive at the fundamental relationships between number (intensity) and phase uncertainty for a coherent-state laser beam,

$$\Delta n\,\Delta\varphi = 1 \tag{6a}$$

$$\Delta n=\sqrt{n} \tag{6b}$$

$$\Delta\varphi_{\text{SNL}} = \frac{1}{\Delta n}=\frac{1}{\sqrt{n}} \tag{6c}$$

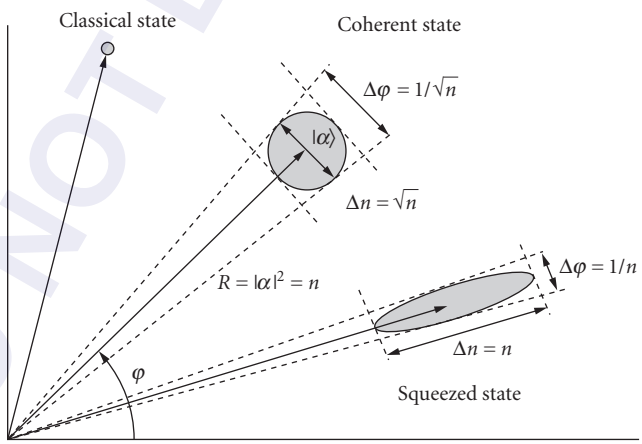

FIGURE 3 Phase-space diagram showing quantum fluctuations. Fluctuations in the radial direction correspond to intensity and those in the angular direction phase. A coherent state is a disk and has fluctuations equal in intensity and phase (a "true" classical state is a point and has no fluctuations). Also shown is a phase squeezed state, which has fluctuations decreased in the angular (phase) direction, at the expense of increase fluctuation in the radial (intensity) direction. Such a phase-squeezed state can be used to beat the shot-noise limit.

The first relation, Eq. (6*a*), tells us that we have equality in Eq. (5); that is a coherent state in a minimum uncertainty state (MUS). Such a state saturates the Heisenberg number-phase uncertainty relation with equality. This is the best you can do according to the laws of quantum mechanics. The second relation, Eq. (6*b*), describes the fact that the number fluctuations are poissonian with a mean of n and a deviation of $\Delta n = \sqrt{n}$, a well-known property of the Poisson distribution and the consequent number statistics for coherent-state laser beams.[22] Putting back the dimensions we arrive at

$$\Delta\varphi_{\mathrm{SNL}} = \sqrt{\frac{I_0}{I}} \tag{7}$$

which is called the shot-noise limit (SNL). The term "shot noise" comes from the notion that the photon-number fluctuations arise from the scatter in arrival times of the photons at the beam splitter, much like buckshot from a shotgun ricocheting off a metal plate. We can also import the SNL into our classical analysis above. Consider Eq. (4), where we now take $I_A = I_0 n$, $\Delta M = \sqrt{I_0 n}$, and $\varphi = \pi/2$. We again recover Eq. (6*c*) for the phase uncertainty. Hence quantum mechanics puts a quantitative limit on the uncertainty of the optical intensity, and that intensity reflects itself in a consequent quantitative uncertainty of the phase measurement.

In classical electromagnetism, we can also represent a monochromatic plane wave on the phasor diagram of Fig. 3—but instead of a disk the classical field is depicted as a point. The radial vector to the point is proportional to the electric field amplitude E and the phase angle corresponds to the classical phase of the field. The phase-space point represents the idea that, classically, we can measure number and phase simultaneously and with infinite precision. As we have seen above, quantum mechanically this is not so. The Heisenberg uncertainty principle (HUP) of Eq. (5) tells us that both phase and intensity cannot be measured simultaneously with infinite precision. For a minimum uncertainty state (MUS), such as a coherent state $|\alpha\rangle$, we have equality in the HUP, as given in Eq. (6*a*). Then, combined with the poissonian-statistical distribution of photon number for a coherent state, Eq. (6*b*), we arrive at the shot-noise limit.

23.3 HEISENBERG LIMIT

In 1981, Carlton Caves first proposed the idea of using nonclassical states of light—the so-called squeezed states—to improve the sensitivity of optical interferometers to below even the shot-noise limit.[26] This notion came as somewhat of a surprise to the interferometer community, as it was thought at the time that the shot-noise limit was the ultimate limit on sensitivity as imposed by quantum mechanics. However, there are other minimum uncertainty states besides the coherent state. The easiest way to see this is to look again at the representation of the coherent state as a disk in phase space (Fig. 3). The fact that it is a disk indicates that the fluctuations are the same in all directions, and that the area of the disk is a constant $\mathcal{A}$. The pictogram and the HUP then tells us that any quantum state must have an area greater or equal to $\mathcal{A}$, and that the MUS has an area equal to $\mathcal{A}$. This is, for a coherent state, equivalent to stating the three conditions of Eq. (6). However, we can relax Eq. (6*b*) and (6*c*), while still maintaining the HUP of Eq. (6*a*).

That is, we can decrease $\Delta\varphi$, at the expense of increasing Δn at the same time, so that the product $\Delta\varphi\Delta n = 1$ remains constant and the area of the disk remains the same value $\mathcal{A}$. Pictorially this amounts to squeezing the coherent-state disk in the angular direction, while allowing it to expand in the radial direction, as shown in Fig. 3. The important point is that the area $\mathcal{A}$ of the ellipse remains unchanged so that the HUP is obeyed. However, we can decrease phase uncertainty at the expense of increasing the number uncertainty. Furthermore, it is possible to produce such squeezed states of light in the laboratory, using nonlinear optical devices and ordinary lasers.[27–30]

Now the question is: What is the most uncertainty we can produce in photon number, given that the mean photon number n is a fixed constant, and that we still want to maintain the MUS condition—that the area of the ellipse remains a constant $\mathcal{A}$. Intuitively one cannot easily imagine a scenario where

the fluctuations in the energy, $\Delta E = \hbar\omega\Delta n$, exceeds the total energy of the laser beam, $E = \hbar\omega n$. Hence the best we can hope to achieve is $\Delta E = E$ or, canceling out some constants, $\Delta n = n$. Inserting this expression in the HUP of Eq. (6*a*), we obtain what is called the Heisenberg limit:

$$\Delta\varphi_{\mathrm{HL}} = \frac{1}{n} \tag{8}$$

Putting back the dimensions we get

$$\Delta\phi_{\mathrm{HL}} = \frac{I_0}{I} \tag{9}$$

This is exactly the limit one gets with a rigorous derivation using squeezed light in the limit of infinite squeezing.[31,32] It is called the Heisenberg limit as it saturates the number-phase HUP, and also because it can be proven that this is the best you can do in a passive interferometer with finite average photon number n. Converting to minimum detectable displacement we get

$$\Delta x = \frac{\lambda\!\!\!^{-}}{n} = \lambda\!\!\!^{-}\frac{I_0}{I} \tag{10}$$

where I_0 is the single photon intensity, defined above.

So far, we have considered the situation that we send light in port A and analyzed what came out of ports C and D for the MZI shown in Fig. 1. What about input port B? Classically there is no light coming in port B, and hence it is irrelevant. But, it is not so. In his 1981 paper, Caves showed that no matter what state of the photon field you put in port A, so long as you put nothing (quantum vacuum) in port B, you will always recover the SNL. In quantum electrodynamics, even an interferometer mode with no photons in it experiences electric field fluctuations in that mode.

In the MZI these vacuum fluctuations have another important effect; at the first BS they enter through port B and mix with whatever is coming in port A to give the SNL in overall sensitivity. It becomes clear then, from this result, that the next thing to try would be to plug that unused port B with something besides vacuum. It was Caves' idea to plug the unused port B with squeezed light (squeezed vacuum to be exact). That, with coherent laser light in port A as before—and in the limit of infinite squeezing—then the SNL rolls over into the HL.

In the laboratory, however, infinite squeezing is awfully hard to come by. With current technology,[33–35] the expected situation is to sit somewhere between SNL and HL but a lot closer to the former than the latter. Recent analyses by a Caltech group, on exploiting squeezed light in LIGO, indicates a potential for about a one-order-of-magnitude improvement in a future LIGO upgrade.[36] Not the twelve orders of magnitude that was advertised above, but enough to allow the observatory to sample about 80 times the original volume of space for gravitational-wave sources. That, for LIGO, is a big deal.

23.4 "DIGITAL" APPROACHES

Squeezing is an "analog" approach to quantum optical interferometry, in that the average photon number and the degree of squeezing are continuous variables. There is another approach, exploiting discrete photon number and path-entangled optical states, where the photon number is fixed. There is a large body of literature on using entangled particles or photons in a Mach-Zehnder interferometer in order to beat the shot-noise limit. The first such proposal was by Bernard Yurke in the context of neutron interferometry.[37]

In 1986, the use of photon-number eigenstates, the so-called Fock states, to improve the interferometer phase sensitivity by Yurke et al.,[38] and independently by Yuen.[39] They showed that with a

suitably correlated input state the phase sensitivity can be improved to the one proportional to 1/*N*. The correlated input state—which we call the Yurke state—is given by

$$|\psi\rangle_Y = \left|\frac{N}{2}, \frac{N}{2}\right\rangle + \left|\frac{N}{2}+1, \frac{N}{2}-1\right\rangle \tag{11}$$

where the normalization constant of $1/\sqrt{2}$ has been dropped for convenience. The two numbers inside the brackets represent the number of photons entering the input ports A and B, respectively. As is the case of the squeezed state, the Fock-state approaches also require the light field incident upon *both* input ports of the MZI. If *N* photons entered into each input port of the interferometer in nearly equal numbers, then it is possible to obtain the asymptotic phase sensitivity scaling of order 1/*N* for large *N*, the Heisenberg-limit.[40]

In 1993, Hillery and Mlodinow showed that the SU(2)-squeezed minimum-uncertainty states can also be used for the input state of the Mach-Zehnder interferometer to achieve Heisenberg-limited sensitivity.[41] They called such a state the "intelligent" state. The intelligent state has a fixed number of photons. However, it consists of all the possible combination of the photon number distribution in the input modes such that

$$|\psi\rangle_{INT} = \sum_{k=0}^{N} C_{N,k} |N-k, k\rangle \tag{12}$$

where the probability amplitude $C_{N,k}$ varies with *N* and *k* as well as the degree of squeezing.[42] Although it contains a fixed number of photons, the exact form of the intelligent state depends on the degree of squeezing. Hence, we may put this approach in between the analog and the digital ones.

In 1993, on the other hand, Holland and Burnett proposed the use of the so-called dual-Fock states for the two input ports of the MZI in order to achieve Heisenberg-limited sensitivity.[43] The dual-Fock state has the same number of photons at each input mode such that the quantum state can be written as

$$|\psi\rangle_{DF} = \left|\frac{N}{2}, \frac{N}{2}\right\rangle \tag{13}$$

We see that the dual-Fock state has a much simpler form, compared to the Yurke state of Eq. (11). Why is it that this simple looking dual-Fock state had been overlooked in the earlier investigation? Using the dual-Fock state input, the measurement of the difference intensity does not yield any signal. In other words, the difference between the two output modes is always zero regardless of the amount of phase shift. This prevents the use of dual-Fock state for the interferometer input when the difference signal is measured, and because of that it was discarded, not overlooked. What Holland and Burnett suggested is to construct a probability distribution of the estimated phase, conditioned on the number of photons at each output port. Then, they showed, after sufficient number of trials, the probability distribution becomes narrow such that the phase uncertainty approaches to the 1/*N* Heisenberg limit. Heisenberg-limited phase measurements have also been proposed for Ramsey-type atom interferometry, where the degenerate Bose-Einstein condensates play the role of atomic dual-Fock states.[44,45]

The conditional probability distributions are generally used for parameter estimation. The phase is not a quantum mechanical observable (that is represented by a self-adjoint operator),[46] and it has to be estimated. Here, instead of direct inversion for the phase shift as performed with the difference-intensity measurement in Eq. (2), the probability distribution is constructed to infer the phase shift given the measurement results (photon counts at C and D ports separately).[47] The error in the phase estimation is then given by the variance of that distribution.

Such phase estimation protocols with conditional probabilities are applied to look for optimal quantum states of the input light field as well as the optimal output measurement schemes.[48–52] Given that the output detection does not have to be the conventional difference intensity measurement,

Sanders and Milburn proposed an ideal canonical measurement based on phase state projection.[48] Using such an ideal measurement strategy, Berry and Wiseman suggested an optimal state that minimizes the so-called Holevo phase variance.[49] They further developed an adaptive measurement scheme that approximates the ideal measurement scheme by Sanders and Milburn. With other measurement strategies such as coincident measurement that exploits the forth-order correlation, it is also possible to obtain the phase sensitivity beyond the shot-noise limit with the dual-Fock state.[53–57]

23.5 N00N STATE

Let us now consider a two-mode, path-entangled, photon-number state, commonly called the N00N state. The idea is that we have a fixed finite number of photons N that are either all in the upper mode A or all in the lower mode B, but we cannot tell—even in principle—which is which. The state of all up and none down is written $|\text{up}\rangle = |N\rangle_A|0\rangle_B$ and the state of all down and none up is similarly $|\text{down}\rangle = |0\rangle_A|N\rangle_B$. The notation indicates a product state of N photons either in A or B (but not both) such that

$$|\text{N00N}\rangle \equiv |\text{up}\rangle + |\text{down}\rangle = |N,0\rangle + |0,N\rangle \tag{14}$$

where a normalization constant of $1/\sqrt{2}$ has again been dropped for convenience. The N00N state was first discussed in 1989 by Barry Sanders, who was particularly interested in the Schrödinger-cat aspect and how that affected quantum decoherence.[58] It was rediscovered in the context of quantum imaging—particularly for quantum lithography[59]—to circumvent the Rayleigh diffraction limit. The N00N state has the interesting property that it is quantum entangled between the two modes and rigorously violates what is known as a Bell inequality for nonclassical correlations.[18]

To see why a N00N state has the magical properties—super sensitivity and super resolution, in particular—we take a brief look at the difference in behavior between a number state $|N\rangle$ and a coherent state $|\alpha\rangle$ in an MZI. When a coherent state passes through a phase shifter φ, such as depicted in Fig. 1, it picks up a phase of φ. This is a property of a classical monochromatic light beam that coherent states inherit quantum mechanically. However, number states are already highly nonclassical states to begin with. Their behavior in the phase shifter is radically different.

When a monochromatic beam of number states passes through a phase shifter, the phase shift is directly proportional to N, the number of photons. There is no n-dependence in the phase shift for the coherent state (n is the average number of photons). In terms of a unitary evolution of the state, the evolution for any photon state passing through a phase shifter φ is governed by

$$\hat{U}(\varphi) \equiv \exp(i\varphi\hat{n}) \tag{15}$$

where $\hat{n}$ is the photon number operator. The phase shift operator can be shown to have the following two different effects on coherent versus number states,[22]

$$\hat{U}_\varphi|\alpha\rangle = |e^{i\varphi}\alpha\rangle \tag{16a}$$

$$\hat{U}_\varphi|N\rangle = e^{iN\varphi}|N\rangle \tag{16b}$$

Notice that the phase shift for the coherent state is independent of number, but that there is an N dependence in the exponential for the number state. The number state then evolves in phase N times more rapidly than the coherent state. After the phase shifter the N00N state evolves into

$$|N,0\rangle + |0,N\rangle \rightarrow e^{iN\phi}|N,0\rangle + |0,N\rangle \tag{17}$$

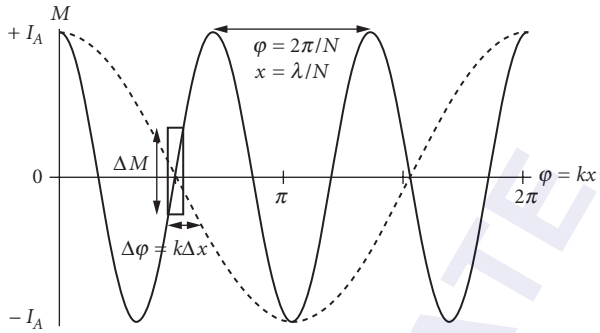

FIGURE 4 Comparison of the detection signal of a coherent state (dotted) and a N00N state (solid). The N00N state signal oscillates N times as fast as the coherent state and has maximum slope that is N times as steep ($N = 3$). The effect is as if the N00N state was composed of photons with an effective wavelength of λ/N instead of λ.

which is the origin of the quantum improvement phase sensitivity. If we now carry out an N-photon detecting analyzer (still different from the conventional difference intensity measurement), we obtain

$$M_{\text{N00N}}(\phi) = I_A \cos(N\phi) \tag{18}$$

which is the solid curve in Fig. 4. The N00N signal (solid) oscillates N times as fast as the coherent state (dotted). Two things are immediately clear. The distance between peaks goes from $\lambda \rightarrow \lambda / N$, which is the quantum lithography effect—we now beat the Rayleigh diffraction limit of λ by a factor of N. This sub-Rayleigh-diffraction-limit effect is now commonly called "super resolution." The slope of the curve at the horizontal axis crossing point gets larger as well, also by a factor of N. Now the minimal detectable phase, given by Eq. (4), consequently goes down. However, the signal M for this N00N state is not the same as for the coherent state scheme, as we are now counting photons N at a time. And it turns out then that $\Delta M_{\text{N00N}} = 1$ for the new scheme, and then Eq. (4) gives

$$\Delta\varphi_{\text{N00N}} = 1/N \tag{19}$$

which is precisely the Heisenberg limit of Eq. (8). This Heisenberg limit, or the beating of the shot-noise limit, is now commonly called "super sensitivity."

For $N = 1$ and $N = 2$ (low N00N) it is fairly straightforward to make such states with nonclassical sources of photon number states of either the form $|1\rangle_A|0\rangle_B$ or $|1\rangle_A|1\rangle_B$, that is one photon in mode A and none in B, or one photon in each of modes A and B. The standard approach utilizes spontaneous parametric down-conversion (SPDC), where an ultraviolet (UV) photon is down converted into a pair of number states. The effect of a simple beam splitter transformation on these states[22] is to convert them to low-N00N states, as follows:

$$|1\rangle_A|0\rangle_B \xrightarrow{\text{BS}} |1\rangle_{A'}|0\rangle_{B'} + |0\rangle_{A'}|1\rangle_{B'} \tag{20a}$$

$$|1\rangle_A|1\rangle_B \xrightarrow{\text{BS}} |2\rangle_{A'}|0\rangle_{B'} + |0\rangle_{A'}|2\rangle_{B'} \tag{20b}$$

where Eq. (20*a*) shows that a single photon cannot be split in two, and Eq. (20*b*) is illustrative of the more subtle Hong-Ou-Mandel effect—if two single photons are incident on a 50-50 beam splitter they will "stick" and both photons will go one way or both will go the other way, but you never get one photon out each port.[60]

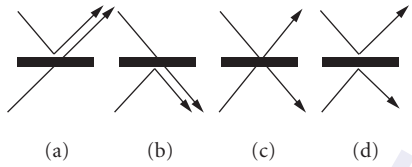

FIGURE 5 Four possibilities of the output, when sending a $|1\rangle_A|1\rangle_B$ state through a beam splitter. The diagrams (*c*) and (*d*) lead to the same final state, interfering destructively; (*c*) no phase acquired for transmission-transmission; and (*d*) a total of π phase shift for refection-reflection.

As depicted in Fig. 5, it is the probability amplitude for the transition $|1\rangle_A|1\rangle_B \xrightarrow{\text{BS}} |1\rangle_{A'}|1\rangle_{B'}$ that completely cancels out due to destructive interference. On the other hand, the probability amplitude for the transition indicated by Eq. (20*b*) adds up, due to constructive interference. So it is relatively easy, once you have a source of single photons, to create low-N00N states. The challenge is then, how to go to high N00N?

One of the first proposals for making high-N00N states was introduced in 2002 by Gerry and Campos, motivated by their applications in lithography and metrology.[61] The idea is to make a kind of quantum computing gate (a Fredkin gate) so that a single photon in the upper MZI-1 controls the phase shift in the lower MZI-2, as shown in Fig. 6.[62] A nonlinear optical material called a cross-Kerr phase shifter couples the two MZIs.

The strength of the cross-Kerr effect, however, is so tiny at the single photon level[63–65] that is it comes up 20 orders of magnitude too small for making a good N00N-state generator. There are two

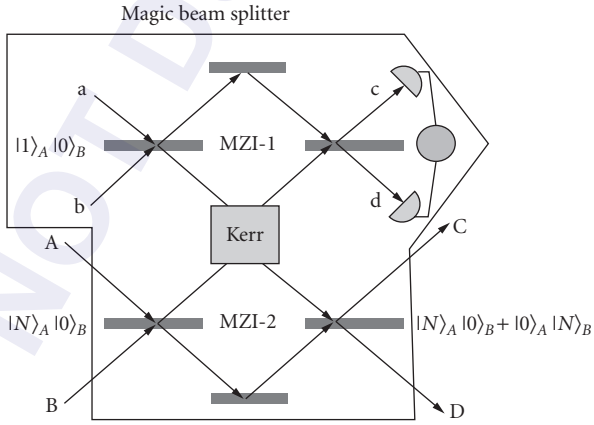

FIGURE 6 N00N-state generator by Gerry and Campos.[61] In the lower interferometer if *N* photons enter upper port A, they will always emerge in lower port D for a balanced Mach-Zehnder. Now if the lower interferometer is coupled to the upper one, via a strong cross-Kerr nonlinearity, a single photon in the lower branch of the upper interferometer causes a π phase shift, directing all *N* photons to emerge out port C. If the upper device is also an interferometer, one can arrange a superposition of zero and one photons in the Kerr box, giving rise to a superposition of a 0 and π phase shift. This Kerr superposition results in the N00N state, the number state superposition in the output modes C and D of the lower interferometer.

well-known ways to boost the Kerr effect: put in an optical micro-cavity around the atoms in the Kerr material,[66] or coherently lock the atoms together in an approach known as electromagnetically induced transparency.[67–69] Both roads have their complication and technical challenges. There is, however, a third path.

Here is where the universe of quantum-optical-metrology took some hints from the world of quantum-optical computing. The Gerry-Campos idea is based on an optical Fredkin gate, a sort of a single photon transistor. If such a device could be made easily, it would be a quick and easy road to the all-optical quantum computer. In 2001, Knill, LaFlamme, and Milburn (KLM) proposed an all-optical, digital, scheme for quantum computing that exploited discrete entangled photon states distributed over the modes of an optical interferometer.[70] This discovery ignited a huge international collaborative research and development program on the optical quantum computer. In this scheme, the Kerr nonlinearity is replaced with additional ancillary, mirrors, phase shifters, beam splitters and—most importantly—detectors. The KLM idea is that the detection process in the ancillary devices induces an effective Kerr nonlinearity.[71]

While still not perfect, the effective Kerr produced this way can be much stronger than the usual Kerr materials. So instead of working one time in 10^{20}, our new device works one time in 10, which is a 19-order-of-magnitude improvement. Our group, then at the NASA Jet Propulsion Laboratory, proposed the first high-N00N generation scheme based on all linear-optical devices.[72] The idea is to make the upper and lower mirrors into additional beam splitters and to put detectors just past them. Such a N00N-generating scheme can be stacked to produce N00N states with N that is arbitrarily high.[73,74] However, at least initially, all such schemes produced N00N states with a probability that scaled exponentially badly as N increased. The larger and larger you make N, the far more likely it is that you get only non-N00N states. Recently there has been a great deal of work on the development of schemes that produce N00N "efficiently."[75–77] So we are well along the digital quantum-computer-paved road to super resolution and super sensitivity—at least in theory.

The demonstration of the doubling of the effective wavelength was made in 1999,[78] and a proof-of-principle demonstration of the super-resolving application to sub-Rayleigh lithography was carried out by the group of Yanhua Shih in 2001.[79] Then in 2004 the $N = 2$ barrier was breached; the group of Steinberg demonstrated super resolution for $N = 3$, and, for $N = 4$, the group of Zeilinger demonstrated it as well.[80–82] These 2004 experiments exploited the *effective* Kerr nonlinearities extracted from the photodetection process. While not "optical" metrology, there has been a lot of work on precision frequency measurements with trapped ions. In particular, the so-called maximally entangled states have been exploited to show super resolution and super sensitivity.[83–89]

Then, in 2007, the group of Andrew White demonstrated $N = 6$ super resolution in a process that used classical photons with a nonlinear N-photon detection scheme.[86] While interesting, such an approach can never achieve super sensitivity due to its semiclassical nature, as the authors pointed out. The first demonstration of both super sensitivity and super resolution in a single experiment also appeared in late 2007 in a collaborative Japanese and UK experiment.[87] This was the first experiment to beat the shot-noise limit, using N00N states, with $N > 2$. However, the results still were not quite at the Heisenberg limit. It lies between the shot-noise limit and the Heisenberg limit.

Another Australian collaboration, of the groups of Geoffrey Pryde and Howard Wiseman, carried out an experiment that produced N single-photon states of the form of Eq. (20*a*), and recycled them through the MZI in a feedback-loop implementation of a quantum computing protocol known as the Kitaev phase estimation algorithm[88–90] with the effective $N = 378$. The idea is that instead of making such a large N00N state, they make 378 passes through the interferometer, with feedback, using the low $N = 1$ N00N state. Since all N00N states are equally entangled and violate a Bell inequality for any nonzero value of N, the trade-off is that of a complicated N00N-state generating scheme with a less complicated single-photon detection scheme with some electronic feedback.[18] Such a protocol is, surprisingly, easier to implement than the high-N00N approach, and arrives at the same performance in sensitivity scaling, the Heisenberg limit. This Australian experiment, once again, illustrates the close connection between quantum optical computing and quantum metrology, as it achieves super sensitivity by running a quantum computational algorithm. A quantum computer is nothing more than a (complicated) quantum sensor, and hence one can design a quantum sensor by exploiting ideas from quantum computing.

23.6 QUANTUM IMAGING

Quantum imaging is a new subfield of quantum optics that exploits quantum correlations, such as quantum entanglement of the electromagnetic field, in order to image objects with a resolution (or other imaging criteria) that is beyond what is possible in classical optics. Examples of quantum imaging are quantum ghost imaging, quantum lithography, and sub-Rayleigh imaging.[91,92] In 2000, it was pointed out that N00N states had the capability to beat the Rayleigh diffraction limit by a factor of N. This super-resolution feature is due to the high-frequency oscillations of the N00N state in the interferometer, as illustrated in Fig. 4. For the quantum lithography application, the idea is to realize that if one has an N-photon absorbing material, used as a lithographic resist, then these high-frequency oscillations are written onto the material in real space and are not just a trace on an oscilloscope. Mathematically, the N-photon absorption and the N-photon detection process have a similar structure, that is,

$$\langle \mathrm{N00N}|(\hat{a}^{\dagger})^{N}(\hat{a})^{N}|\mathrm{N00N}\rangle = 1+\cos(N\varphi) \tag{21}$$

where $\hat{a}$ and $\hat{a}^{\dagger}$ are the mode annihilation and creation operators. From Fig. 4, we see in the solid curve this oscillates N times faster than if we were using single photons, or coherent light, as in the dotted curve. Recall that, for our MZI, we have $\varphi = kx = 2\pi x/\lambda$, where x is the displacement between the two arms. For lithography x is also the distance measured on the photographic plate or lithographic resist. If we compare the classical resolution to the N00N resolution we may write, $\varphi_{\mathrm{N00N}} = N\varphi_{\mathrm{classical}}$, which we can solve for

$$\lambda_{\mathrm{N00N}} = \frac{\lambda_{\mathrm{classical}}}{N} \tag{22}$$

Written this way, we can say the effective wavelength of the N photons bundled together N at a time into the N00N state is N times smaller than the classical wavelength. This is another way to understand the super-resolution effect. The N entangled photons conspire to behave as a single classical photon of a wavelength smaller by a factor of N.[93] Since the Rayleigh diffraction limit for lithography is couched in terms of the minimal resolvable distance $\Delta x = \lambda_{\mathrm{classical}}$, then we have $\Delta x_{\mathrm{N00N}} = \lambda_{\mathrm{N00N}} = \lambda_{\mathrm{classsical}}/N$.

Another interesting application is so-called "ghost imaging." This effect exploits the temporal and spatial correlations of photon pairs, also from spontaneous parametric down conversion, to image an object in one branch of the interferometer by looking at correlations in the coincidence counts of the photons.[94] There is no image in the single-photon counts in either arm, but only in the double photon counts in both arms. The image is in a sense stored nonlocally.

A particular application of this more general idea of quantum imaging has been seen in quantum coherence tomography.[95] In this experiment, they image a phase object placed in one arm of the interferometer, using entangled photons in an $N = 2$ N00N state. They see not only the factor of two improvement in resolving power, predicted by Eq. (22), but also as a bonus they get a dispersion cancellation in the imaging system due to frequency entanglement between the photons.

Current experiments on N00N states have used rather dim sources of entangled photons, from UV pumped $\chi^{(2)}$ crystals in a spontaneous parametric down conversion (SPDC) setup.[96] For bright sources of N00N states, one can turn to optical parametric amplifiers (OPA), which is the same setup as SPDC, but in which we crank up the pump power.[97] In this regime of high gain, the creation of entangled photon pairs of the form of Eq. (13) occurs, but we have many, many pairs and the output can be written

$$|\mathrm{OPA}\rangle = \sum_{n=0}^{\infty} a_n |n\rangle_A |n\rangle_B \tag{23}$$

where the probability of a large twin-number state $|N\rangle_A|N\rangle_B$ is given by $|a_N|^2$, which can be quite large in the limit of high pump powers. Passing the OPA state through a 50-50 beam splitter gives the generalized Hong-Ou-Mandel effect term by term, so that we get,

$$|\text{OPA}\rangle \xrightarrow{\text{BS}} \sum_{n=0}^{\infty}\sum_{m=0}^{n} c_{nm}|2n-2m\rangle|2m\rangle \tag{24}$$

where again the coefficients c_{nm} can be quite large for high pump powers. Taking the term $n = 1$ we immediately get the $N = 2$ N00N state from the regular Hong-Ou-Mandel effect. For larger $n \geq 1$, we find that there is always a large N00N component along with the non-N00N. For an $N = 2$ absorber, the visibility of the $N = 2$ N00N oscillations was predicted to saturate at a visibility of 20 percent.[98,99] This 20 percent visibility is more than enough to exploit for lithography and imaging, and has recently been measured in a recent experiment in the group of DeMartini in Rome,[100] in collaboration with our activity at Louisiana State University.

Current commercial lithography exploits extreme ultraviolet light of around 100 nm and plans are to go to x-ray in the future. The problem is that the lithography system for x-ray cannot use the same lenses, mirrors, and other imaging devices as did the optical system and so each reduction in wavelength involves a huge cost in technology and hardware investment. But what if we could etch 50-nm-sized features using 500-nm wavelength photons by exploiting quantum entanglement? This is the promise of quantum lithography. However, no real demonstration of quantum lithography has been had, so far, due to the N-photon resist problem.[101]

23.7 TOWARD QUANTUM REMOTE SENSING

Improvements in optical metrology and imaging have a natural application in the realm of optical remote sensing, such as in coherent optical laser interferometric radar (LIDAR) or in sensor miniaturization.[102,103] On the other hand, the group of Lloyd at MIT proposed a quantum optical clock synchronization protocol that eliminates the timing jitter of optical pulses that are transmitted through a fluctuating atmosphere.[104] These atmospheric fluctuations are currently the limiting source of noise in the global positioning system. Of course, when the N00N states propagating over distances of kilometers through the atmosphere, then photon scattering and loss and other issues such as atmospheric turbulence become an issue that are not apparent in a table top quantum interferometry demonstration.

The primary issue associated with photon loss is that the visibility of the interference pattern decreases, and that of the N00N state pattern decreases more rapidly than that of the single photon or coherent state interferometer. Hence, when the loss is sufficiently high, the slope of the N00N oscillations in Fig. 4 decreases to the point that, as far as super sensitivity is concerned, we do worse with N00N states than with either single photons or coherent states.[105,106] There are, however, Fock states that offer super resolution and sensitivity better than shot noise that degrade less quickly under loss than N00N states.[107] What we've termed M&M states, of the form

$$|m, m'\rangle \equiv |m, m'\rangle + |m', m\rangle \tag{25}$$

(where a normalization constant of $1/\sqrt{2}$ has again been dropped for convenience) contain a trade-off of being more resilient to environmental decoherence, but having a greater minimum phase uncertainty of $1/(m-m')$.

In quantum optics, the photon loss (as well as the detector inefficiency) is modeled by a series of beam splitters.[25] In doing so, we first need to enlarge the Hilbert space to include the modes that represent the scattered photons and then, after the scattering, trace out those modes.[107] Here, instead of going into details, we use a simple (not necessarily correct) phase-shifter model and give a brief estimation of the loss effect. Consider Eq. (16), describing how coherent states and number states

behave upon passing through a phase shifter. The photon loss might be incorporated in the phase shifter by making the substitution $\varphi \to \varphi + i\gamma$, where γ is the rate at which photons are absorbed. We see then the effect of this loss in Eq. (16) is to produce an exponential loss factor that depends on N, for number states

$$|\alpha\rangle \xrightarrow{\varphi+i\gamma} |e^{-\gamma} e^{i\varphi}\alpha\rangle \tag{26a}$$

$$|N\rangle \xrightarrow{\varphi+i\gamma} e^{-N\gamma} e^{iN\varphi} |N\rangle \tag{26b}$$

Typically, we have $\gamma = gL$, where g is the loss per unit length and L the distance traveled through the lossy medium. The exponential dependence of the loss in the coherent (classical) state of Eq. (26*a*) is called Beer's law for optical absorption. We see that for N-photon number states, Eq. (26*b*), we have a super-exponential behavior, or what we call super-Beer's law. It implies that the N00N states are much more fragile in a lossy environment than a classical coherent state.

Of course, for the number states, such a simple phase-shifter model fails to describe the quantum states of the lesser number of photons, and we need to carry out the detailed analysis mentioned above. Will we then be able to overcome such fragility of the entangled states and achieve super sensitivity in remote sensing? We may have to seek an answer from the field of quantum compuing—the tools to fight against decoherence such as quantum error correction or decoherence free subspace.[108,109]

Due to its "digital" nature, the entangled-number-state approach has recently benefited tremendously from an influx of ideas and experimental techniques originally developed in the context of all-optical "digital" quantum computing.[110] The idea is that an optical quantum computer is a giant optical quantum interferometer, where the quantum entanglement between photons is exploited to carry out mathematical calculations, which are impossible on any classical computer. However, in the proposed quantum interferometers the entanglement is exploited to make ultimate precise measurements not possible with any classical optical machine. The optical quantum computer can be turned into an optical quantum interferometric measuring device, and vice versa. Theoretical and experimental tricks, devised for the former, can be exploited in the latter. Since, for over the past 10 years, a lot of efforts have gone into the development of quantum computers, we are now able to leverage this research for quantum optical metrology, imaging, and sensing.

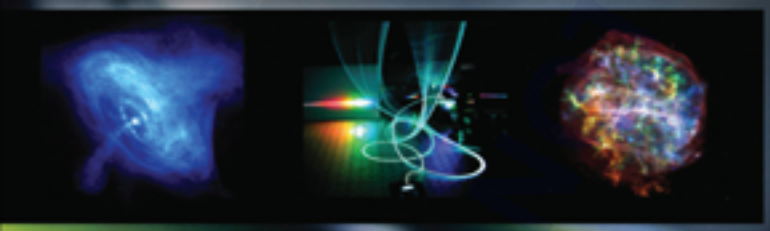
HANDBOOK OF OPTICS

Volume V

Atmospheric Optics, Modulators, Fiber Optics, X-Ray and Neutron Optics



Editor-in-Chief:
Michael Bass

Associate Editors:
Casimer M. DeCusatis
Jay M. Enoch
Vasudevan Lakshminarayanan
Guifang Li
Carolyn MacDonald
Virendra N. Mahajan
Eric Van Stryland

OSA

HANDBOOK OF OPTICS

ABOUT THE EDITORS

Editor-in-Chief: Dr. Michael Bass is professor emeritus at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

Associate Editors:
Dr. Casimer M. DeCusatis is a distinguished engineer and technical executive with IBM Corporation, Poughkeepsie, New York.

Dr. Jay M. Enoch is dean emeritus and professor at the School of Optometry at the University of California, Berkeley.

Dr. Vasudevan Lakshminarayanan is professor of Optometry, Physics, and Electrical Engineering at the University of Waterloo, Ontario, Canada.

Dr. Guifang Li is a professor at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

Dr. Carolyn MacDonald is professor and chair of physics at the University at Albany, SUNY, and the director of the Albany Center for X-Ray Optics.

Dr. Virendra N. Mahajan is a distinguished scientist at The Aerospace Corporation.

Dr. Eric Van Stryland is a professor at CREOL, The College of Optics and Photonics, University of Central Florida, Orlando, Florida.

COVER ILLUSTRATIONS

Boadband supercontinuum. Generated in a photonic crystal fiber using a mode-locked Ti:Sapphire laser as pump source. The spectrum is much broader than seen in the photograph, extending from 400 nm to beyond 2 μm. (*Photo courtesy of the Optoelectronics Group, University of Bath.*)

Supernova remnant. A Chandra X-Ray Space Telescope image of the supernova remnant G292.0+1.8. The colors in the image encode the X-ray energies emitted by the supernova remnant; the center of G292.0+1.8 contains a region of high energy X-ray emission from the magnetized bubble of high-energy particles that surrounds the pulsar, a rapidly rotating neutron star that remained behind after the original, massive star exploded. (*This image is from NASA/CXC/Penn State/S.Park et al. and more detailed information can be found on the Chandra website: http://chandra.harvard.edu/photo/2007/g292/.*)

Crab Nebula. A Chandra X-Ray Space Telescope image of the Crab Nebula—the remains of a nearby supernova explosion first seen on Earth in 1054 AD. At the center of the bright nebula is a rapidly spinning neutron star, or pulsar, that emits pulses of radiation 30 times a second. (*This image is from NASA/CXC/ASU/J.Hester et al. and more detailed information can be found on the Chandra website: http://chandra.harvard.edu/photo/2002/0052/.*)

BRIEF CONTENTS OF ALL VOLUMES

VOLUME I. GEOMETRICAL AND PHYSICAL OPTICS, POLARIZED LIGHT, COMPONENTS AND INSTRUMENTS

VOLUME II. DESIGN, FABRICATION, AND TESTING; SOURCES AND DETECTORS; RADIOMETRY AND PHOTOMETRY

PART 1. DESIGN

PART 2. FABRICATION

PART 3. TESTING

PART 4. SOURCES

PART 5. DETECTORS

PART 6. IMAGING DETECTORS

PART 7. RADIOMETRY AND PHOTOMETRY

VOLUME III. VISION AND VISION OPTICS

VOLUME IV. OPTICAL PROPERTIES OF MATERIALS, NONLINEAR OPTICS, QUANTUM OPTICS

PART 1. PROPERTIES

PART 5. X-RAY AND NEUTRON OPTICS

Subpart 5.1. Introduction and Applications

Subpart 5.2. Refractive and Interference Optics

Subpart 5.3. Reflective Optics

EDITORS' PREFACE

The third edition of the *Handbook of Optics* is designed to pull together the dramatic developments in both the basic and applied aspects of the field while retaining the archival, reference book value of a handbook. This means that it is much more extensive than either the first edition, published in 1978, or the second edition, with Volumes I and II appearing in 1995 and Volumes III and IV in 2001. To cover the greatly expanded field of optics, the *Handbook* now appears in five volumes. Over 100 authors or author teams have contributed to this work.

Volume I is devoted to the fundamentals, components, and instruments that make optics possible. Volume II contains chapters on design, fabrication, testing, sources of light, detection, and a new section devoted to radiometry and photometry. Volume III concerns vision optics only and is printed entirely in color. In Volume IV there are chapters on the optical properties of materials, nonlinear, quantum and molecular optics. Volume V has extensive sections on fiber optics and x ray and neutron optics, along with shorter sections on measurements, modulators, and atmospheric optical properties and turbulence. Several pages of color inserts are provided where appropriate to aid the reader. A purchaser of the print version of any volume of the *Handbook* will be able to download a digital version containing all of the material in that volume in PDF format to one computer (see download instructions on bound-in card). The combined index for all five volumes can be downloaded from www.HandbookofOpticsOnline.com.

It is possible by careful selection of what and how to present that the third edition of the *Handbook* could serve as a text for a comprehensive course in optics. In addition, students who take such a course would have the *Handbook* as a career-long reference.

Topics were selected by the editors so that the *Handbook* could be a desktop (bookshelf) general reference for the parts of optics that had matured enough to warrant archival presentation. New chapters were included on topics that had reached this stage since the second edition, and existing chapters from the second edition were updated where necessary to provide this compendium. In selecting subjects to include, we also had to select which subjects to leave out. The criteria we applied were: (1) was it a specific application of optics rather than a core science or technology and (2) was it a subject in which the role of optics was peripheral to the central issue addressed. Thus, such topics as medical optics, laser surgery, and laser materials processing were not included. While applications of optics are mentioned in the chapters there is no space in the *Handbook* to include separate chapters devoted to all of the myriad uses of optics in today's world. If we had, the third edition would be much longer than it is and much of it would soon be outdated. We designed the third edition of the *Handbook of Optics* so that it concentrates on the principles of optics that make applications possible.

Authors were asked to try to achieve the dual purpose of preparing a chapter that was a worthwhile reference for someone working in the field and that could be used as a starting point to become acquainted with that aspect of optics. They did that and we thank them for the outstanding results seen throughout the *Handbook*. We also thank Mr. Taisuke Soda of McGraw-Hill for his help in putting this complex project together and Mr. Alan Tourtlotte and Ms. Susannah Lehman of the Optical Society of America for logistical help that made this effort possible.

We dedicate the third edition of the *Handbook of Optics* to all of the OSA volunteers who, since OSA's founding in 1916, give their time and energy to promoting the generation, application, archiving, and worldwide dissemination of knowledge in optics and photonics.

PREFACE TO VOLUME V

Volume V begins with Measurements, Atmospheric Optics, and Optical Modulators. There are chapters on scatterometers, spectroscopic measurements, transmission through the atmosphere, imaging through turbulence, and adaptive optics to overcome distortions as well as chapters on electro- and acousto-optic modulators and liquid crystal spatial light modulators. These are followed by the two main parts of this volume—Fiber Optics and X-Ray and Neutron Optics.

Optical fiber technology is truly an interdisciplinary field, incorporating aspects of solid-state physics, material science, and electrical engineering, among others. In the section on fiber optics, we introduce the fundamentals of optical fibers and cable assemblies, optical connectors, light sources, detectors, and related components. Assembly of the building blocks into optical networks required discussion of the unique requirements of digital versus analog links and telecommunication versus data communication networks. Issues such as optical link budget calculations, dispersion- or attenuation-limited links, and compliance with relevant industry standards are all addressed. Since one of the principle advantages of fiber optics is the ability to create high-bandwidth, long-distance interconnections, we also discuss the design and use of optical fiber amplifiers for different wavelength transmission windows. This leads to an understanding of the different network components which can be fabricated from optical fiber itself, such as splitters, combiners, fiber Bragg gratings, and other passive optical networking elements. We then provide a treatment of other important devices, including fiber sensors, fibers optimized for use in the infrared, micro-optic components for fiber networks and fiber lasers. Note that micro-optics for other applications are covered in Volume I of this *Handbook*. The physics of semiconductor lasers and photodetectors are presented in Volume II. Applications such as time or wavelength-division multiplexing networks provide their own challenges and are discussed in detail. High optical power applications lead us to a consideration of nonlinear optical fiber properties. Advanced topics for high speed, future networks are described in this section, including polarization mode dispersion; readers interested in the physical optics underlying dispersion should consult Volume I of this *Handbook*. This section includes chapters on photonic crystal fibers (for a broader treatment of photonic bandgap materials, see Volume IV) and on the growing applications of optical fiber networks.

Part 5 of this volume discusses a variety of X-Ray and Neutron Optics and their use in a wide range of applications. Part 5.1 is an introduction to the use and properties of x rays. It begins with a short chapter summarizing x-ray interactions and optics, followed by a discussion of coherence effects, and then illustrations of application constraints to the use of optics in seven applications, ranging from materials analysis to medicine, astronomy, and chip manufacturing. Because modeling is an important tool for both optics development and system design, Part 5.1 continues with a discussion of optics simulations, followed by tables of materials properties in the x-ray regime. Parts 5.2 and 5.3 are devoted to the discussion of the three classes of x-ray optics. Part 5.2 covers refractive, interference, and diffractive optics, including gratings, crystals (flat, bent, and polarizing), zone plates, and Laue lenses. It also includes a discussion of multilayer coatings, which are based on interference, but often added to reflective x-ray optics. Reflective optics is the topic of Part 5.3. Since reflective optics in the x-ray regime are used primarily in grazing incidence, the first three chapters of Part 5.3 cover the theory of image formation, aberrations, and metrology of grazing incidence mirrors. This is followed with descriptions of mirrors for astronomy and microscopy, adaptive optics for high heat load synchrotron beam lines, glass capillary reflective optics, also generally used for beam lines, and array optics such as multifoils, pore optics, and polycapillaries. The best choice of optic for a particular function depends on the application requirements, but is also influenced by the properties of the available sources and detectors. Part 5.4 describes six different types of x-ray sources. This is followed by Part 5.5, which includes an introduction to detectors and in-depth

discussions of imaging and spectral detectors. Finally, Part 5.6 describes the similarities and differences in the use of comparable optics technologies with neutrons.

In 1998, Walter Gibson designed the expansion of the x-ray and neutron section of the second edition of the *Handbook* from its original single chapter form. The third edition of this section is dedicated to his memory.

Guifang Li, Casimer M. DeCusatis, Virendra N. Mahajan, and Carolyn MacDonald

In Memoriam Walter Maxwell Gibson *(November 11, 1930–May 15, 2009)*

After a childhood in Southern Utah working as a sheepherder and stunt rider, Walt received his Ph.D. in nuclear chemistry under Nobel Laureate Glen Seaborg in 1956. He then spent 20 years at Bell Labs, where he did groundbreaking research in semiconductor detectors, particle-solid interactions, and in the development of ion beam techniques for material analysis. His interest in materials analysis and radiation detection naturally led him to an early and ongoing interest in developing x-ray analysis techniques, including early synchrotron beam line development. In 1970, he was named a fellow of the American Physical Society. In 1976, Walter was invited to chair the physics department of the University at Albany, SUNY (where he was fond of noting that they must have been confused as he had been neither an academic nor a physicist). He remained with the department for more than 25 years and was honored with the university's first named professorship, the James W. Corbett Distinguished Service Professor of Physics, in 1998. He later retired from the university to become the full-time chief technical officer of X-Ray Optical Systems, Inc., which he had cofounded coincident with UAlbany's Center for X-Ray Optics in 1991. He was the author of more than 300 technical articles and mentor to more than 48 doctoral graduates.

Walter Gibson's boundless energy, enthusiasm, wisdom, caring, courage, and vision inspired multiple generations of scientists.

GLOSSARY AND FUNDAMENTAL CONSTANTS

Introduction

This glossary of the terms used in the *Handbook* represents to a large extent the language of optics. The symbols are representations of numbers, variables, and concepts. Although the basic list was compiled by the author of this section, all the editors have contributed and agreed to this set of symbols and definitions. Every attempt has been made to use the same symbols for the same concepts throughout the entire *Handbook*, although there are exceptions. Some symbols seem to be used for many concepts. The symbol α is a prime example, as it is used for absorptivity, absorption coefficient, coefficient of linear thermal expansion, and more. Although we have tried to limit this kind of redundancy, we have also bowed deeply to custom.

Units

The abbreviations for the most common units are given first. They are consistent with most of the established lists of symbols, such as given by the International Standards Organization ISO[1] and the International Union of Pure and Applied Physics, IUPAP.[2]

Prefixes

Similarly, a list of the numerical prefixes[1] that are most frequently used is given, along with both the common names (where they exist) and the multiples of ten that they represent.

Fundamental Constants

The values of the fundamental constants[3] are listed following the sections on SI units.

Symbols

The most commonly used symbols are then given. Most chapters of the *Handbook* also have a glossary of the terms and symbols specific to them for the convenience of the reader. In the following list, the symbol is given, its meaning is next, and the most customary unit of measure for the quantity is presented in brackets. A bracket with a dash in it indicates that the quantity is unitless. Note that there is a difference between units and dimensions. An angle has units of degrees or radians and a solid angle square degrees or steradians, but both are pure ratios and are dimensionless. The unit symbols as recommended in the SI system are used, but decimal multiples of some of the dimensions are sometimes given. The symbols chosen, with some cited exceptions, are also those of the first two references.

RATIONALE FOR SOME DISPUTED SYMBOLS

The choice of symbols is a personal decision, but commonality improves communication. This section explains why the editors have chosen the preferred symbols for the *Handbook*. We hope that this will encourage more agreement.

Fundamental Constants

It is encouraging that there is almost universal agreement for the symbols for the fundamental constants. We have taken one small exception by adding a subscript B to the k for Boltzmann's constant.

Mathematics

We have chosen i as the imaginary almost arbitrarily. IUPAP lists both i and j, while ISO does not report on these.

Spectral Variables

These include expressions for the wavelength λ, frequency ν, wave number σ, ω for circular or radian frequency, k for circular or radian wave number and dimensionless frequency x. Although some use f for frequency, it can be easily confused with electronic or spatial frequency. Some use $\tilde{\nu}$ for wave number, but, because of typography problems and agreement with ISO and IUPAP, we have chosen σ; it should not be confused with the Stefan-Boltzmann constant. For spatial frequencies we have chosen ξ and η, although f_x and f_y are sometimes used. ISO and IUPAP do not report on these.

Radiometry

Radiometric terms are contentious. The most recent set of recommendations by ISO and IUPAP are L for radiance [$Wcm^{-2}sr^{-1}$], M for radiant emittance or exitance [Wcm^{-2}], E for irradiance or incidance [Wcm^{-2}], and I for intensity [Wsr^{-2}]. The previous terms, W, H, N, and J, respectively, are still in many texts, notably Smith[4] and Lloyd[5] but we have used the revised set, although there are still shortcomings. We have tried to deal with the vexatious term *intensity* by using *specific intensity* when the units are $Wcm^{-2}sr^{-1}$, *field intensity* when they are Wcm^{-2}, and *radiometric intensity* when they are Wsr^{-1}.

There are two sets to terms for these radiometric quantities, which arise in part from the terms for different types of reflection, transmission, absorption, and emission. It has been proposed that the *ion* ending indicate a process, that the *ance* ending indicate a value associated with a particular sample, and that the *ivity* ending indicate a generic value for a "pure" substance. Then one also has reflectance, transmittance, absorptance, and emittance as well as reflectivity, transmissivity, absorptivity, and emissivity. There are now two different uses of the word emissivity. Thus the words *exitance, incidence,* and *sterance* were coined to be used in place of emittance, irradiance, and radiance. It is interesting that ISO uses radiance, exitance, and irradiance whereas IUPAP uses radiance excitance [*sic*], and irradiance. We have chosen to use them both, i.e., emittance, irradiance, and radiance will be followed in square brackets by exitance, incidence, and sterance (or vice versa). Individual authors will use the different endings for transmission, reflection, absorption, and emission as they see fit.

We are still troubled by the use of the symbol E for irradiance, as it is so close in meaning to electric field, but we have maintained that accepted use. The spectral concentrations of these quantities, indicated by a wavelength, wave number, or frequency subscript (e.g., L_λ) represent partial differentiations; a subscript q represents a photon quantity; and a subscript ν indicates a quantity normalized to the response of the eye. Thereby, L_ν is luminance, E_ν illuminance, and M_ν and I_ν luminous emittance and luminous intensity. The symbols we have chosen are consistent with ISO and IUPAP.

The refractive index may be considered a radiometric quantity. It is generally complex and is indicated by $\tilde{n} = n - ik$. The real part is the relative refractive index and k is the extinction coefficient. These are consistent with ISO and IUPAP, but they do not address the complex index or extinction coefficient.

Optical Design

For the most part ISO and IUPAP do not address the symbols that are important in this area.

There were at least 20 different ways to indicate focal ratio; we have chosen FN as symmetrical with NA; we chose f and efl to indicate the effective focal length. Object and image distance, although given many different symbols, were finally called s_o and s_i since s is an almost universal symbol for distance. Field angles are θ and ϕ; angles that measure the slope of a ray to the optical axis are u; u can also be sin u. Wave aberrations are indicated by W_{ijk}, while third-order ray aberrations are indicated by σ_i and more mnemonic symbols.

Electromagnetic Fields

There is no argument about **E** and **H** for the electric and magnetic field strengths, Q for quantity of charge, ρ for volume charge density, σ for surface charge density, etc. There is no guidance from Refs. 1 and 2 on polarization indication. We chose $\perp$ and $\|$ rather than p and s, partly because s is sometimes also used to indicate scattered light.

There are several sets of symbols used for reflection transmission, and (sometimes) absorption, each with good logic. The versions of these quantities dealing with field amplitudes are usually specified with lower case symbols: r, t, and a. The versions dealing with power are alternately given by the uppercase symbols or the corresponding Greek symbols: R and T versus ρ and τ. We have chosen to use the Greek, mainly because these quantities are also closely associated with Kirchhoff's law that is usually stated symbolically as $\alpha = \epsilon$. The law of conservation of energy for light on a surface is also usually written as $\alpha + \rho + \tau = 1$.

Base SI Quantities

length	m	meter
time	s	second
mass	kg	kilogram
electric current	A	ampere
temperature	K	kelvin
amount of substance	mol	mole
luminous intensity	cd	candela

Derived SI Quantities

energy	J	joule
electric charge	C	coulomb
electric potential	V	volt
electric capacitance	F	farad
electric resistance	Ω	ohm
electric conductance	S	siemens
magnetic flux	Wb	weber
inductance	H	henry
pressure	Pa	pascal
magnetic flux density	T	tesla
frequency	Hz	hertz
power	W	watt
force	N	newton
angle	rad	radian
angle	sr	steradian

Prefixes

Symbol	*Name*	*Common name*	*Exponent of ten*
F	exa		18
P	peta		15
T	tera	trillion	12
G	giga	billion	9
M	mega	million	6
k	kilo	thousand	3
h	hecto	hundred	2
da	deca	ten	1
d	deci	tenth	–1
c	centi	hundredth	–2
m	milli	thousandth	–3
μ	micro	millionth	–6
n	nano	billionth	–9
p	pico	trillionth	–12
f	femto		–15
a	atto		–18

Constants

c	speed of light vacuo [299792458 ms^{-1}]
c_1	first radiation constant = $2\pi c^2 h = 3.7417749 \times 10^{-16}$ [Wm^2]
c_2	second radiation constant = hc/k = 0.014838769 [mK]
e	elementary charge [$1.60217733 \times 10^{-19}$ C]
g_n	free fall constant [9.80665 ms^{-2}]
h	Planck's constant [$6.6260755 \times 10^{-34}$ Ws]
k_B	Boltzmann constant [1.380658×10^{-23} JK^{-1}]
m_e	mass of the electron [$9.1093897 \times 10^{-31}$ kg]
N_A	Avogadro constant [6.0221367×10^{23} mol^{-1}]
R_∞	Rydberg constant [10973731.534 m^{-1}]
ϵ_o	vacuum permittivity [$\mu_o^{-1} c^{-2}$]
σ	Stefan-Boltzmann constant [5.67051×10^{-8} Wm^{-1} K^{-4}]
μ_o	vacuum permeability [$4\pi \times 10^{-7}$ NA^{-2}]
μ_B	Bohr magneton [$9.2740154 \times 10^{-24}$ JT^{-1}]

General

B	magnetic induction [Wbm^{-2}, kgs^{-1} C^{-1}]
C	capacitance [f, C^2 s^2 m^{-2} kg^{-1}]
C	curvature [m^{-1}]
c	speed of light in vacuo [ms^{-1}]
c_1	first radiation constant [Wm^2]
c_2	second radiation constant [mK]
D	electric displacement [Cm^{-2}]
E	incidance [irradiance] [Wm^{-2}]
e	electronic charge [coulomb]
E_v	illuminance [lux, lmm^{-2}]
E	electrical field strength [Vm^{-1}]
E	transition energy [J]
E_g	band-gap energy [eV]
f	focal length [m]
f_c	Fermi occupation function, conduction band
f_v	Fermi occupation function, valence band

FN	focal ratio (f/number) [—]
g	gain per unit length [m^{-1}]
g_{th}	gain threshold per unit length [m^1]
H	magnetic field strength [Am^{-1}, Cs^{-1} m^{-1}]
h	height [m]
I	irradiance (see also E) [Wm^{-2}]
I	radiant intensity [Wsr^{-1}]
I	nuclear spin quantum number [—]
I	current [A]
i	$\sqrt{-1}$
Im()	imaginary part of
J	current density [Am^{-2}]
j	total angular momentum [kg m^2 s^{-1}]
$J_1()$	Bessel function of the first kind [—]
k	radian wave number $=2\pi/\lambda$ [rad cm^{-1}]
k	wave vector [rad cm^{-1}]
k	extinction coefficient [—]
L	sterance [radiance] [Wm^{-2} sr^{-1}]
L_v	luminance [cdm^{-2}]
L	inductance [h, m^2 kg C^2]
L	laser cavity length
L, M, N	direction cosines [—]
M	angular magnification [—]
M	radiant exitance [radiant emittance] [Wm^{-2}]
m	linear magnification [—]
m	effective mass [kg]
MTF	modulation transfer function [—]
N	photon flux [s^{-1}]
N	carrier (number) density [m^{-3}]
n	real part of the relative refractive index [—]
$\tilde{n}$	complex index of refraction [—]
NA	numerical aperture [—]
OPD	optical path difference [m]
P	macroscopic polarization [C m^{-2}]
Re()	real part of [—]
R	resistance [Ω]
r	position vector [m]
S	Seebeck coefficient [VK^{-1}]
s	spin quantum number [—]
s	path length [m]
S_o	object distance [m]
S_i	image distance [m]
T	temperature [K, C]
t	time [s]
t	thickness [m]
u	slope of ray with the optical axis [rad]
V	Abbe reciprocal dispersion [—]
V	voltage [V, m^2 kgs^{-2} C^{-1}]
x, y, z	rectangular coordinates [m]
Z	atomic number [—]

Greek Symbols

α	absorption coefficient [cm^{-1}]
α	(power) absorptance (absorptivity)

ϵ	dielectric coefficient (constant) [—]
ϵ	emittance (emissivity) [—]
ϵ	eccentricity [—]
ϵ_1	Re (ϵ)
ϵ_2	lm (ϵ)
τ	(power) transmittance (transmissivity) [—]
ν	radiation frequency [Hz]
ω	circular frequency = $2\pi\nu$ [rads^{-1}]
ω	plasma frequency [H_2]
λ	wavelength [μm, nm]
σ	wave number = $1/\lambda$ [cm^{-1}]
σ	Stefan Boltzmann constant [Wm^{-2}K^{-1}]
ρ	reflectance (reflectivity) [—]
θ, ϕ	angular coordinates [rad, °]
ξ, η	rectangular spatial frequencies [m^{-1}, r^{-1}]
ϕ	phase [rad, °]
ϕ	lens power [m^{-2}]
Φ	flux [W]
χ	electric susceptibility tensor [—]
Ω	solid angle [sr]

Other

$\Re$	responsivity
exp (x)	e^x
$\log_a(x)$	log to the base a of x
ln (x)	natural log of x
log (x)	standard log of x: $\log_{10}(x)$
Σ	summation
Π	product
Δ	finite difference
δx	variation in x
dx	total differential
∂x	partial derivative of x
$\delta(x)$	Dirac delta function of x
δ_{ij}	Kronecker delta

1.1 GLOSSARY

BRDF	bidirectional reflectance distribution function
BTDF	bidirectional transmittance distribution function
BSDF	bidirectional scatter distribution function
f	focal length
L	distance
P	power
R	length
r	radius
TIS	total integrated scatter
θ	angle
θ_N	vignetting angle
θ_{spec}	specular angle
λ	wavelength
σ	rms roughness
Ω	solid angle

1.2 INTRODUCTION

In addition to being a serious source of noise, scatter reduces throughput, limits resolution, and has been the unexpected source of practical difficulties in many optical systems. On the other hand, its measurement has proved to be an extremely sensitive method of providing metrology information for components used in many diverse applications. Measured scatter is a good indicator of surface quality and can be used to characterize surface roughness as well as locate and size

discrete defects. It is also used to measure the quality of optical coatings and bulk optical materials. This chapter reviews basic issues associated with scatter metrology and touches on various industrial applications.

The pioneering scattering instrumentation[1–32] work started in the 1960s and extended into the 1990s. This early work (reviewed in 1995)[11] resulted in commercially available lab scatterometers and written standards in SEMI and ASTM detailing measurement, calibration and reporting.[33–36] Understanding the measurements and the ability to repeat results and communicate them led to an expansion of industrial applications, scatterometry has become an increasingly valuable source of noncontact metrology in industries where surface inspection is important. For example, each month millions of silicon wafers (destined to be processed into computer chips) are inspected for point defects (pits and particles) with "particle scanners," which are essentially just scatterometers. These rather amazing instruments (now costing more than $1 million each) map wafer defects smaller than 50 nm and can distinguish between pits and particles. In recent years their manufacture has matured to the point where system specifications and calibration are now also standardized in SEMI.[37–40] Scatter metrology is also found in industries as diverse as medicine, sheet metal production and even the measurement of appearance—where it has been noted that while beauty is in the eye of the beholder, what we see is scattered light. The polarization state of scatter signals has also been exploited[25–28, 41–44] and is providing additional product information. Many more transitions from lab scatterometer to industry application are expected. They depend on understanding the basic measurement concepts outlined in this chapter.

Although it sounds simple, the instrumentation required for these scatter measurements is fairly sophisticated. Scatter signals are generally small compared to the specular beam and can vary by several orders of magnitude in just a few degrees. Complete characterization may require measurement over a large fraction of the sphere surrounding the scatter source. For many applications, a huge array of measurement decisions (incident angle, wavelength, source and receiver polarization, scan angles, etc.) faces the experimenter. The instrument may faithfully record a signal, but is it from the sample alone? Or, does it also include light from the instrument, the wall behind the instrument, and even the experimenter's shirt? These are not easy questions to answer at nanowatt levels in the visible and get even harder in the infrared and ultraviolet. It is easy to generate scatter data—lots of it. Obtaining accurate values of appropriate measurements and communicating them requires knowledge of the instrumentation as well as insight into the problem being addressed.

In 1961, Bennett and Porteus[1] reported measurement of signals obtained by integrating scatter over the reflective hemisphere. They defined a parameter called the *total integrated scatter* (TIS) as the integrated reflected scatter normalized by the total reflected light. Using a scalar diffraction theory result drawn from the radar literature,[2] they related the TIS to the reflector root mean square (rms) roughness. By the mid-1970s, several scatterometers had been built at various university, government, and industry labs that were capable of measuring scatter as a function of angle; however, instrument operation and data manipulation were not always well automated.[3–6] Scattered power per unit solid angle (sometimes normalized by the incident power) was usually measured. Analysis of scatter data to characterize sample surface roughness was the subject of many publications.[7–11] Measurement comparison between laboratories was hampered by instrument differences, sample contamination, and confusion over what parameters should be compared. A derivation of what is commonly called BRDF (for bidirectional reflectance distribution function) was published by Nicodemus and coworkers in 1970, but did not gain common acceptance as a way to quantify scatter measurements until after publication of their 1977 NBS monograph.[12] With the advent of small powerful computers in the 1980s, instrumentation became more automated. Increased awareness of scatter problems and the sensitivity of many end-item instruments increased government funding for better instrumentation.[13–14] As a result, instrumentation became available that could measure and analyze as many as 50 to 100 samples a day instead of just a handful. Scatterometers became commercially available and the number (and sophistication) of measurement facilities increased.[15–17] Further instrumentation improvements will include more out-of-plane capability, extended wavelength control, and polarization control at both source and receiver. As of 2008 there are written standards for BRDF and TIS in ASTM and SEMI.[33–36]

This review gives basic definitions, instrument configurations, components, scatter specifications, measurement techniques, and briefly discusses calibration and error analysis.

1.3 DEFINITIONS AND SPECIFICATIONS

One of the difficulties encountered in comparing measurements made on early instruments was getting participants to calculate the same quantities. There were problems of this nature as late as 1988 in a measurement round-robin run at 633 nm.[20] But, there are other reasons for reviewing these basic definitions before discussing instrumentation. The ability to write useful scatter specifications (i.e., the ability to make use of quantified scatter information) depends just as much on understanding the defined quantity as it does on understanding the instrumentation and the specific scatter problem. In addition, definitions are often given in terms of mathematical abstractions that can only be approximated in the lab. This is the case for BRDF.

$$\text{BRDF} = \frac{\text{differential radiance}}{\text{differential irradiance}} \approx \frac{dP_s/d\Omega}{P_i \cos\theta_s} \approx \frac{P_s/\Omega}{P_i \cos\theta_s} \tag{1}$$

BRDF has been strictly defined as the ratio of the sample differential radiance to the differential irradiance under the assumptions of a collimated beam with uniform cross section incident on an isotropic surface reflector (no bulk scatter allowed). Under these conditions, the third quantity in Eq. (1) is found, where power P in watts instead of intensity I in W/m^2 has been used. The geometry is shown in Fig. 1. The value θ_s is the polar angle in the scatter direction measured from reflector normal and Ω is the differential solid angle (in steradians) through which dP_s (watts) scatters when P_i (watts) is incident on the reflector. The cosine comes from the definition of radiance and may be viewed as a correction from the actual size of the scatter source to the apparent size (or projected area) as the viewer rotates away from surface normal.

The details of the derivation do not impact scatter instrumentation, but the initial assumptions and the form of the result do. When scattered light power is measured, it is through a finite diameter

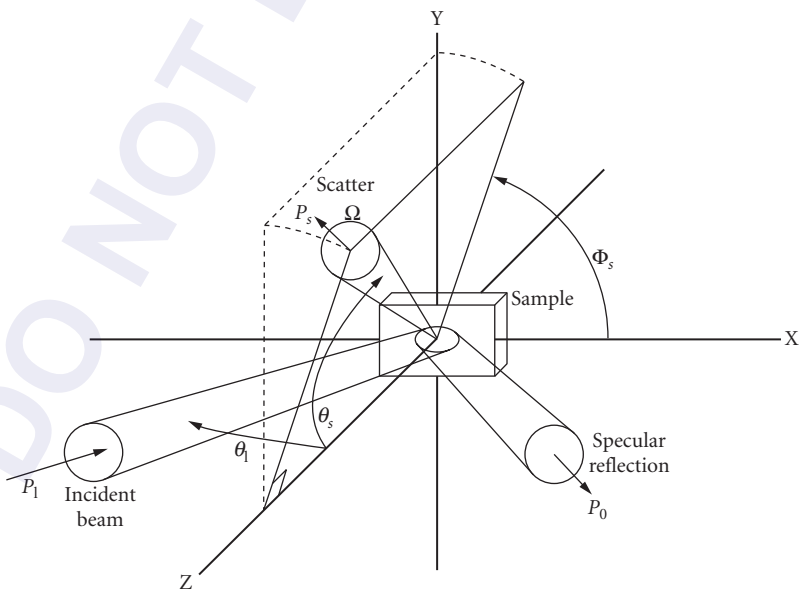

FIGURE 1 Geometry for the definition of BRDF.

aperture; as a result the calculation is for an average BRDF over the aperture. This is expressed in the final term of Eq. (1), where P_s is the measured power through the finite solid angle Ω defined by the receiver aperture and the distance to the scatter source. Thus, when the receiver aperture is swept through the scatter field to obtain angle dependence, the measured quantity is actually the convolution of the aperture over the differential BRDF. This does not cause serious distortion unless the scatter field has abrupt intensity changes, as it does near specular or near diffraction peaks associated with periodic surface structure. But there are even more serious problems between the strict definition of BRDF (as derived by Nicodemus) and practical measurements. There are no such things as uniform cross-section beams and isotropic samples that scatter only from surface structure. So, the third term of Eq. (1) is not exactly the differential radiance/irradiance ratio for the situations we create in the lab with our instruments. However, it makes perfect sense to measure normalized scattered power density as a function of direction [as defined in the fourth term of Eq. (1)] even though it cannot be exactly expressed in convenient radiometric terms.

A slightly less cumbersome definition (in terms of writing scatter specifications) is realized if the cosine term is dropped. This is referred to as "the cosine-corrected BRDF," or sometimes, "the scatter function." Its use has caused some of the confusion surrounding measurement differences found in scatter round robins. In accordance with the original definition, accepted practice, and BRDF Standards,[33,36] the BRDF contains the cosine, as given in Eq. (1), and the cosine-corrected BRDF does not. It also makes sense to extend the definition to volume scatter sources and even make measurements on the transmissive side of the sample. The term BTDF (for bidirectional transmission distribution function) is used for transmissive scatter, and BSDF (bidirectional scatter distribution function) is all-inclusive.

The BSDF has units of inverse steradians and, unlike reflectance and transmission (which vary from 0.0 to 1.0), can take on very large values as well as very small values.[1,21] For near-normal incidence, a measurement made at the specular beam of a high reflectance mirror results in a BSDF value of approximately $1/\Omega$, which is generally a large number. Measured values at the specular direction on the order of 10^6 sr^{-1} are common for a HeNe laser source. For low-scatter measurements, large apertures are generally used and values fall to the noise equivalent BSDF (or NEBSDF). This level depends on incident power and polar angle (position) as well as aperture size and detector noise, and typically varies from 10^{-4} sr^{-1} to 10^{-10} sr^{-1}. Thus, the measured BSDF can easily vary by over a dozen orders of magnitude in a given angle scan. This large variation results in challenges in instrumentation design as well as data storage, analysis, and presentation, and is another reason for problems with comparison measurements.

Instrument signature is the measured background scatter signal caused by the instrument and not the sample. It is caused by a combination of scatter created within the instrument and by the NEBSDF. Any instrument scatter that reaches the receiver field of view (FOV) will contribute to it. Common causes are scatter from source optics and the system beam dump. It is typically measured without a sample in place; however, careful attention has to be paid to the receiver FOV to ascertain that this is representative of the sample measurement situation. It is calculated as though the signal came from the sample (i.e., the receiver/sample solid angle is used) so that it can be compared to the measured sample BSDF. Near specular, the signal can be dominated by scatter (or diffraction) contributions from the source, called instrument signature. At high scatter angles it can generally be limited to NEBSDF levels. Sample measurements are always a combination of desired signal and instrument signature. Reduction of instrument signature, especially near specular, is a prime consideration in instrument design and use.

BSDF specifications always require inclusion of incident angle, source wavelength, and polarization as well as observation angles, scatter levels, and sample orientation. Depending on the sample and the measurement, they may also require aperture information to account for convolution effects. Specifications for scatter instrumentation should include instrument signature limits and the required NEBSDF. Specifications for the NEBSDF must include the polar angle, the solid angle, and the incident power to be meaningful.

TIS measurements are made by integrating the BSDF over a majority of either the reflective or transmissive hemispheres surrounding the scatter source. This is usually done with instrumentation that gathers (integrates) the scattered light signal. The TIS can sometimes be calculated from BSDF

data. If an isotropic sample is illuminated at near-normal incidence with circularly polarized light, data from a single measurement scan is enough to calculate a reasonably accurate TIS value for an entire hemisphere of scatter. The term "total integrated scatter" is a misnomer in that the integration is never actually "total," as some scatter is never measured. Integration is commonly performed from a few degrees from specular to polar angles approaching 90° (approaching 1° to more than 45° in the SEMI Standard).[34] Measurements can be made of either transmissive or reflective scatter. TIS is calculated by ratioing the integrated scatter to the reflected (or transmitted) power as shown below in Eq. (2). For optically smooth components, the scatter signal is small compared to the specular beam and is often ignored. For reflective scatter the conversion to rms roughness (σ) under the assumption of an optically smooth, clean, reflective surface, via Davies' scalar theory,[2] is also given. This latter calculation does not require gaussian surface statistics (as originally assumed by Davies) or even surface isotropy, but will work for other distributions, including gratings and machined optics.[8,11] There are other issues (polarization and the assumption of mostly near specular scatter) that cause some error in this conversion. Comparison of TIS-generated roughness to profile-generated values is made difficult by a number of issues (bandwidth limits, one-dimensional profiling of a two-dimensional surface, etc.) that are beyond the scope of this section (see Ref. 11 for a complete discussion). One additional caution is that the literature and more than one stray radiation analysis program define TIS as scattered power normalized by incident power (which is essentially diffuse reflectance). This is a seriously incorrect distortion of TIS. Such a definition obviously cannot be related to surface roughness, as a change in reflectance (but not roughness) will change the ratio.

$$\text{TIS} = \frac{\text{integrated scattered power}}{\text{total reflected power}} \cong \left(\frac{4\pi\sigma}{\lambda}\right)^2 \tag{2}$$

TIS is one of three ratios that may be formed from the incident power, the specular reflected (or transmitted) power, and the integrated scatter. The other two ratios are the diffuse reflectance (or transmittance) and the specular reflectance (or transmittance). Typically, all three ratios may be obtained from measurements taken in TIS or BSDF instruments. Calculation, or specification, of any of these quantities that involve integration of scatter, also requires that the integration limits be given, as well as the wavelength, angle of incidence, source polarization, and sample orientation.

1.4 INSTRUMENT CONFIGURATIONS AND COMPONENT DESCRIPTIONS

The scatterometer shown in Fig. 2 is representative of the most common instrument configuration in use. The source is fixed in position. The sample is rotated to the desired incident angle, and the receiver is rotated about the sample in the plane of incidence. Although dozens of instruments have been built following this general design, other configurations are in use. For example, the source and receiver may be fixed and the sample rotated so that the scatter pattern moves past the receiver. This is easier mechanically than moving the receiver at the end of an arm, but complicates analysis because the incident angle and the observation angle change simultaneously. Another combination is to fix the source and sample together, at constant incident angle, and rotate this unit (about the point of illumination on the sample) so that the scatter pattern moves past a fixed receiver. This has the advantage that a long receiver/sample distance can be used without motorizing a long (heavy) receiver arm. It has the disadvantage that heavy (or multiple) sources are difficult to deal with. Other configurations, with everything fixed, have been designed that employ several receivers to merely sample the BSDF and display a curve fit of the resulting data. This is an economical solution if the BSDF is relatively uniform without isolated diffraction peaks. Variations on this last combination are common in industry where the samples are moved through the beam (sometimes during the manufacturing process) and the scatter measured in one or more directions.

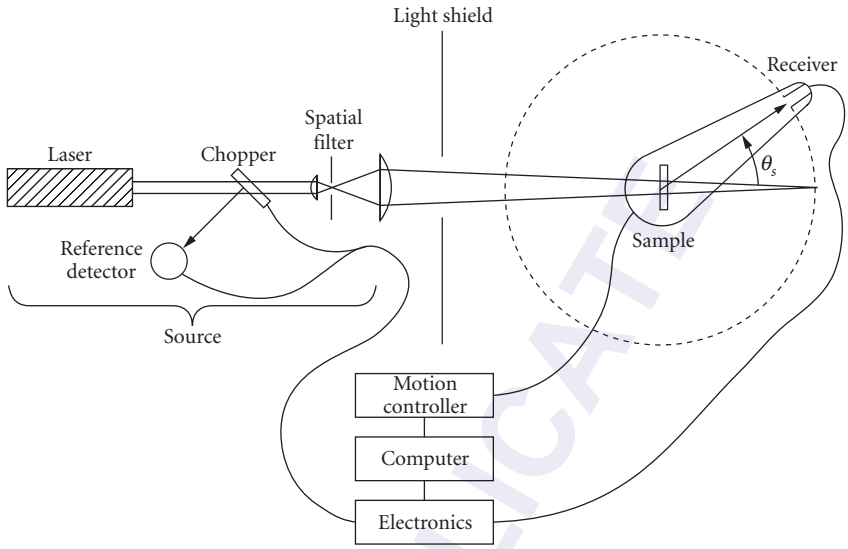

FIGURE 2 Components of a typical BSDF scatterometer.

Computer control of the measurement is essential to maximize versatility and minimize measurement time. The software required to control the measurement plus display and analyze the data can expected to be a significant portion of total instrument development cost. The following paragraphs review typical design features (and issues) associated with the source, sample mount, and receiver components.

The source in Fig. 2 is formed by a laser beam that is chopped, spatially filtered, expanded, and finally brought to a focus on the receiver path. The beam is chopped to reduce both optical and electronic noise. This is accomplished through the use of lock-in detection in the electronics package which suppresses all signals except those at the chopping frequency. Low-noise, programmable gain electronics are essential to reducing NEBSDF. The reference detector is used to allow the computer to ratio out laser power fluctuations and, in some cases, to provide the necessary timing signal to the lock-in electronics. Polarizers, wave plates, and neutral density filters are also commonly placed prior to the spatial filter when required in the source optics. The spatial filter removes scatter from the laser beam and presents a point source which is imaged by the final focusing element to the detector zero position. Although a lens is shown in Fig. 2, the use of a mirror, which works over a larger range of wavelengths and generally scatters less light, is more common. For most systems the relatively large focal length of the final focusing element allows use of a spherical mirror and causes only minor aberration. Low-scatter spherical mirrors are easier to obtain than other conic sections. The incident beam is typically focused at the receiver to facilitate near specular measurement. Another option (a collimated beam at the receiver) is sometimes used and will be considered in the discussion on receivers. In either case, curved samples can be accommodated by adjusting the position of the spatial filter with respect to the final focusing optic. The spot size on the sample is obviously determined by elements of the system geometry and can be adjusted by changing the focal length of the first lens (often a microscope objective). The source region is completed by a shield that isolates stray laser light from the detector.

Lasers are convenient sources, but are not necessary. Broadband sources are often required to meet a particular application or to simulate the environment where a sample will be used. Monochromators and filters can be used to provide scatterometer sources of arbitrary wavelength.[20] Noise floor with these tunable incoherent sources increases dramatically as the spectral bandpass is narrowed, but they have the advantage that the scatter pattern does not contain laser speckle.

The sample mount can be very simple or very complex. In principle, 6° of mechanical freedom are required to fully adjust the sample. Three translational degrees of freedom allow the sample area (or volume) of interest to be positioned at the detector rotation axis and illuminated by the source. Three rotational degrees of freedom allow the sample to be adjusted for angle of incidence, out-of-plane tilt, and rotation about sample normal. The order in which these stages are mounted affects the ease of use (and cost) of the sample holder. In practice, it often proves convenient to either eliminate, or occasionally duplicate, some of these degrees of freedom. Exact requirements for these stages differ depending on whether the sample is reflective or transmissive, as well as with size and shape. In addition, some of these axes may be motorized to allow the sample area to be raster-scanned to automate sample alignment or to measure reference samples. The order in which these stages are mounted affects the ease of sample alignment. As a general rule, the scatter pattern is insensitive to small changes in incident angle but very sensitive to small angular deviations from specular. Instrumentation should be configured to allow location of the specular reflection (or transmission) very accurately.

The receiver rotation stage should be motorized and under computer control so that the input aperture may be placed at any position on the observation circle (dotted line in Fig. 2). Data scans may be initiated at any location. Systems vary as to whether data points are taken with the receiver stopped or "on the fly." The measurement software is less complicated if the receiver is stopped. Unlike many TIS systems, the detector is always approximately normal to the incoming scatter signal. In addition to the indicated axis of rotation, some mechanical freedom is required to ensure that the receiver is at the correct height and pointed (tilted) at the illuminated sample. Sensitivity, low noise, linearity, and dynamic range are the important issues in choosing a detector element and designing the receiver housing. In general, these requirements are better met with photovoltaic detectors than photoconductive detectors. Small area detectors reduce the NEBSDF.

Receiver designs vary, but changeable apertures, bandpass filters, polarizers, lenses, and field stops are often positioned in front of the detector element. Figure 3 shows two receiver configurations, one designed for use with a converging source and one with a collimated source. In Fig. 3*a*, the illuminated sample spot is imaged on a field stop in front of the detector. This configuration is commonly

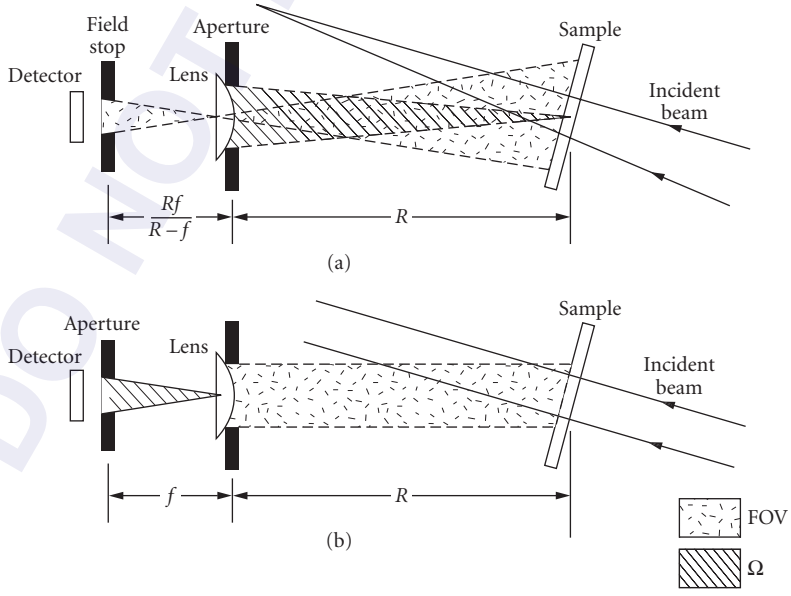

FIGURE 3 Receiver configurations: (*a*) converging source and (*b*) collimated source.

used with the source light converging on the receiver path. The field stop determines the receiver FOV. The aperture at the front of the receiver determines the solid angle over which scatter is gathered. Any light entering this aperture that originates from within the FOV will reach the detector and become part of the signal. This includes instrument signature contributions scattered through small angles by the source optics. It will also include light scattered by the receiver lens so that it appears to come from the sample. The configuration in Fig. 3*a* can be used to obtain near specular measurements by bringing a small receiver aperture close to the focused specular beam. With this configuration, reducing the front aperture does not limit the FOV. The receiver in Fig. 3*b* is in better accordance with the strict definition of BRDF in that a collimated source can be used. An aperture is located one focal length behind a collecting lens (or mirror) in front of the detector. The intent is to measure bundles of nearly parallel rays scattered from the sample. The angular spread of rays allowed to pass to the detector defines the receiver solid angle, which is equal to the aperture size divided by the focal length of the lens. This ratio (not the front aperture/sample distance) determines the solid angle of this receiver configuration. The FOV is determined by the clear aperture of the lens, which must be kept larger than the illuminated spot on the sample. The Fig. 3*b* design is unsuitable for near specular measurement because the relatively broad collimated specular beam will scatter from the receiver lens for several degrees from specular. It is also limited in measuring large incident angle situations where the elongated spot may exceed the FOV. If the detector (and its stop) can be moved in relation to the lens, receivers can be adjusted from one configuration to the other. Away from the specular beam, in low instrument signature regions, there is no difference in the measured BSDF values between the two systems. Commercially available research scatterometers are available that measure both in and out of the incident plane and from the mid-IR to the near UV.

The two common methods of approaching TIS measurements are shown in Fig. 4. The first one, employed by Bennett and Porteus in their early instrument,[1] uses a hemispherical mirror (or Coblentz sphere) to gather scattered light from the sample and image it onto a detector. The specular beam enters and leaves the hemisphere through a small circular hole. The diameter of that hole defines the near specular limit of the instrument. The reflected beam (not the incident beam) should be centered in the hole because the BSDF will be symmetrical about it. Alignment of the hemispherical mirror is critical in this approach. The second approach involves the use of an integrating sphere. A section of the sphere is viewed by a recessed detector. If the detector FOV is limited to a section of the sphere

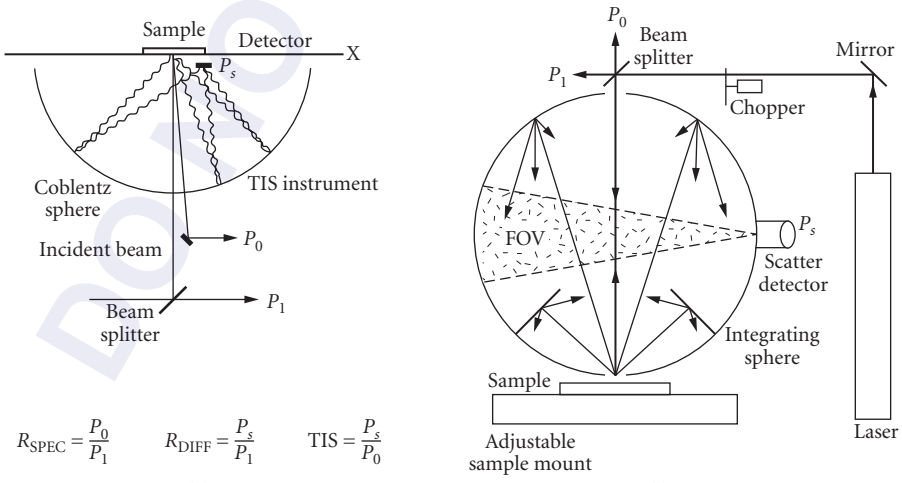

FIGURE 4 TIS measurement with a (*a*) Coblentz sphere and (*b*) diffuse integrating sphere.

that is not directly illuminated by scatter from the sample, then the signal will be proportional to total scatter from the sample. Again, the reflected beam should be centered on the exit hole. The Coblentz Sphere method presents more signal to the detector; however, some of this signal is incident on the detector at very high angles. Thus, this approach tends to discriminate against high-angle scatter (which is often much smaller for many samples). The integrating sphere is easier to align, but has a lower signal-to-noise ratio (less signal on the detector) and is more difficult to build in the IR where uniform diffuse surfaces are harder to obtain. Even so, sophisticated integrating sphere systems have become commercially available that can measure down to 0.5 angstroms rms roughness. A common mistake with TIS measurements is to assume that for near-normal incidence, the orientation between source polarization and sample orientation is not an issue. TIS measurements made with a linearly polarized source on a grating at different orientations will quickly demonstrate this dependence.

TIS measurements can be made over very near specular ranges by utilizing a diffusely reflecting plate with a small hole in it. A converging beam is reflected off the sample and through the hole. Scatter is diffusely reflected from the plate to a receiver designed to uniformly view the plate. The reflected power is measured by moving the plate so the specular beam misses the hole. Measurements starting closer than 0.1° from specular can be made in this manner, and it is an excellent way to check incoming optics or freshly coated optics for low scatter.

1.5 INSTRUMENTATION ISSUES

Measurement of near specular scatter is often one of the hardest requirements to meet when designing an instrument and has been addressed in several publications.[21–23] The measured BSDF may be divided into two regions relative to the specular beam, as shown in Fig. 5. Outside the angle θ_N from specular is a low-signature region where the source optics are not in the receiver FOV. Inside θ_N, at least some of the source optics scatter directly into the receiver and the signature increases rapidly until the receiver aperture reaches the edge of the specular beam. As the aperture moves

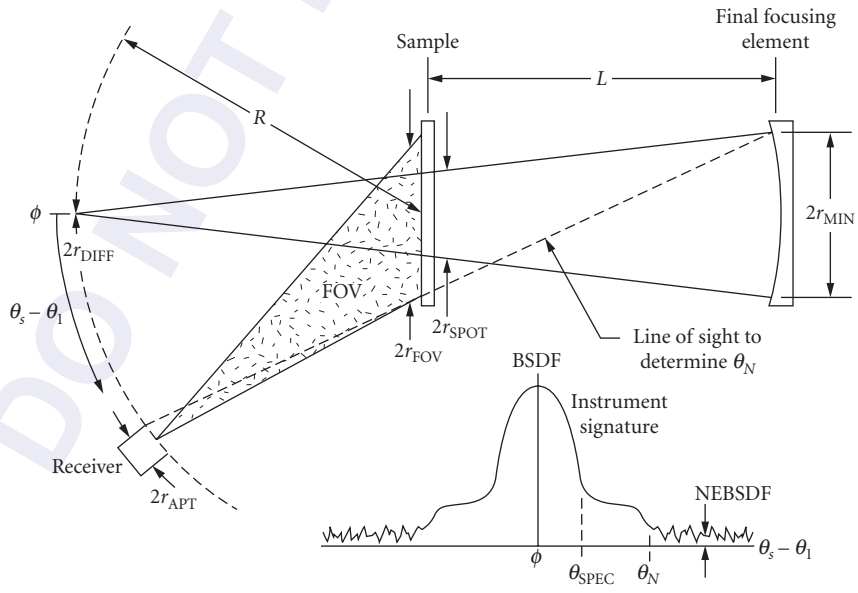

FIGURE 5 Near specular geometry and instrument signature.

closer to specular center, the measurement is dominated by the aperture convolution of the specular beam, and there is no opportunity to measure scatter. The value θ_N is easily calculated (via a small-angle approximation) using the instrument geometry and parameters identified in Fig. 5, where the receiver is shown at the θ_N position. The parameter F is the focal length of the sample.

$$\theta_N = (r_{\mathrm{MIR}} + r_{\mathrm{FOV}})/L + (r_{\mathrm{FOV}} + r_{\mathrm{apt}})/R - r_{\mathrm{spot}}/F \tag{3}$$

It is easy to achieve values of θ_N below 10° and values as small as 1° can be realized with careful design. The offset angle from specular, θ_{spec}, at which the measurement is dominated by the specular beam, can be reduced to less than a tenth of a degree at visible wavelengths and is given by

$$\theta_{\mathrm{spec}} = \frac{r_{\mathrm{diff}} + r_{\mathrm{apt}}}{R} \approx \frac{3\lambda}{D} + \frac{r_{\mathrm{apt}}}{R} \tag{4}$$

Here, r_{diff} and r_{apt} are the radius of the focused spot and the receiver aperture, respectively (see Fig. 5 again). The value of r_{diff} can be estimated in terms of the diameter D of the focusing optic and its distance to the focused spot, $R + L$ (estimated as $2.5R$). The diffraction limit has been doubled in this estimate to allow for aberrations.

To take near specular measurements, both angles and the instrument signature need to be reduced. The natural reaction is to "increase R to increase angular resolution." Although a lot of money has been spent doing this, it is an unnecessarily expensive approach. Angular resolution is achieved by reducing r_{apt} and by taking small steps. The radius r_{apt} can be made almost arbitrarily small so the economical way to reduce the r_{apt}/R terms is by minimizing r_{apt}—not by increasing R. A little thought about r_{FOV} and r_{diff} reveals that they are both proportional to R, so nothing is gained in the near specular game by purchasing large-radius rotary stages.

The reason for building a large-radius scatterometer is to accommodate a large FOV. This is often driven by the need to take measurements at large incident angles or by the use of broadband sources, both of which create larger spots on the sample. When viewing normal to the sample, the FOV requirements can be stringent. Because the maximum FOV is proportional to detector diameter (and limited at some point by minimum receiver lens FN), increasing R is the only open-ended design parameter available. It should be sized to accommodate the smallest detector likely to be used in the system. This will probably be in the mid-IR where uniform high-detectivity photovoltaic detectors are more difficult to obtain. On the other hand, a larger detector diameter means increased electronic noise and a larger NEBSDF.

Scatter sources of instrument signature can be reduced by these techniques.

1. Use the lowest-scatter focusing element in the source that you can afford and learn how to keep it clean. This will probably be a spherical mirror.
2. Keep the source area as "black" as possible. This especially includes the sample side of the spatial filter pinhole which is conjugate with the receiver aperture. Use a black pinhole.
3. Employ a specular beam dump that rides with your receiver and additional beam dumps to capture sample reflected and transmitted beams when the receiver has left the near specular area. Use your instrument to measure the effectiveness of your beam dumps.[26]
4. Near specular scatter caused by dust in the air can be significantly reduced through the use of a filtered air supply over the specular beam path. A filtered air supply is essential for measuring optically smooth surfaces.

Away from specular, reduction of NEBSDF is the major factor in measuring low-scatter samples and increasing instrument quality. Measurement of visible scatter from a clean semiconductor wafer will take many instruments right down to instrument signature levels. Measurement of cross-polarized scatter requires a low NEBSDF for even high-scatter optics. For a given receiver solid angle, incident power, and scatter direction, the NEBSDF is limited by the noise equivalent power of the receiver (and associated electronics), once optical noise contributions are eliminated. The electronic contributions to NEBSDF are easily measured by simply covering the receiver aperture during a measurement.

TABLE 1 Comparison of Characteristics for Detectors Used at Different Wavelengths

Detector (2 mm dia.)	NEP (W/Hz)	Wavelength (nm)	P_i (W)	NEBSDF (sr^{-1})
PMT	10^{-15}	633	0.005	10^{-10}
Si	10^{-13}	633	0.005	10^{-8}
Ge	3×10^{-13}	1,320	0.001	10^{-7}
InSb	10^{-12}*	3,390	0.002	5×10^{-7}
HgMgTe	10^{-11}*	10,600	2.0	10^{-8}
Pyro	10^{-8}	10,600	2.0	10^{-5}

*Detector at 77 K.

Because the resulting signal varies in a random manner, NEBSDF should be expressed as an rms value (roughly equal to one-third of the peak level). An absolute minimum measurable scatter signal (in watts) can be found from the product of three terms: the required signal-to-noise ratio, the system noise equivalent power (or NEP given in watts per square root hertz), and the square root of the noise bandwidth (BW_n). The system NEP is often larger than the detector NEP and cannot be reduced below it. The detector NEP is a function of wavelength and increases with detector diameter. Typical detector NEP values (2-mm diameter) and wavelength ranges are shown as follows for several common detectors in Table 1. Notice that NEP tends to increase with wavelength. The noise bandwidth varies as the reciprocal of the sum of the system electronics time constant and the measurement integration time. Values of 0.1 to 10 Hz are commonly achieved. In addition to system NEP, the NEBSDF may be increased by contributions from stray source light, room lights, and noise in the reference signal. Table 1 also shows achievable rms NEBSDF values that can be realized at unity cosine, a receiver solid angle of 0.003 sr, 1-second integration, and the indicated incident powers. This column can be used as a rule of thumb in system design or to evaluate existing equipment. Simply adjust by the appropriate incident power, solid angle, and so on, to make the comparison. Adjusted values substantially higher than these indicate there is room for system improvement (don't worry about differences as small as a factor of 2). Further reduction of the instrument signature under these geometry and power conditions will require dramatically increased integration time (because of the square root dependence on noise bandwidth) and special attention to electronic dc offsets. Because the NEP tends to increase with wavelength, higher powers are needed in the mid-IR to reach the same NEBSDFs that can be realized in the visible. Because scatter from many sources tends to decrease at longer wavelengths, a knowledge of the instrument NEBSDF is especially critical in the mid-IR.

As a final configuration comment, the software package (both measurement and analysis) is crucial for an instrument that is going to be used for any length of time. Poor software will quickly cost work-years of effort due to errors, increased measurement and analysis time, and lost business. Expect to expend 1 to 2 man-years with experienced programmers writing a good package—it is worth it.

1.6 MEASUREMENT ISSUES

Sample measurement should be preceded (and sometimes followed) by a measurement of the instrument signature. This is generally accomplished by removing the sample and measuring the apparent BSDF from the sample as a transmissive scan. This is not an exact measure of instrument noise during sample measurement, but if the resulting BSDF is multiplied by sample reflectance (or transmission) before comparison to sample data, it can define some hard limits over which the sample data cannot be trusted. The signature should also be compared to the NEBSDF value obtained with the receiver aperture blocked. Obtaining the instrument signature also presents an opportunity to measure the incident power, which is required for calculation of the BSDF. The ability to see the data displayed as it is taken is an extremely helpful feature when it comes to reducing instrument signature and eliminating measurement setup errors.

Angle scans, which have dominated the preceding discussion, are an obvious way to take measurements. BSDF is also a function of position on the sample, source wavelength, and source polarization, and scans can also be taken at fixed angle (receiver position) as a function of these variables. Obviously, a huge amount of data is required to completely characterize scatter from a sample.

Raster scans are taken to measure sample uniformity or locate (map) discrete defects. A common method is to fix the receiver position and move the sample in its own x-y plane, recording the BSDF at each location. Faster approaches involve using multiple detectors (e.g., array cameras) with large area illumination, and scanning the source over the sample. Results can be presented using color maps or 3D isometric plots. Results can be further analyzed via histograms and various image-processing techniques.

There are three obvious choices for making wavelength scans. Filters (variable or discrete) can be employed at the source or receiver. A monochromator can be used as a source.[20] Finally, there is some advantage to using a Fourier transforming infrared spectrometer (FTIR) as a source in the mid-IR.[20] Details of these techniques are beyond the scope of this discussion; however, a couple of generalities will be mentioned. Even though these measurements often involve relatively large bandwidths at a given wavelength (compared to a laser), the NEBSDF is often larger by a few orders because of the smaller incident power. Further, because the bandwidths change differently between the various source types given above, meaningful measurement comparisons between instruments are often difficult to make.

Polarization scans are often limited to SS, SP, PS, and PP (source/receiver) combinations. However, complete polarization dependence of the sample requires the measurement of the sample Mueller matrix. This is found by creating a set of Stokes vectors at the source and measuring the resulting Stokes vector in the desired scatter direction.[10,11,25–28] This is an area of instrumentation development that is the subject of increasing attention.[41–44]

Speckle effects in the BSDF from a laser source can be eliminated in several ways. If a large receiver solid angle is used (generally several hundred speckles in size) there is not a problem. The sample can be rotated about its normal so that speckle is time averaged out of the measurement. This is still a problem when measuring very near the specular beam because sample rotation unavoidably moves the beam slightly during the measurement. In this case, the sample can be measured several times at slightly different orientations and the results averaged to form one speckle-free BSDF.

Scatter measurement in the retrodirection (back into the incident beam) has been of increasing interest in recent years and represents an interesting measurement challenge. Measurement requires the insertion of a beam splitter in the source. This also scatters light and, because it is closer to the receiver than the sample, dramatically raises the NEBSDF. Diffuse samples can be measured this way, but not much else. A clever (high tech) Doppler-shift technique, employing a moving sample, has been reported[29] that allows separation of beam-splitter scatter from sample scatter and allows measurement of mirror scatter. A more economical (low tech) approach simply involves moving the source chopper to a location between the receiver and the sample.[30] Beam-splitter scatter is now dc and goes unnoticed by the ac-sensitive receiver. Noise floor is now limited by scatter from the chopper which must be made from a low-scatter, specular, absorbing material. Noise floors as low as 3×10^{-8} sr^{-1} have been achieved.

1.7 INCIDENT POWER MEASUREMENT, SYSTEM CALIBRATION, AND ERROR ANALYSIS

Regardless of the type of BSDF measurement, the degree of confidence in the results is determined by instrument calibration, as well as by attention to the measurement limitations previously discussed. Scatter measurements have often been received with considerable skepticism. In part, this has been due to misunderstanding of the definition of BSDF and confusion about various measurement subtleties, such as instrument signature or aperture convolution. However, quite often the measurements have been wrong and the skepticism is justified.

Instrument calibration is often confused with the measurement of P_i, which is why these topics are covered in the same section. To understand the source of this confusion, it is necessary to first consider the various quantities that need to be measured to calculate the BSDF. From Eq. (1), they

are P_s, θ_s, Ω, and P_i. The first two require measurement over a wide range of values. In particular, P_s, which may vary over many orders of magnitude, is a problem. In fact, linearity of the receiver to obtain a correct value of P_s, is a key calibration issue. Notice that an absolute measurement of P_s is not required, as long as the P_s/P_i ratio is correctly evaluated. P_i and Ω generally take on only one (or just a few) discrete values during a data scan. The value of Ω is determined by system geometry. The value of P_i is generally measured in one of two convenient ways.[11]

The first technique, sometimes referred to as *the absolute method* makes use of the scatter detector (and sometimes a neutral density filter) to directly measure the power incident upon the sample. This method relies on receiver linearity (as does the overall calibration of BSDF) and on filter accuracy when one is used. The second technique, sometimes referred to as *the reference method* makes use of a known BSDF reference sample (usually a diffuse reflector and unfortunately often referred to as the "calibration sample") to obtain the value of P_i. Scatter from the reference sample is measured and the result used to infer the value of P_i via Eq. (1). The $P_i\Omega$ product may be evaluated this way. This method depends on knowing the absolute BSDF of the reference. Both techniques become more difficult in the mid-IR, where "known" neutral density filters and "known" reference samples are difficult to obtain. Reference sample uniformity in the mid-IR is often the critical issue and care must be exercised. Variations at 10.6 μm as large as 7:1 have been observed across the face of a diffuse gold reference "of known BRDF." The choice of measurement methods is usually determined by whether it is more convenient to measure the BSDF of a reference or the total power P_i. Both are equally valid methods of obtaining P_i. However, neither method constitutes a system calibration, because calibration issues such as an error analysis and a linearity check over a wide range of scatter values are not addressed over the full range of BSDF angles and powers when P_i is measured (or calculated). The use of a reference sample is an excellent system check regardless of how P_i is obtained.

System linearity is a key part of system calibration. In order to measure linearity, the receiver transfer characteristic, signal out as a function of light in, must be found. This may be done through the use of a known set of neutral density filters or through the use of a comparison technique[31] that makes use of two data scans—with and without a single filter. However, there are other calibration problems than just linearity. The following paragraph outlines an error analysis for BSDF systems.

Because the calculation of BSDF is very straightforward, the sources of error can be examined through a simple analysis[11,32] under the assumption that the four defining parameters are independent.

$$\frac{\Delta \text{BSDF}}{\text{BSDF}} = \left[\left(\frac{\Delta P_s}{P_s}\right)^2 + \left(\frac{\Delta P_i}{P_i}\right)^2 + \left(\frac{\Delta \Omega}{\Omega}\right)^2 + \left(\frac{\Delta \theta_s \sin\theta_s}{\cos^2\theta_s}\right)^2\right]^{1/2} \tag{5}$$

In similar fashion, each of these terms may be broken into the components that cause errors in it. When this is done, the total error may be found as a function of angle. Two high-error regions are identified. The first is the near specular region (inside 1°), where errors are dominated by the accuracy to which the receiver aperture can be located in the cross-section direction. Or, in other words, did the receiver scan exactly through the specular beam, or did it just miss it? The second relatively high error region is near the sample plane where cos θ_s approaches zero. In this region, a small error in angular position results in a large error in calculated BSDF. These errors are often seen in BSDF data as an abrupt increase in calculated BSDF in the grazing scatter direction, the result of division by a very small cosine into the signal gathered by a finite receiver aperture (and/or a dc offset voltage in the detector electronics). This is another example where use of the cosine-corrected BSDF makes more sense.

Accuracy is system dependent; however, at signal levels well above the NEBSDF, uncertainties less than ±10 percent can be obtained away from the near specular and grazing directions. With expensive electronics and careful error analysis, these inaccuracies can be reduced to the ±1 percent level.

Full calibration is not required on a daily basis. Sudden changes in instrument signature are an indication of possible calibration problems. Measurement of a reference sample that varies over several orders of magnitude is a good system check. It is prudent to take such a reference scan with data sets in case the validity of the data is questioned at a later time. A diffuse sample, with nearly constant BRDF, is a good reference choice for the measurement of P_i but a poor one for checking system calibration.

1.8 SUMMARY

The art of scatter measurement has evolved to an established form of metrology within the optics industry. Because scatter measurements tend to be a little more complicated than many other optical metrology procedures, a number of key issues must be addressed to obtain useful information. System specifications and measurements need to be given in terms of accepted, well-defined (and understood) quantities (BSDF, TIS, etc.). All parameters associated with a measurement specification need to be given (such as angle limits, receiver solid angles, noise floors, wavelength, etc.). Measurement of near specular scatter and/or low BSDF values are particularly difficult and require careful attention to instrument signature values; however, if the standardized procedures are followed, the result will be repeatable, accurate data.

TIS and BSDF are widely accepted throughout the industry and their measurement is defined by SEMI and ASTM standards. Scatter measurements are used routinely as a quality check on optical components. BSDF specifications are now often used (as they should be) in place of scratch/dig or rms roughness, when scatter is the issue. Conversion of surface scatter data to other useful formats, such as surface roughness statistics, is commonplace. The sophistication of the instrumentation (and analysis) applied to these problems is still increasing. Out-of-plane measurements and polarization-sensitive measurements are two areas that are experiencing rapid advances. Measurement of scatter outside the optics community is also increasing. Although the motivation for scatter measurement differs in industrial situations, the basic measurement and instrumentation issues encountered are essentially the ones described here.

SPECTROSCOPIC MEASUREMENTS

Brian Henderson

Department of Physics and Applied Physics
University of Strathclyde
Glasgow, United Kingdom

2.1 GLOSSARY

A_{ba}	Einstein coefficient for spontaneous emission
a_o	Bohr radius
B_{if}	Einstein coefficient between initial state $\|i\rangle$ and final state $\|f\rangle$
e	charge on the electron
ED	electric dipole term
E_{DC}	Dirac Coulomb term
$\mathbf{E}_{hf}$	hyperfine energy
E_n	eigenvalues of quantum state n
EQ	electric quadrupole term
$\mathbf{E}(t)$	electric field at time t
$\mathbf{E}(\omega)$	electric field at frequency ω
g_a	degeneracy of ground level
g_b	degeneracy of excited level
g_N	gyromagnetic ratio of nucleus
h	Planck's constant
H_{SO}	spin-orbit interaction Hamiltonian
I	nuclear spin
$I(t)$	emission intensity at time t
$\mathbf{j}$	total angular momentum vector given by $\mathbf{j} = \mathbf{l} \pm \frac{1}{2}$
l_i	orbital state
m	mass of the electron
MD	magnetic dipole term
M_N	mass of nucleus N
$n_\omega(T)$	equilibrium number of photons in a blackbody cavity radiator at angular frequency ω and temperature T

QED	quantum electrodynamics
$R_{nl}(r)$	radial wavefunction
R_∞	Rydberg constant for an infinitely heavy nucleus
s	spin quantum number with value $\frac{1}{2}$
s_i	electronic spin
T	absolute temperature
W_{ab}	transition rate in absorption transition between states a and b
W_{ba}	transition rate in emission transition from state b to state a
Z	charge on the nucleus
$\alpha = e^2/4\pi\varepsilon_0\hbar c$	fine structure constant
$\Delta\omega$	natural linewidth of the transition
$\Delta\omega_{\mathrm{D}}$	Doppler width of transition
ε_0	permittivity of free space
$\zeta(r)$	spin-orbit parameter
μ_{B}	Bohr magneton
$\rho(\omega)$	energy density at frequency ω
τ_R	radiative lifetime
ω	angular frequency
ω_k	mode k with angular frequency ω
$\langle f \vert v^1 \vert i \rangle$	matrix element of perturbation V

2.2 INTRODUCTORY COMMENTS

The conceptual basis of optical spectroscopy and its relationship to the electronic structure of matter as presented in the chapter entitled "Optical Spectroscopy and Spectroscopic Lineshapes" in Vol. I, Chap. 10 of this *Handbook*. The chapter entitled "Optical Spectrometers" in Vol. I, Chap. 31 of this *Handbook* discusses the operating principles of optical spectrometers. This chapter illustrates the underlying themes of the earlier ones using the optical spectra of atoms, molecules, and solids as examples.

2.3 OPTICAL ABSORPTION MEASUREMENTS OF ENERGY LEVELS

Atomic Energy Levels

The interest in spectroscopic measurements of the energy levels of atoms is associated with tests of quantum theory. Generally, the optical absorption and luminescence spectra of atoms reveal large numbers of sharp lines corresponding to transitions between the stationary states. The hydrogen atom has played a central role in atomic physics because of the accuracy with which relativistic and quantum electrodynamic shifts to the one-electron energies can be calculated and measured. Tests of quantum electrodynamics usually involve transitions between low-lying energy states (i.e., states with small principal quantum number). For the atomic states $|a\rangle$ and $|b\rangle$, the absorption and luminescence lines occur at exactly the same wavelength and both spectra have the same gaussian lineshape. The 1s $\rightarrow$ 2p transitions on atomic hydrogen have played a particularly prominent role, especially since the development of sub-Doppler laser spectroscopy.[1] Such techniques resulted in values of $R_\infty = 10973731.43\,\mathrm{m}^{-1}$, $36.52\,\mathrm{m}^{-1}$ for the spin-orbit splitting in the $n = 2$ state and a Lamb shift of $3.53\,\mathrm{m}^{-1}$ in the $n = 1$ state. Accurate isotope shifts have been determined from hyperfine structure measurements on hydrogen, deuterium, and tritium.[2]

Helium is the simplest of the multielectron atoms, having the ground configuration ($1s^2$). The energy levels of helium are grouped into singlet and triplet systems. The observed spectra arise *within* these systems (i.e., singlet-to-singlet and triplet-to-triplet); normally transitions between singlet and triplet levels are not observed. The lowest-lying levels are 1^1S, 2^3S, 2^1S, 2^3P, and 2^1P in order of increasing energy. The $1^1S \rightarrow 2^1S$ splitting is of order 20.60 eV and transitions between these levels are not excited by photons. Transitions involving the 2^1S and 2^3S levels, respectively, and higher-lying spin singlet and spin triplet states occur at optical wavelengths. Experimental work on atomic helium has emphasized the lower-lying triplet levels, which have long excited-state lifetimes and large quantum electrodynamic (QED) shifts.

As with hydrogen, the spectra of He atoms are inhomogeneously broadened by the Doppler effect. Precision measurements have been made using two-photon laser spectroscopy (e.g., $2^3S \rightarrow n^3S$ ($n = 4 - 6$) and n^3D ($n = 3 - 6$), or laser saturation absorption spectroscopy ($2^3S \rightarrow 2^3P$ and $3^3P \rightarrow 3^3D$).[3–6] The $2^1S \rightarrow 3^1P$ and two photon $2^1S \rightarrow n^1D$ ($n = 3 - 7$) spectra have been measured using dye lasers.[7, 8] The wide tune ranging of the Ti-sapphire laser and the capability for generating frequencies not easily accessible with dye lasers using frequency-generation techniques makes it an ideal laser to probe transitions starting on the 2S levels of He.[9] Two examples are the two-photon transition $2^3S \rightarrow 3^3S$ at 855 nm and the $2^3S \rightarrow 3^3P$ transition of 389 nm. The power of Doppler-free spectroscopy is shown to advantage in measurements of the $2^3S \rightarrow 2^3P$ transition.[10] Since both ^3S and ^3P are excited levels, the homogeneous width is determined by the sum of the reciprocal lifetimes of the two levels. Since both 2^3S and 2^3P levels are long-lived, the resulting homogeneous width is comparatively narrow. Figure 1*a* shows the Doppler-broadened profile of the $2^3S \rightarrow 2^3P$ transition of ^4He for which the FWHM is about 5.5 GHz. The inhomogeneously broadened line profile shown in Fig. 1*a* also shows three very weak "holes" corresponding to saturated absorption of the Ti-sapphire laser radiation used to carry out the experiment. These components correspond to the $2^3S_1 \rightarrow 3^3P_2$ and $2^3S_1 \rightarrow 3^3P_1$ transitions and their crossover resonance. The amplitude of the saturated signal is some 1–2 percent of the total absorption. The relativistic splittings including spin-orbit coupling of $^3P_0 - {}^3P_1$ and $^3P_1 - {}^3P_2$ are 8.1 GHz and 658.8 MHz, respectively. Frequency modulation of the laser (see Vol. I, Chap. 31 of this *Handbook*) causes the "hole" to be detected as a first derivative of the absorption line, Fig. 1*b.* The observed FWHM of the Doppler-free signals was only 20 MHz. The uncertainty in the measured $2^3S \rightarrow 3^3P$ interval was two parts in 10^9 (i.e., 1.5 MHz), an improvement by a factor of 60 on earlier measurements. A comparison of the experimental results with recent calculations of the non-QED terms[11] gives a value for the one-electron Lamb shift of –346.5 (2.8) MHz, where the uncertainty in the quoted magnitude is in parentheses. The theoretical value is –346.3 (13.9) MHz. Finally, the frequencies of the $2^3S_1 \rightarrow 3^3P_1$, 3^3P_2 transitions were determined to be 25708.60959 (5) cm^{-1} and 25708.58763 (5) cm^{-1}, respectively.

The H^- ion is another two-electron system, of some importance in astrophysics. It is the simplest quantum mechanical three-body species. Approximate quantum mechanical techniques give a wave function and energy eigenvalue which are exact, for all practical purposes. Experimentally, the optical absorption spectrum of H^- is continuous, a property of importance in understanding the opacity of the sun. H^- does not emit radiation in characteristic emission lines. Instead the system sheds its excess (absorbed) energy by ejecting one of the electrons. The radiant energy associated with the ejected electron consists of photons having a continuous energy distribution. Recent measurements with high-intensity pulsed lasers, counterpropagating through beams of 800-MeV H^- ions, have produced spectacular "doubly excited states" of the He^- ion. Such ions are traveling at 84 percent of the velocity of light and, in this situation, the visible laboratory photons are shifted into the vacuum ultraviolet region. At certain energies the H^- ion is briefly excited into a system in which both electrons are excited prior to one of the electrons being ejected. Families of new resonances up to the energy level $N = 8$ have been observed.[12] These resonances are observed as windows in the continuous absorption spectrum, at energies given by a remarkably simple relation reminescent of the Bohr equation for the Balmer series in hydrogen.[13] The resonance line with the lowest energy in each family corresponds to both electrons at comparable distances from the proton.

These experiments on H^- are but one facet of the increasingly sophisticated measurements designed to probe the interaction between radiation and matter driven by experiments in laser technology. "Quantum jump" experiments involving single ions in an electromagnetic trap have become almost commonplace. Chaos has also become a rapidly growing subfield of atomic spectroscopy.[14]

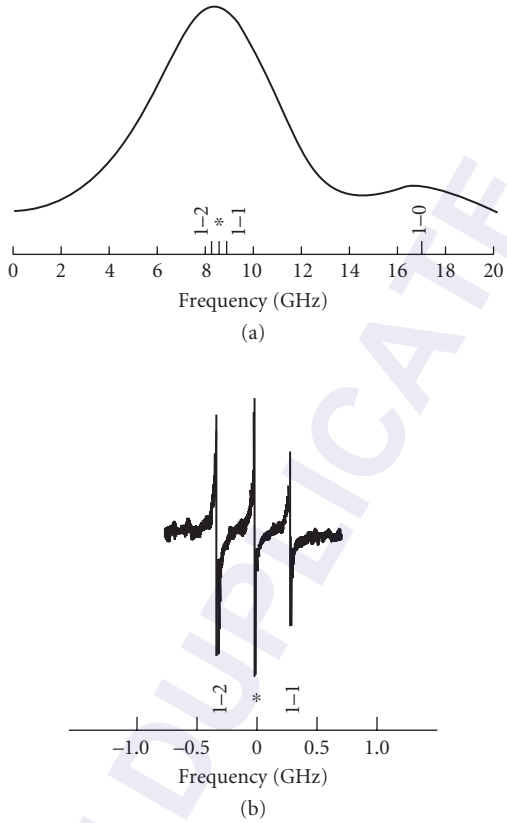

FIGURE 1 (*a*) Inhomogeneously broadened line profile of the $2^3S \rightarrow 2^3P$ absorption in ^4He, including the weak "holes" due to saturated absorption and the position of the $2^3S \rightarrow 2^3P_2$, $^3P_1$, and $^3P_0$ components. (*b*) Doppler-free spectra showing the $2^3S \rightarrow 2^3P_2$, $^3P_1$ transitions, and the associated crossover resonance. (*After Adams, Riis, and Ferguson*.[10])

The particular conditions under which chaos may be observed in atomic physics include hydrogenic atoms in strong homogeneous magnetic fields such that the cyclotron radius of the electron approaches the dimensions of the atomic orbitals. A more easily realizable situation using magnetic field strengths of only a few tesla uses highly excited orbitals close to the ionization threshold. Iu et al.[15] have reported the absorption spectrum of transitions from the 3s state of Li to bound and continuum states near the ionization limit in a magnetic field of approximately six tesla. There is a remarkable coincidence between calculations involving thousands of energy levels and experiments involving high-resolution laser spectroscopy.

Atomic processes play an important role in the energy balance of plasmas, whether they be created in the laboratory or in star systems. The analysis of atomic emission lines gives much information on the physical conditions operating in a plasma. In laser-produced plasmas, the densities of charged ions may be in the range $10^{20} - 10^{25}$ ions cm^{-3}, depending on the pulse duration of the laser. The spectra of many-electron ions are complex and may have the appearance of an unresolved transition

array between states belonging to specific initial and final configurations. Theoretical techniques have been developed to determine the average ionization state of the plasma from the observed optical spectrum. In many cases, the spectra are derived from ionic charge states in the nickel-like configuration containing 28 bound electrons. In normal nickel, the outershell configuration is $(3d^8)(4s^2)$, the 4s levels having filled before 3d because the electron-electron potentials are stronger than electron-nuclear potentials. However, in highly ionized systems, the additional electron-nuclear potential is sufficient to shift the configuration from $(3d^8)(4s^2)$ to the closed shell configuration $(3d^{10})$. The resulting spectrum is then much simpler than for atomic nickel. The Ni-like configuration has particular relevance in experiments to make x-ray lasers. For example, an analog series of collisionally pumped lasers using Ni-like ions has been developed, including a Ta^{45+} laser operating at 4.48 nm and a W^{46+} laser operating at 4.32 nm.[16]

Molecular Spectroscopy

The basic principles of gas-phase molecular spectroscopy were also discussed in "Optical Spectroscopy and Spectroscopic Lineshapes," Vol. I, Chap. 10 of this *Handbook*. The spectra of even the simplest molecules are complicated by the effects of vibrations and of rotations about an axis. This complexity is illustrated elsewhere in this *Handbook* in Fig. 8 of this chapter, which depicts a photographically recorded spectrum of the $2\Pi \rightarrow 3\Sigma$ bands of the diatomic molecule NO, which was interpreted in terms of progressions and line sequences associated with the *P*-, *Q*-, and *R*-branches. The advent of Fourier transform spectroscopy led to great improvements in resolution and greater efficiency in revealing all the fine details that characterize molecular spectra. Figure 2*a* is a Fourier-transform infrared spectrum of nitrous oxide, N_2O, which shows the band center at 2462 cm^{-1} flanked by the *R*-branch and a portion of the *P*-branch; the density of lines in the *P*- and *R*-branch is evident. On an expanded scale, in Fig. 2*b,* there is a considerable simplification of the rotational-vibrational structure at the high-energy portion of the *P*-branch. The weaker lines are the so-called "hot bands."

More precise determinations of the transition frequencies in molecular physics are measured using Lamb dip spectroscopy. The spectrum shown in Fig. 3*a* is a portion of the laser Stark spectrum of methyl fluoride measured using electric fields in the range 20 to 25 KV cm^{-1} with the 9-μm *P*(18) line of the CO_2 laser, which is close to the ν_3 band origin of CH_3F.[17] The spectrum in Fig. 3*a* consists of a set of $\Delta \mathbf{M}_J = \pm 1$ transitions, brought into resonance at different values of the static electric field. Results from the alternative high-resolution technique using a supersonic molecular beam and bolometric detector are shown in Fig. 3*b*: this spectrum was obtained using CH_3F in He mixture expanded through a 35-μm nozzle. The different $\mathbf{M}_J$ components of the *Q*(1, 0), *Q*(2, 1), and *Q*(3, 3) components of the *Q*-branch are shown to have very different intensities relative to those in Fig. 3*a* on account of the lower measurement temperature.

There has been considerable interest in the interaction of intense laser beams with molecules. For example, when a diatomic molecule such as N_2 or CO is excited by an intense (10^{15} W cm^{-2}), ultrashort (0.6 ps) laser pulse, it multiply ionizes and then fragments as a consequence of Coulomb repulsion. The charge and kinetic energy of the resultant ions can be determined by time-of-flight (TOF) mass spectrometry. In this technique, the daughter ions of the "Coulomb explosion" drift to a cathode tube at different times, depending on their weight. In traditional methods, the TOF spectrum is usually averaged over many laser pulses to improve the signal-to-noise ratio. Such simple averaging procedures remove the possibility of correlations between particular charged fragments. This problem was overcome by the *covariance mapping* technique developed by Frasinski and Codling.[18] Experimentally, a linearly polarized laser pulse with **E**-vector pointing toward the detector is used to excite the molecules, which line up with their internuclear axis parallel to the **E**-field. Under Coulomb explosion, one fragment heads toward the detector and the other away from the detector. The application of a dc electric field directs the "backward" fragment ion to the detector, arriving at some short time after the forward fragment. This temporal separation of two fragments arriving at the detector permits the correlation between molecular fragments to be retained. In essence, the TOF spectrum, which plots molecular weight versus counts, is arranged both horizontally (forward ions) and vertically

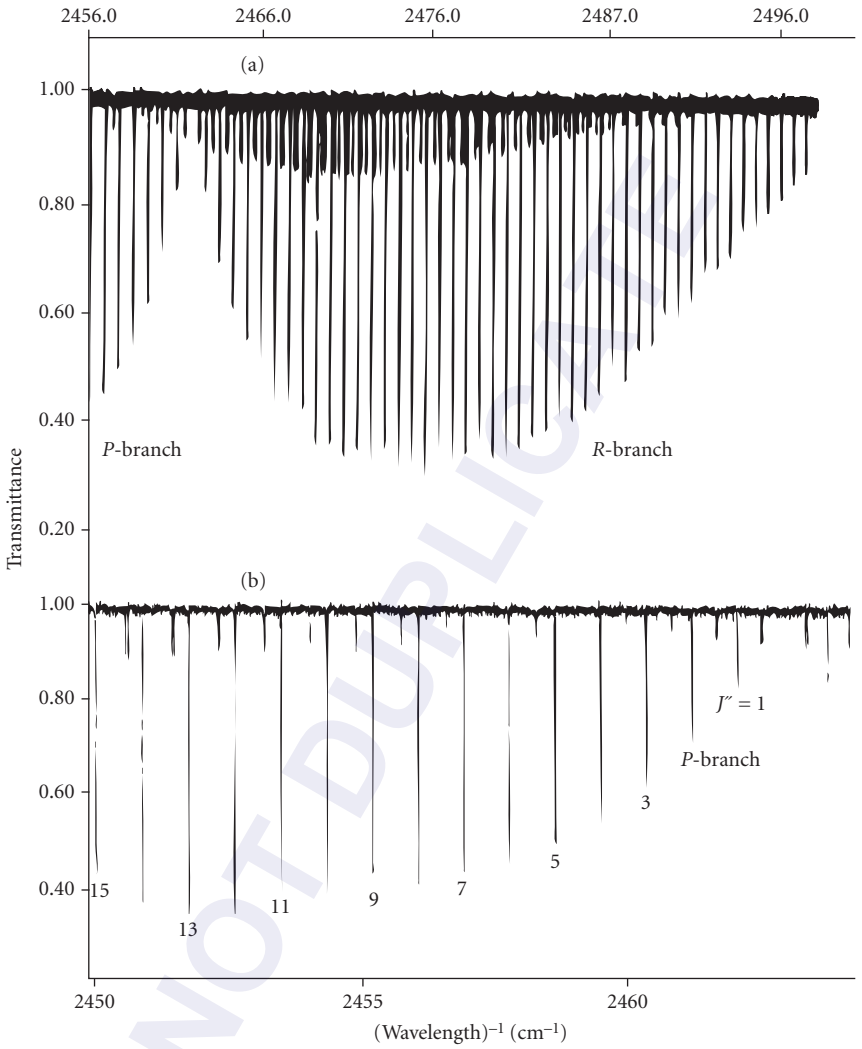

FIGURE 2 (*a*) *P*- and *R*-branches for the nitrous oxide molecule measured using Fourier-transform infrared spectroscopy. The gas pressure was 0.5 torr and system resolution 0.006 cm^{-1}, (*b*) on an expanded scale, the high-energy portion of the *P*-branch up to $J'' = 15$.

(backward ions) on a two-dimensional graph. A coordinate point on a preliminary graph consists of two ions along with their counts during a single pulse. Coordinates from 10^4 pulses or so are then assembled in a final map. Each feature on the final map relates to a specific fragmentation channel, i.e., the pair of fragments and their parent molecule. The strength of the method is that it gives the probability for the creation and fragmentation of the particular parent ion. Covariance mapping experiments on N_2 show that 610- and 305-nm pulses result in fragmentation processes that are predominantly charge-symmetric. In other words, the Coulomb explosion proceeds via the production of ions with the same charge.

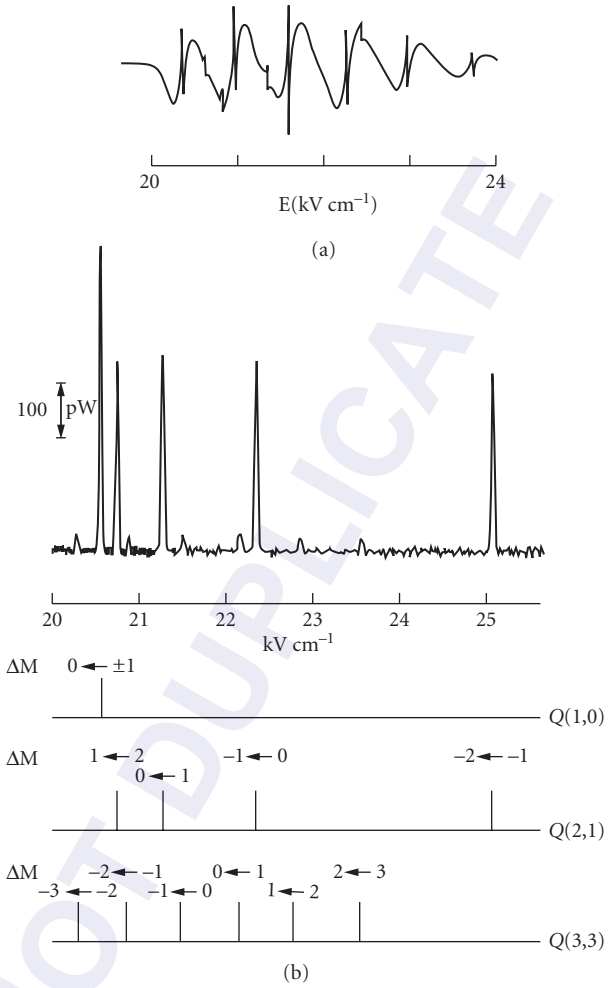

FIGURE 3 (*a*) Laser Stark absorption spectrum of methyl fluoride measured at 300 K using Lamb dip spectroscopy with a gas pressure of 5 mTorr and (*b*) the improved resolution obtained using molecular-beam techniques with low-temperature bolometric detection and CH_3F in He expanded through a 35-μm nozzle. (*After Douketic and Gough.*[17])

Optical Spectroscopy of Solids

One of the more fascinating aspects of the spectroscopy of electronic centers in condensed matter is the variety of lineshapes displayed by the many different systems. Those discussed in Vol. I, Chap. 10 include Nd^{3+} in YAG (Fig. 6), O_2^- in KBr (Fig. 11), Cr^{3+} in YAG (Fig. 12), and F centers in KBr (Fig. 13). The very sharp Nd^{3+} lines (Fig. 6) are zero-phonon lines, inhomogeneously broadened by strain. The abundance of sharp lines is characteristic of the spectra of trivalent rare-earth ions in ionic crystals. Typical low-temperature linewidths for Nd^{3+}: YAG are 0.1–0.2 cm^{-1}. There is particular interest in the spectroscopy of Nd^{3+} because of the efficient laser transitions from the $^4F_{3/2}$ level into the ^4I_j-manifold. The low-temperature luminescence transitions between $^4F_{3,2} \rightarrow {}^4I_{15/2}$, $^4I_{13/2}$, $^4I_{11/2}$, and $^4I_{9/2}$ levels are

shown in Fig. 6: all are split by the effects of the crystalline electric field. Given the relative sharpness of these lines, it is evident that the Slater integrals $F^{(k)}$, spin-orbit coupling parameters ζ, and crystal field parameters, B_t^k, may be measured with considerable accuracy. The measured values of the $F^{(k)}$ and ζ vary little from one crystal to another.[19] However, the crystal field parameters, B_t^k, depend strongly on the rare-earth ion-ligand-ion separation. Most of the $4f^n$ ions have transitions which are the basis of solid-state lasers. Others such as Eu^{3+} and Tb^{3+} are important red-emitting and green-emitting phosphor ions, respectively.[20]

Transition-metal ion spectra are quite different from those of the rare-earth ions. In both cases, the energy-level structure may be determined by solving the Hamiltonian

$$H = H_o + H' + H_{so} + H_c \tag{1}$$

in which H_o is a sum of one-electron Hamiltonians including the central field of each ion, H' is the interaction between electrons in the partially filled $3d^n$ or $4f^n$ orbitals, H_{so} is the spin-orbit interaction, and H_c is the interaction of the outer shell electrons with the crystal field. For rare-earth ions $H', H_{so} \gg H_c$, and the observed spectra very much reflect the free-ion electronic structure with small crystal field perturbations. The spectroscopy of the transition-metal ions is determined by the relative magnitudes of $H' \simeq H_c >> H_{so}$.[19,21] The simplest of the transition-metal ions is Ti^{3+}: in this $3d^1$ configuration a single 3d electron resides outside the closed shells. In this situation, $H' = 0$ and only the effect of H_c needs be considered (Fig. 4*a*). The Ti^{3+} ion tends to form octahedral complexes, where the 3d configuration is split into ^2E and $^2T_2$ states with energy separation $10Dq$. In cation sites with weak, trigonally symmetric distortions, as in Al_2O_3 and $Y_3Al_5O_{12}$, the lowest-lying state, $^2T_2$, splits into $^2A_1$ and ^2E states (using the C_{3v} group symmetry labels). In oxides, the octahedral splitting is of order $10Dq \approx 20{,}000\ cm^{-1}$ and the trigonal field splitting $\nu \simeq 700 - 1000^{-1}$. Further splittings of the levels

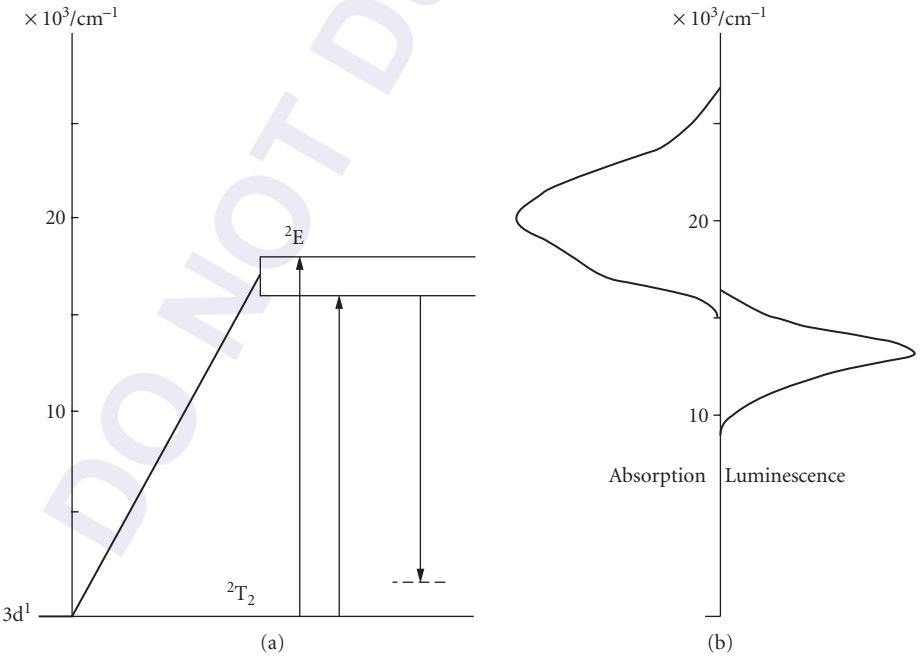

FIGURE 4 Absorption and emission spectra of Ti^{3+} ions [$(3d^1)$ configuration] in Al_2O_3 measured at 300 K.

occur because of spin-orbit coupling and the Jahn-Teller effect. The excited ^2E state splits into $2\bar{A}$ and $\bar{E}$ (from $^2A_1$), and $\bar{E}$ and $2\bar{A}$ (from ^2E). The excited state splitting by a *static* Jahn-Teller effect is large, ~2000 to 2500 cm^{-1}, and may be measured from the optical absorption spectrum. In contrast, ground-state splittings are quite small: a *dynamic* Jahn-Teller effect has been shown to strongly quench the spin-orbit coupling ζ and trigonal field splitting v parameters.[22] In Ti^{3+}: Al_2O_3 the optical absorption transition, $^2T_2 \rightarrow {}^2E$, measured at 300 K, Fig. 4*b,* consists of two broad overlapping bands separated by the Jahn-Teller splitting, the composite band having a peak at approximately 20,000 cm^{-1}. Luminescence occurs only from the lower-lying excited state $2\bar{A}$, the emission band peak occurring at approximately 14,000 cm^{-1}. As Fig. 4 shows, both absorption and emission bands are broad because of strong electron-phonon coupling. At low temperatures the spectra are characterized by weak zero-phonon lines, one in absorption due to transitions from the $2\bar{A}$ ground state and three in emission corresponding to transitions in the $\bar{E}$, and $2\bar{A}$ levels of the electronic ground state.[22, 23] These transitions are strongly polarized.

For ions with $3d^n$ configuration it is usual to neglect H_c and H_{so} in Eq. (1), taking into account only the central ion terms and the Coulomb interaction between the 3d electrons. The resulting energies of the free-ion LS terms are expressed in terms of the Racah parameters *A*, *B*, and *C*. Because energy differences between states are measured in spectroscopy, only *B* and *C* are needed to categorize the free-ion levels. For pure d-functions, $C/B = 4.0$. The crystal field term H_c and H_{so} also are treated as perturbations. In many crystals, the transition-metal ions occupy octahedral or near-octahedral cation sites. The splittings of each free-ion level by an octahedral crystal field depend in a complex manner on *B*, *C*, and the crystal field strength *Dq* given by

$$Dq = \left(\frac{Ze^2}{24\pi\varepsilon_0}\right)\frac{\langle r^4\rangle 3d}{a^5} \tag{2}$$

The parameters *D* and *q* always occur as a product. The energy levels of the $3d^n$ transition-metal ions are usually represented on Tanabe-Sugano diagrams, which plot the energies $E(\Gamma)$ of the electronic states as a function of the octahedral crystal field.[19,21] The crystal field levels are classified by irreducible representations Γ of the octahedral group, O_h. The Tanabe-Sugano diagram for the $3d^3$ configuration, shown in Fig. 5*a*, was constructed using a C/B ratio = 4.8: the vertical broken line drawn at $Dq/B = 2.8$ is appropriate for Cr^{3+} ions in ruby. If a particular value of C/B is assumed, only two variables, *B* and *Dq*, need to be considered: in the diagram $E(\Gamma)/B$ is plotted as a function of Dq/B. The case of ruby, where the ^2E level is below $^4T_2$, is referred to as the *strong field* case. Other materials where this situation exists include $YAlO_3$, $Y_3Al_5O_{12}$ (YAG), and MgO. In many fluorides, Cr^{3+} ions occupy *weak field* sites, where $E(^4T_2) < E(^2E)$ and Dq/B is less than 2.2. When the value of Dq/B is close to 2.3, the *intermediate* crystal field, the $^4T_2$ and ^2E states almost degenerate. The value of Dq/B at the level crossing between $^4T_2$ and ^2E depends slightly on the value of *C*.

The Tanabe-Sugano diagram represents the static lattice. In practice, electron-phonon coupling must be taken into account: the relative strengths of coupling to the states involved in transitions and the consequences may be inferred from Fig. 5*a.* Essentially ionic vibrations modulate the crystal field experienced by the central ion at the vibrational frequency. Large differences in slope of the E versus *Dq* graphs indicate large differences in coupling strengths and hence large homogeneous bandwidths. Hence, absorption and luminescence transitions from the $^4A_2$ ground state to the $^4T_2$ and $^4T_1$ states will be broadband due to the large differences in coupling of the electronic energy to the vibrational energy. For the $^4A_2 \rightarrow {}^2E, {}^2T_1$ transition, the homogeneous linewidth is hardly affected by lattice vibrations, and sharp line spectra are observed.

The Cr^{3+} ion occupies a central position in the folklore of transition-metal ion spectroscopy, having been studied by spectroscopists for over 150 years. An extensive survey of Cr^{3+} luminescence in many compounds was published as early as 1932.[24] The Cr^{3+} ions have the outer shell configuration, $3d^3$, and their absorption and luminescence spectra may be interpreted using Fig. 5. First, the effect of the octahedral crystal field is to remove the degeneracies of the free-ion states ^4F and ^2G. The ground term of the free ion, $^4F_{3/2}$, is split by the crystal field into a ground-state orbital singlet, $^4A_{2g}$, and two orbital triplets $^4T_{2g}$ and $^4T_{1g}$, in order of increasing energy. Using the energy of the $^4A_2$ ground state as the zero, for all values of Dq/B, the energies of the $^4T_{2g}$ and $^4T_{1g}$ states are seen to vary strongly as a function of the octahedral crystal field. In a similar vein, the ^2G free-ion state splits into ^2E, $^2T_1$,

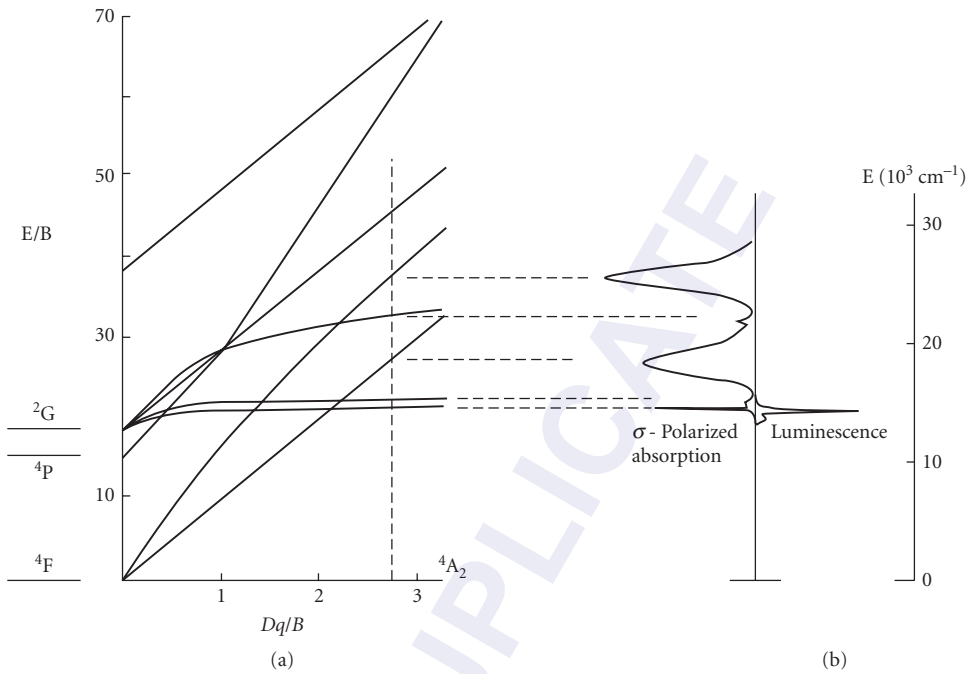

FIGURE 5 Tanabe-Sugano diagram for Cr^{3+} ions with $C/B = 4.8$, appropriate for ruby for which $Dq/B = 2.8$. On the right of the figure are shown the optical absorption and photoluminescence spectrum of ruby measured at 300 K.

$^2T_2$, and $^2A_1$ states, the two lowest of which, ^2E and $^2T_1$, vary very little with Dq. The energies $E(^2T_2)$ and $E(^2A_1)$ are also only weakly dependent on Dq/B . The free-ion term, ^4P, which transforms as the irreducible representation $^4T_1$ of the octahedral group is derived from (e^2t_2) configuration: this term is not split by the octahedral field although its energy is a rapidly increasing function of Dq/B. Low-symmetry distortions lead to strongly polarized absorption and emission spectra.[25]

The σ-polarized optical absorption and luminescence spectra of ruby are shown in Fig. 5*b.* The expected energy levels predicted from the Tanabe-Sugano diagram are seen to coincide with appropriate features in the absorption spectrum. The most intense features are the vibronically broadened $^4A_2 \rightarrow {}^4T_1$, $^4T_2$ transitions. These transitions are broad and characterized by large values of the Huang-Rhys factor ($S \simeq 6-7$). These absorptions occur in the blue and yellow-green regions, thereby accounting for the deep red color of ruby. Many other Cr^{3+}-doped hosts have these bands in the blue and orange-red regions, by virtue of smaller values of Dq/B; the colors of such materials (e.g., MgO, $Gd_3Sc_2Ga_3O_{12}$, $LiSrAlF_6$, etc.) are different shades of green. The absorption transitions, $^4A_2 \rightarrow {}^2E$, $^2T_1$, $^2T_2$ levels are spin-forbidden and weakly coupled to the phonon spectrum ($S < 0.5$). The spectra from these transitions are dominated by sharp zero-phonon lines. However, the low-temperature photoluminescence spectrum of ruby is in marked contrast to the optical absorption spectrum since only the sharp zero-phonon line (R-line) due to the $^2E \rightarrow {}^4A_2$ transition being observed. Given the small energy separations between adjacent states of Cr^{3+}, the higher excited levels decay nonradiatively to the lowest level, ^2E, from which photoluminescence occurs across a bandgap of approximately 15,000 cm^{-1}. Accurate values of the parameters Dq, B, and C may be determined from these absorption data. First, the peak energy of the $^4A_2 \rightarrow {}^4T_2$ absorption band is equal to $10Dq$. The energy shift between the $^4A_2 \rightarrow {}^4T_2$, $^4T_1$ bands is dependent on both Dq and B, and the energy separation between the two broad absorption bands is used to determine B. Finally, the position of the R-line varies with Dq, B, and C: in consequence, once Dq and B are known, the magnitude of C may be determined from the position of the $^4A_2 \rightarrow {}^2E$ zero-phonon line.

This discussion of the spectroscopy of the Cr^{3+} ion is easily extended to other multielectron configurations. The starting points are the Tanabe-Sugano diagrams collected in various texts.[19,21] Analogous series of elements occur in the fifth and sixth periods of the periodic table, respectively, where the $4d^n$ (palladium) and $5d^n$ (platinum) groups are being filled. Compared with electrons in the 3d shell, the 4d and 5d shell electrons are less tightly bound to the parent ion. In consequence, charge transfer transitions, in which an electron is transferred from the cation to the ligand ion (or vice versa), occur quite readily. The charge transfer transitions arise from the movement of electronic charge over a typical interatomic distance, thereby producing a large dipole moment and a concomitant large oscillator strength for the absorption process. For the Fe-group ions ($3d^n$ configuration), such charge transfer effects result in the absorption of ultraviolet photons.

For example, the Fe^{3+} ion in MgO absorbs in a broad structureless band with peak at 220 nm and half-width of order 120 nm (i.e., 0.3 eV). The Cr^{2+} ion also absorbs by charge transfer process in this region. In contrast, the palladium and platinum groups have lower-lying charge transfer states. The resulting intense absorption bands in the visible spectrum may overlap spectra due to low-lying crystal field transitions. Rare-earth ions also give rise to intense charge transfer bands in the ultraviolet region.

Various metal cations have been used as broadband visible region phosphors. For example, transitions between the $4f^n$ and $4f^{(n-1)}$ 5d levels of *divalent* rare-earth ions give rise to intense broad transitions which overlap many of the sharp $4f^n$ transitions of the *trivalent* rare-earth ions. Of particular interest are Sm^{2+}, Dy^{2+}, Eu^{2+}, and Tm^{2+}. In Sm^{2+} ($4f^6$) broadband absorption transitions from the ground state $^7F_1$ to the $4f^5$ 5d level may result in either broadband emission (from the vibronically relaxed $4f^5$ 5d level) or sharp line emission from $^5D_0$ ($4f^6$) depending upon the host crystal. The $4f^5$ 5d level, being strongly coupled to the lattice, accounts for this variability. There is a similar material-by-material variation in the absorption and emission properties of the Eu^{2+} ($4f^7$ configuration), which has the $^8S_{7/2}$ ground level. The next highest levels are derived from the $4f^6$ 5d state, which is also strongly coupled to the lattice. This state is responsible for the varying emission colors of Eu^{2+} in different crystals, e.g., violet in $Sr_2P_2O_7$, blue in $BaAl_{12}O_{19}$, green in $SrAl_2O_4$, and yellow in Ba_2SiO_5.

The heavy metal ions Tl^+, In^+, Ga^+, Sn^{2+}, and Pb^{2+} may be used as visible-region phosphors. These ions all have two electrons in the ground configuration ns^2 and excited configurations $(ns)(np)$. The lowest-lying excited states, in the limit of Russell Saunders coupling, are then $^1S_0(ns^2)$, $^3P_{0,1,2}$, and $^1P_1$ from $(ns)/(np)$. The spectroscopy of Tl^+ has been much studied especially in the alkali halides. Obviously $^1S_0 \rightarrow {}^1P_1$ is the strongest absorption transition, occurring in the ultraviolet region. This is labeled as the *C*-band in Fig. 6. Next in order of observable intensity is the *A*-band, which is a spin-forbidden absorption transition $^1S_0 \rightarrow {}^3P_1$, in which the relatively large oscillator strength is borrowed from the $^1P_1$ state by virtue of the strong spin-orbit interaction in these heavy metal ions. The *B* and *D* bands, respectively, are due to absorption transitions from $^1S_0$ to the $^3P_2$ and $^3P_0$ states induced by vibronic mixing.[26] A phenomenological theory[26,27] quantitatively accounts for both absorption spectra and the triplet state emission spectra.[28,29]

The examples discussed so far have all concerned the spectra of ions localized in levels associated with the central fields of the nucleus and closed-shells of electrons. There are other situations which warrant serious attention. These include electron-excess centers in which the positive potential of an anion vacancy in an ionic crystal will trap one or more electrons. The simplest theory treats such a *color center* as a particle in a finite potential well.[19,27] The simplest such center is the *F*-center in the alkali halides, which consist of one electron trapped in an anion vacancy. As we have already seen (e.g., Fig. 13 in "Optical Spectroscopy and Spectroscopic Lineshapes", Vol. I, Chap. 10 of this *Handbook*), such centers give rise to broadbands in both absorption and emission, covering much of the visible and near-infrared regions for alkali halides. *F*-aggregate centers, consisting of multiple vacancies arranged in specific crystallographic relationships with respect to one another, have also been much studied. They may be positive, neutral, or negative in charge relative to the lattice depending upon the number of electrons trapped by the vacancy aggregate.[30]

Multiquantum wells (MQWs) and strained-layer superlattices (SLSs) in semiconductors are yet another type of *finite-well* potential. In such structures, alternate layers of two different semiconductors are grown on top of each other so that the bandgap varies in one dimension with the periodicity

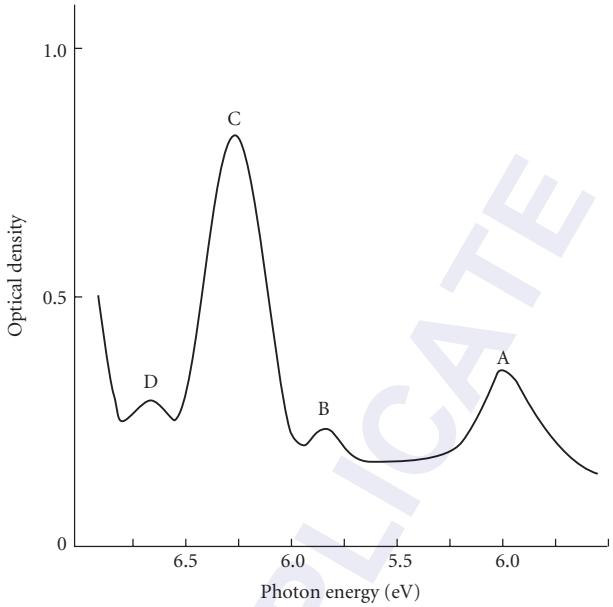

FIGURE 6 Ultraviolet absorption spectrum of Tl^+ ions in KCl measured at 77 K. (*After Delbecq et al.*[26])

of the epitaxial layers. A modified Kronig-Penney model is often used to determine the energy eigenvalues of electrons and holes in the conduction and valence bands, respectively, of the narrower gap material. Allowed optical transitions between valence band and conduction band are then subject to the selection rule $\Delta n = 0$, where $n = 0, 1, 2$, etc. The example given in Fig. 7 is for SLSs in the II–VI family of semiconductors ZnS/ZnSe.[31] The samples were grown by metalo-organic vapor phase epitaxy[32]

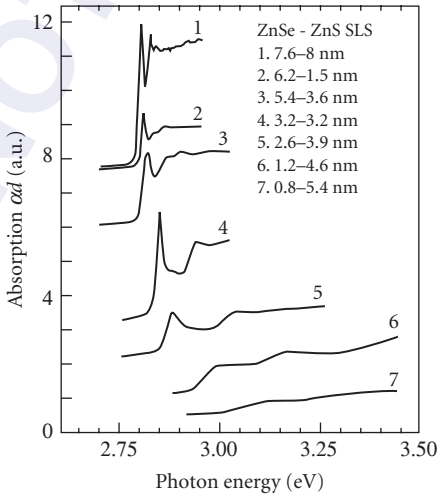

FIGURE 7 Optical absorption spectra of SLSs of ZnS/ZnSe measured at 14 K. (*After Fang et al.*[31])

with a superlattice periodicity of 6 to 8 nm while varying the thickness of the narrow gap material (ZnSe) between 0.8 and 7.6 nm. The splitting between the two sharp features occurs because the valence band states are split into "light holes" (lh) and "heavy holes" (hh) by spin-orbit interaction. The absorption transitions then correspond to transitions from the $n = 1$ lh- and hh-levels in the valence band to the $n = 1$ electron states in the conduction band. Higher-energy absorption transitions are also observed. After absorption, electrons rapidly relax down to the $n = 1$ level from which emission takes place down to the $n = 1$, lh-level in the valence band, giving rise to a single emission line at low temperature.

2.4 THE HOMOGENEOUS LINESHAPE OF SPECTRA

Atomic Spectra

The homogeneous widths of atomic spectra are determined by the uncertainty principle, and hence by the radiative decaytime, τ_R (as discussed in Vol. I, Chap. 10, "Optical Spectroscopy and Spectroscopic Lineshapes"). Indeed, the so-called natural or homogeneous width of $\Delta\omega$, is given by the Einstein coefficient for spontaneous emission, $A_{ba} = (\tau_R)^{-1}$. The homogeneously broadened line has a Lorentzian lineshape with FWHM given by $(\tau_R)^{-1}$. In gas-phase spectroscopy, atomic spectra are also broadened by the Doppler effect: random motion of atoms broadens the lines in-homogeneously leading to a guassian-shaped line with FWHM proportional to $(T/M)^{-1/2}$, where T is the absolute temperature and M the atomic mass. Saturated laser absorption or optical hole-burning techniques are among the methods which recover the true homogeneous width of an optical transition. Experimental aspects of these types of measurement were discussed in this *Handbook* in Vol. I, Chap. 31, "Optical Spectroscopy," and examples of Doppler-free spectra (Figs. 1 and 3, Vol. I, Chap. 10) were discussed in terms of the fundamental tests of the quantum and relativistic structure of the energy levels of atomic hydrogen. Similar measurements were also discussed for the case of He (Fig. 1) and in molecular spectroscopy (Fig. 3). In such examples, the observed lineshape is very close to a true Lorentzian, typical of a lifetime-broadened optical transition.

Zero-Phonon Lines in Solids

Optical hole burning (OHB) reduces the effects of inhomogeneous broadening in solid-state spectra. For rare-earth ions, the homogeneous width amounts to some 0.1–1.0 MHz, the inhomogeneous widths being determined mainly by strain in the crystal. Similarly, improved resolution is afforded by fluorescence line narrowing (FLN) in the R-line of Cr^{3+} (Vol. I, Chap. 10, Fig. 12). However, although the half-width measured using OHB is the true homogeneous width, the observed FLN half-width, at least in resonant FLN, is a convolution of the laser width and twice the homogeneous width of the transition.[33] In solid-state spectroscopy, the underlying philosophy of OHB and FLN experiments may be somewhat different from that in atomic and molecular physics. In the latter cases, there is an intention to relate theory to experiment at a rather sophisticated level. In solids, such high-resolution techniques are used to probe a range of other dynamic processes than the natural decay rate. For example, hole-burning may be induced by photochemical processes as well as by intrinsic lifetime processes.[34,35] Such photochemical hole-burning processes have potential in optical information storage systems. OHB and FLN may also be used to study distortions in the neighborhood of defects. Figure 8 is an example of Stark spectroscopy and OHB on a zero-phonon line at 607 nm in irradiated NaF.[34] This line had been attributed to an aggregate of four F-centers in nearest-neighbor anion sites in the rocksalt-structured lattice on the basis of the polarized absorption/emission measurements. The homogeneous width in zero electric field was only 21 MHz in comparison with the inhomogeneous width of 3 GHz. Interpretation of these results is inconsistent with the four-defect model.

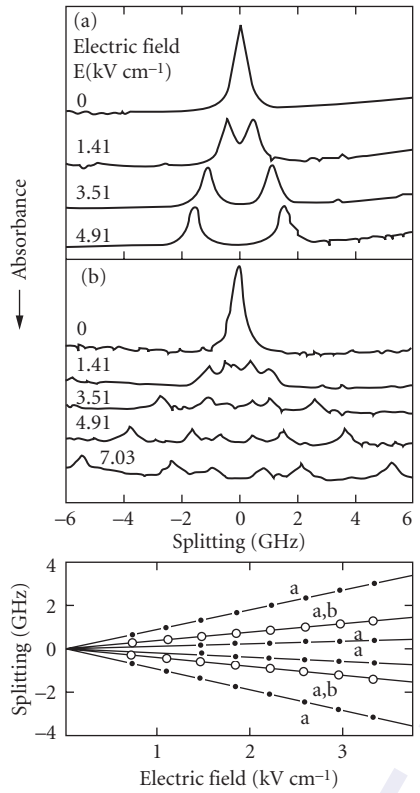

FIGURE 8 Effects of an applied electric field in a hole burned in the 607-nm zero-phonon line observed in irradiated NaF. (*After Macfarlane et al.*[22])

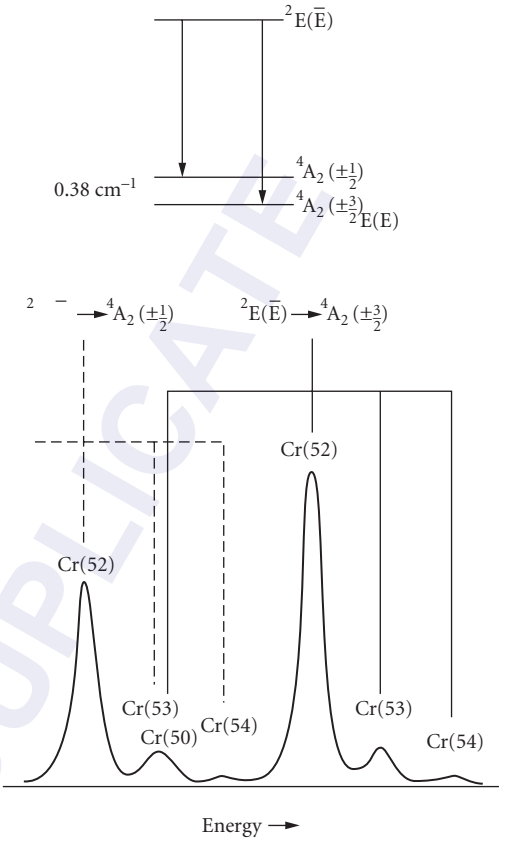

FIGURE 9 Fine structure splitting in the $^4A_2$ ground state and the isotope shifts of Cr^{3+} in the R_1-line of ruby measured using FLN spectroscopy. (*After Jessop and Szabo.*[36])

The FLN technique may also be used to measure the effects of phonon-induced relaxation processes and isotope shifts. Isotope and thermal shifts have been reported for Cr^{3+}:Al_2O_3[36] and Nd^{3+}:$LaCl_3$.[37] The example given in Fig. 9 shows both the splitting in the ground $^4A_2$ state of Cr^{3+} in ruby and the shift between lines due to the Cr(50), Cr(52), Cr(53), and Cr(54) isotopes. The measured differential isotope shift of 0.12 cm^{-1} is very close to the theoretical estimate.[19] Superhyperfine effects by the 100 percent abundant Al isotope with $I = 5/2$ also contribute to the homogeneous width of the FLN spectrum of Cr^{3+} in Al_2O_3 (Fig. 12 in Vol. I, Chap. 10).[36] Furthermore, in antiferromagnetic oxides such as $GdAlO_3$, $Gd_3Ga_5O_{12}$, and $Gd_3Sc_2Ga_3O_{12}$, spin-spin coupling between the Cr^{3+} ions ($S = 3/2$) and nearest-neighbor Gd^{3+} ions ($S = 3/2$) contributes as much to the zero-phonon R-linewidth as inhomogeneous broadening by strain.[38]

Configurational Relaxation in Solids

In the case of the broadband $^4T_2 \rightarrow {}^4A_2$ transition of Cr^{3+} in YAG (Fig. 12 in Vol. I, Chap. 10) and MgO (Fig. 6), the application of OHB and FLN techniques produce no such narrowing because the

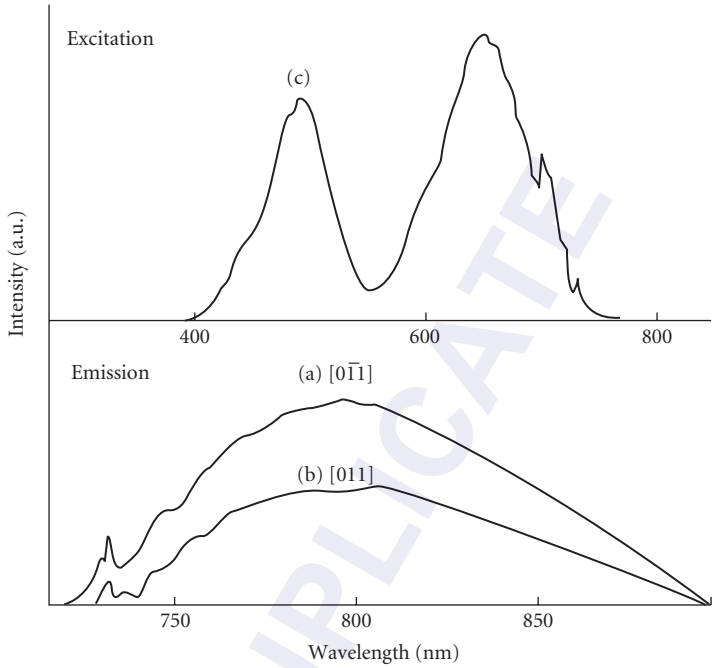

FIGURE 10 Polarized emission of the $^4T_2 \rightarrow {}^4A_2$ band from Cr^{3+} ions in orthorhombic sites in MgO. Shown also, (*c*) is the excitation spectrum appropriate to (*a*). (*After Yamaga et al.*[48])

vibronic sideband is the homogeneously broadened shape determined by the phonon lifetime rather than the radiative lifetime. It is noteworthy that the vibronic sideband emission of Cr^{3+} ions in orthorhombic sites in MgO, Fig. 10, shows very little structure. In this case, the Huang-Rhys factor $S \simeq 6$, i.e, the strong coupling case, where the multiphonon sidebands tend to lose their separate identities to give a smooth bandshape on the lower-energy side of the peak. By way of contrast, the emission sideband of the *R*-line transition of Cr^{3+} ions in octahedral sites in MgO is very similar in shape to the known density of one-phonon vibrational modes of MgO[39] (Fig. 11), although there is a difference in the precise positions of the peaks, because the Cr^{3+} ion modifies the lattice vibrations in its neighborhood relative to those of the perfect crystal. Furthermore, there is little evidence in Fig. 11 of higher-order sidebands which justifies treating the MgO *R*-line process in the weak coupling limit. The absence of such sidebands suggests that $S < 1$, as the discussion in "Optical Spectroscopy and Spectroscopic Lineshapes" (Vol. I, Chap. 10 of this *Handbook*) showed. That the relative intensities of the zero-phonon line and broadband, which should be about e^{-s}, is in the ratio 1:4 shows that the sideband is induced by odd parity phonons. In this case it is partially electric-dipole in character, whereas the zero-phonon line is magnetic-dipole in character.[19]

There has been much research on bandshapes of Cr^{3+}-doped spectra in many solids. This is also the situation for *F*-centers and related defects in the alkali halides. Here, conventional optical spectroscopy has sometimes been supplemented by laser Raman and sub-picosecond relaxation spectroscopies to give deep insights into the dynamics of the optical pumping cycle. The *F*-center in the alkali halides is a halide vacancy that traps an electron. The states of such a center are reminiscent of a particle in a finite potential well[19] and strong electron-phonon coupling. Huang-Rhys factors in the range $S = 15 - 40$ lead to broad, structureless absorption/luminescence bands with large Stokes

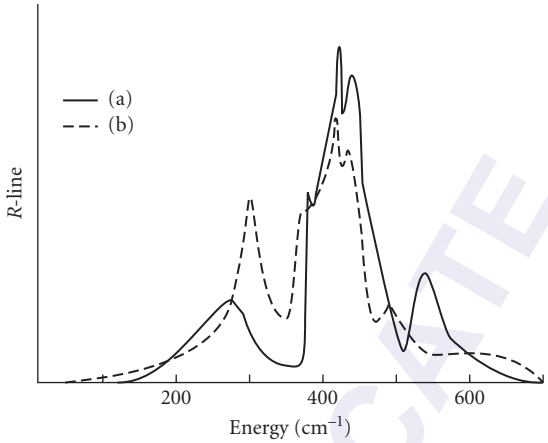

FIGURE 11 A comparison of (*a*) the vibrational sideband accompanying the $^2E \rightarrow {}^4A_2$ *R*-line of Cr^{3+}: MgO with (*b*) the density of phonon modes in MgO as measured by Peckham et al.,[39] using neutron scattering. (*After Henderson and Imbusch.*[19])

shifts (see Fig. 13 in Vol. I, Chap. 10). Raman-scattering measurements on *F*-centers in NaCl and KCl (Fig. 23 in Vol. I, Chap. 31), showed that the first-order scattering is predominantly due to defect-induced local modes.[40]

The F_A-center is a simple variant on the *F*-center in which one of the six nearest cation neighbors of the *F*-center is replaced by an alkali impurity.[41] In KCl the K^+ may be replaced by Na^+ or Li^+. For the case of the Na^+ substituent, the F_A(Na) center has tetragonal symmetry about a ⟨100⟩ crystal axis, whereas in the case of Li^+ an off-axis relaxation in the excited state leads to interesting polarized absorption/emission characteristics.[19,41] The most dramatic effect is the enormous Stokes shift between absorption and emission bands, of order 13,000 cm^{-1}, which has been used to advantage in color center lasers.[42,43] For F_A (Li) centers, configurational relaxation has been probed using picosecond relaxation and Raman-scattering measurements. Mollenauer et al.[44] used the experimental system shown in Fig. 10 in Vol. I, Chap. 31 to carry out measurements of the configurational relaxation time of F_A(Li) centers in KCl. During deexcitation many phonons are excited in the localized modes coupled to the electronic states which must be dissipated into the continuum of lattice modes. Measurement of the relaxation time constitutes a probe of possible phonon damping. A mode-locked dye laser producing pulses of 0.7-ps duration at 612 nm was used both to pump the center in the F_{A2}-absorption band and to provide the timing beam. Such pumping leads to optical gain in the luminescence band and prepares the centers in their relaxed state. The probe beam, collinear with the pump beam, is generated by a CW F_A(Li)-center laser operating at 2.62 μm. The probe beam and gated pulses from the dye laser are mixed in a non-linear optical crystal (lithium iodate). A filter allows only the sum frequency at 496 nm to be detected. The photomultiplier tube then measures the rise in intensity of the probe beam which signals the appearance of gain where the F_A(Li)-centers have reached the relaxed excited state. The pump beam is chopped at low frequency to permit phase-sensitive detection. The temporal evolution of F_A(Li)-center gains (Fig. 12*a* and *b*) was measured by varying the time delay between pump and gating pulses. In this figure, the solid line is the instantaneous response of the system, whereas in *b* the dashed line is the instantaneous response convolved with a 1.0-ps rise time.

Measurements of the temperature dependence of the relaxation times of F_A(Li)-centers in potassium chloride (Fig. 12*c*) show that the process is very fast, typically of order 10 ps at 4 K. Furthermore, configurational relaxation is a multiphonon process which involves mainly the creation of some 20 low-energy phonons of energy $E_p/hc \simeq 47\,cm^{-1}$. That only about $(20 \times 47/8066)\,eV = 0.1\,eV$ deposited into the 47 cm^{-1} mode, whereas 1.6 eV of optical energy is lost to the overall relaxation process, indicates

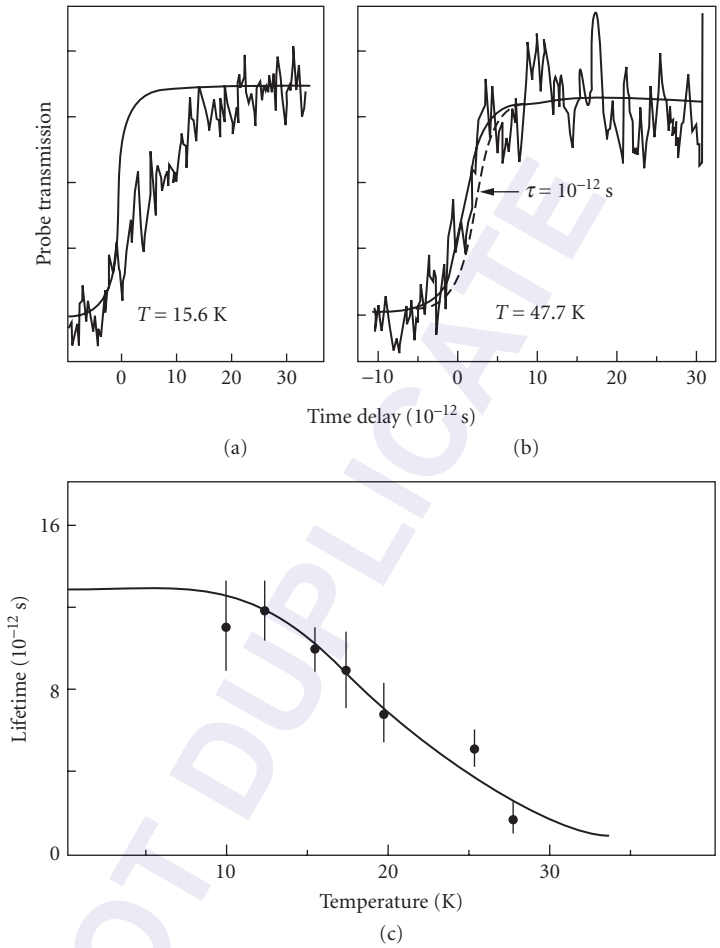

FIGURE 12 (*a*) Temporal evolution of gain in the F_A(Li) center emission in picosecond pulse probe measurements; (*b*) the temperature-dependence of the gain process; and (*c*) temperature dependence of the relaxation time. (*After Mollenauer et al.* [44])

that other higher-energy modes of vibrations must be involved.[44] This problem is resolved by Raman-scattering experiments. For F_A(Li)-centers in potassium chloride, three sharp Raman-active local modes were observed with energies of 47 cm^{-1}, 216 cm^{-1}, and 266 cm^{-1}, for the ^{7}Li isotope.[45] These results and later polarized absorption/luminescence studies indicated that the Li^+ ion lies in an off-center position in a $\langle 110 \rangle$ crystal direction relative to the z axis of the F_A center. Detailed polarized Raman spectroscopy resonant and nonresonant with the F_A-center absorption bands are shown in Fig. 13.[46] These spectra show that under resonant excitation in the F_{A1} absorption band, each of the three lines due to the sharp localized modes is present in the spectrum. The polarization dependence confirms that the 266 cm^{-1} mode is due to Li^+ ion motion in the mirror plane and parallel to the defect axis. The 216 cm^{-1} mode is stronger under nonresonant excitation, reflecting the off-axis vibrations of the Li^+ ion vibrating in the mirror plane perpendicular to the z axis. On the other hand, the low-frequency mode is an amplified band mode of the center which hardly involves the motion of the Li^+ ion.

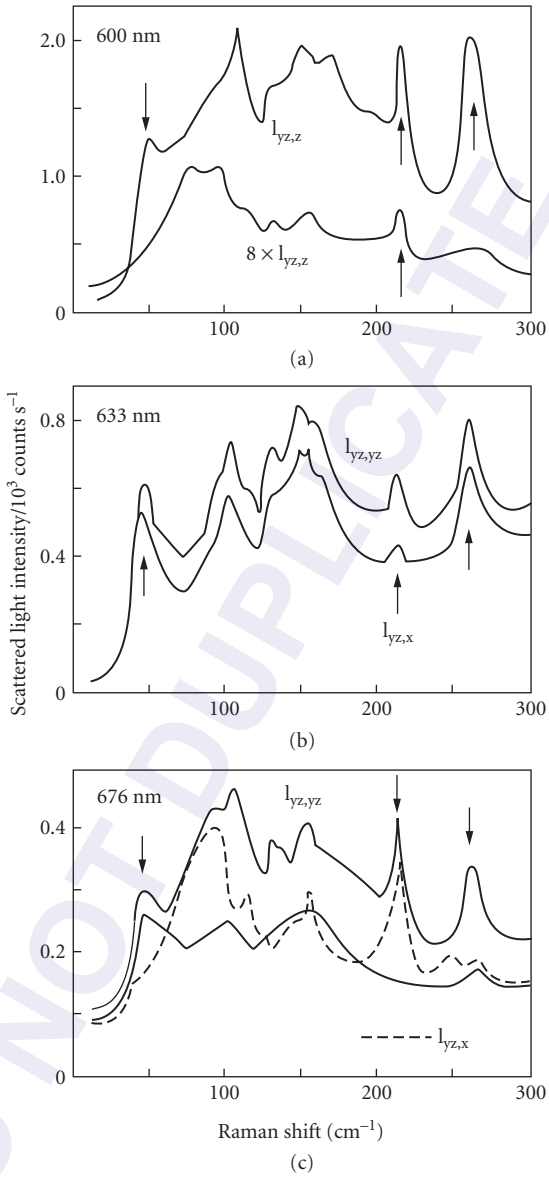

FIGURE 13 Raman spectra of F_A (Li) centers in potassium chloride measured at 10 K for different senses of polarization. In (*a*) the excitation wavelength $\lambda = 600$ nm is midway between the peaks of the F_{A1} bands; (*b*) $\lambda = 632.8$ nm is resonant with the F_{A1} band; and (*c*) $\lambda = 676.4$ nm is nonresonant. (*After Joosen et al.*[44])

2.5 ABSORPTION, PHOTOLUMINESCENCE, AND RADIATIVE DECAY MEASUREMENTS

The philosophy of solid-state spectroscopy is subtly different from that of atomic and molecular spectroscopies. It is often required not only to determine the nature of the absorbing/emitting species but also the symmetry and structure of the local environment. Also involved is the interaction of the electronic center with other neighboring ions, which leads to lineshape effects as well as time-dependent phenomena. The consequence is that a combination of optical spectroscopic techniques may be used in concert. This general approach to optical spectroscopy of condensed matter phenomena is illustrated by reference to the case of Al_2O_3 and MgO doped with Cr^{3+}.

Absorption and Photoluminescence of Cr^{3+} in Al_2O_3 and MgO

The absorption and luminescence spectra may be interpreted using the Tanabe-Sugano diagram shown in Fig. 5, as discussed previously. Generally, the optical absorption spectrum of Cr^{3+}: Al_2O_3 (Fig. 14) is dominated by broadband transitions from the $^4A_2 \rightarrow {}^4T_2$ and $^4A_2 \rightarrow {}^4T_1$. The crystal used in this measurement contained some 10^{18} Cr^{3+} ions cm^{-3}. Since the absorption coefficient at the peak of the $^4A_2 \rightarrow {}^4T_2$ band is only 2 cm^{-1}, it is evident from Eq. (6) in Chap. 31, "Optical Spectrometers," in Vol. I, that the cross section at the band peak is $\sigma_o \cong 5 \times 10^{-19} cm^2$. The spin-forbidden absorption transitions $^4A_2 \rightarrow {}^2E$, $^2T_1$ are just distinguished as weak absorptions ($\sigma_o \sim 10^{21} cm^2$) on the long-wavelength side of the $^4A_2 \rightarrow {}^4T_2$ band. This analysis strictly applies to the case of octahedral symmetry. Since the cation site in ruby is distorted from perfect octahedral symmetry, there are additional electrostatic energy terms associated with this reduced symmetry. One result of this distortion, as illustrated in Fig. 14, is that the absorption and emission spectra are no longer optically isotropic. By measuring the peak shifts of the $^4A_2 \rightarrow {}^4T_2$ and $^4A_2 \rightarrow {}^4T_1$ absorption transitions between π and σ senses of polarization, the trigonal field splittings of the $^4T_2$ and $^4T_1$ levels may be determined.[25]

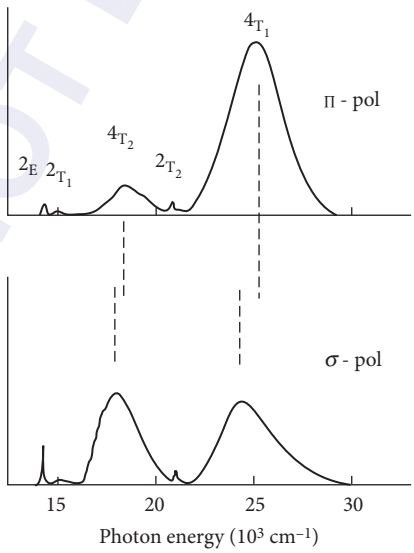

FIGURE 14 Polarized optical absorption spectrum of a ruby Cr^{3+}:Al_2O_3 crystal containing $2 \times 10^{18} Cr^{3+}$ ions cm^{-3} measured at 77 K.

The Cr^{3+} ion enters the MgO substitutionally for the Mg^{2+} ion. The charge imbalance requires that for every two impurity ions there must be one cation vacancy. At low-impurity concentrations, charge-compensating vacancies are mostly remote from the Cr^{3+} ions. However, some 10 to 20 percent of the vacancies occupy sites close to individual Cr^{3+} ions, thereby reducing the local symmetry from octahedral to tetragonal or orthorhombic.[19] The optical absorption spectrum of Cr^{3+} : MgO is also dominated by broadband $^4A_2 \rightarrow {}^4T_2$, $^4T_1$ transitions; in this case, there are overlapping contributions from Cr^{3+} ions in three different sites. There are substantial differences between the luminescence spectra of Cr^{3+} in the three different sites in MgO (Fig. 15), these overlapping spectra being determined by the ordering of the $^4T_2$ and ^2E excited states. For strong crystal fields, $Dq/B > 2.5$, ^2E lies lowest and nonradiative decay from $^4T_1$ and $^4T_2$ levels to ^2E results in very strong emission in the sharp *R*-lines, with rather weaker vibronic sidebands. This is the situation from Cr^{3+} ions in octahedral and tetragonal sites in MgO.[19] The $^2E \rightarrow {}^4A_2$ luminescence transition is both spin- and parity-forbidden (see Vol. I, Chap. 10) and this is signaled by relatively long radiative lifetimes—11.3 ms for octahedral sites and 8.5 ms for tetragonal sites at 77 K. This behavior is in contrast to that of Cr^{3+} in orthorhombic sites, for which the $^4T_2$ level lies below the ^2E level. The stronger electron-phonon coupling for the $^4T_2 \rightarrow {}^4A_2$ transition at

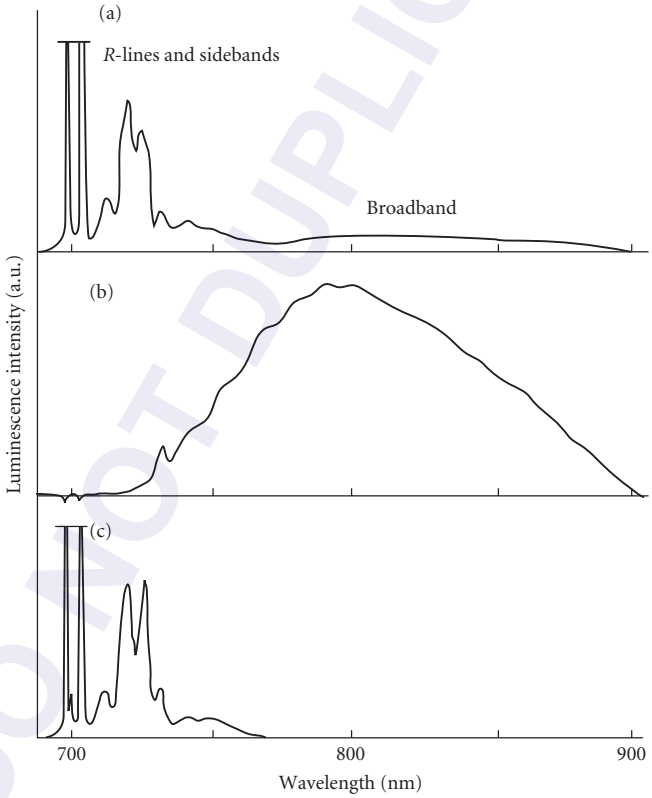

FIGURE 15 Photoluminescence spectra of Cr^{3+} : MgO using techniques of phase-sensitive detection. In (*a*) the most intense features are sharp *R*-lines near 698 to 705 nm due to Cr^{3+} ions at sites with octahedral and tetragonal symmetry; a weak broadband with peak at 740 nm is due to Cr^{3+} ions in sites of orthorhombic symmetry. By adjusting the phase-shift control on the lock-in amplifier (Fig. 4 in Vol. I, Chap. 31), the relative intensities of the three components may be adjusted as in parts (*b*) and (*c*).

orthorhombic sites leads to a broadband luminescence with peak at 790 nm. Since this is a spin-allowed transition, the radiative lifetime is much shorter—only 35 μs.[47]

As noted previously the decay time of the luminescence signals from Cr^{3+} ions in octahedral and tetragonal symmetry are quite similar, and good separation of the associated *R*-lines using the phase-nulling technique are then difficult. However, as Fig. 15 shows, good separation of these signals from the $^4T_2 \rightarrow {}^4A_2$ broadband is very good. This follows from the applications of Eqs. (8) through (12) in Vol. I, Chap. 31. For Cr^{3+} ions in cubic sites, the long lifetime corresponds to a signal phase angle of 2°: the *R*-line intensity can be suppressed by adjusting the detector phase angle to (90° + 2°). In contrast, the Cr^{3+} ions in orthorhombic sites give rise to a phase angle of 85°: this signal is reduced to zero when $\phi_D = (90° + 85°)$.

Excitation Spectroscopy

The precise positions of the $^4A_2 \rightarrow {}^4T_2$, $^4T_1$ absorption peaks corresponding to the sharp lines and broadbands in Fig. 15 may be determined by excitation spectroscopy (see Vol. I, Chap. 31). An example of the application of this technique is given in Fig. 10, which shows the emission band of the $^4T_2 \rightarrow {}^4A_2$ transition at centers with orthorhombic symmetry, Figs. 10*a* and *b*, and its excitation spectrum, Fig. 10*c*.[47] The latter was measured by setting the wavelength of the detection spectrometer at $\lambda = 790$ nm, i.e., the emission band peak, and scattering the excitation monochromator over the wavelength range 350 to 750 nm of the Xe lamp. Figure 10 gives an indication of the power of excitation spectroscopy in uncovering absorption bands not normally detectable under the much stronger absorptions from cubic and tetragonal centers. Another example is given in Fig. 16—in this case, of recombining excitons in the smaller gap material (GaAs) in GaAs/AlGaAs quantum wells. In this case, the exciton luminescence peak energy, $h\nu_x$, is given by

$$h\nu_x = E_G + E_{1e} + E_{1h} + E_b \tag{3}$$

where E_G is the bandgap of GaAs, E_{1e} and E_{1h} are the $n = 1$ state energies of electrons (e) and holes (h) in conduction and valence bands, respectively, and E_b is the electron-hole binding energy. Optical transitions involving electrons and holes in these structures are subject to the $\Delta n = 0$ selection rule. In consequence, there is a range of different absorption transitions at energies above the bandgap. Due to the rapid relaxation of energy in levels with $n > 1$, the recombination luminescence occurs between the $n = 1$ electron and hole levels only, in this case at 782 nm. The excitation spectrum in which this luminescence is detected and excitation wavelength varied at wavelengths shorter than 782 nm reveals the presence of absorption transitions above the bandgap. The first absorption transition shown is the 1lh $\rightarrow$ 1*e* transition, which occurs at slightly longer wavelength than the 1hh $\rightarrow$ 1*e* transition. The light hole (lh)-heavy hole (hh) splitting is caused by spin-orbit splitting and strain in these epilayer structures. Other, weaker transitions are also discernible at higher photon energies.

Polarization Spectroscopy

The discussions on optical selection rules, in Vol. 1, Chaps. 10 and 31, showed that when a well-defined axis is presented, the strength of optical transitions may depend strongly on polarization. In atomic physics the physical axis is provided by an applied magnetic field (Zeeman effect) or an applied electric field (Stark effect). Polarization effects in solid-state spectroscopy may be used to give information about the site symmetry of optically active centers. The optical properties of octahedral crystals are normally isotropic. In this situation, the local symmetry of the center must be lower than octahedral so that advantage may be taken of the polarization-sensitivity of the selection rules. Several possibilities exist in noncubic crystals. If the local symmetry of all centers in the crystal point in the same direction, then the crystal as a whole displays an axis of symmetry. Sapphire (Al_2O_3) is an example, in which the Al^{3+} ions occupy trigonally distorted octahedral sites. In consequence, the optical absorption and luminescence spectra of ions in this crystal are naturally polarized. The observed π- and σ-polarized absorption spectra of ruby shown in Fig. 14 are in general agreement with the calculated selection rules,[25]

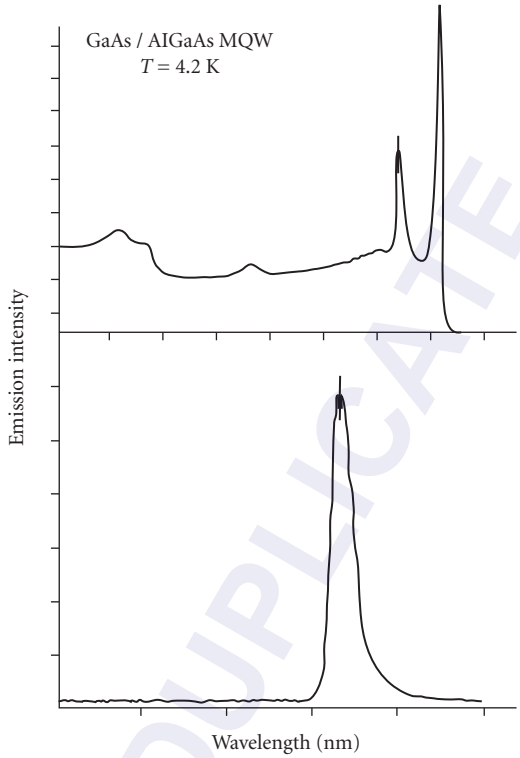

FIGURE 16 Luminescence spectrum and excitation spectrum of multiple quantum wells in GaAs/AlGaAs samples measured at 6 K. (*P. Dawson, 1986 private communication to the author.*)

although there are undoubtedly vibronic processes contributing to these broadband intensities.[47] The other important ingredient in the spectroscopy of the Cr^{3+} ions in orthorhombic symmetry sites in MgO is that the absorption and luminescence spectra are strongly polarized. It is then quite instructive to indicate how the techniques of polarized absorption/luminescence help to determine the symmetry axes of the dipole transitions. The polarization of the ${}^4T_2 \rightarrow {}^4A_2$ emission transition in Fig. 10 is clear. In measurements employing the "straight-through" geometry, Henry et al.[47] reported the orientation intensity patterns shown in Fig. 17 for the broadband spectrum. A formal calculation of the selection rules and the orientation dependence of the intensities shows that the intensity at angle θ is given by

$$I(\theta) = (A_\pi - A_\sigma)(E_\pi - E_\sigma) \sin^2\left(\theta + \frac{\pi}{4}\right) + \text{constant} \tag{4}$$

where A and E refer to the absorbed and emitted intensities for π- and σ-polarizations.[48] The results in Fig. 17 are consistent with the dipoles being aligned along $\langle 110 \rangle$ directions of the octahedral MgO lattice. This is in accord with the model of the structure of the Cr^{3+} ions in orthorhombic symmetry, which locates the vacancy in the nearest neighbor cation site relative to the Cr^{3+} ion along a $\langle 110 \rangle$ direction.

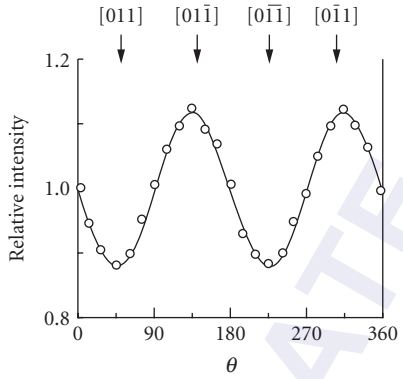

FIGURE 17 The polarization characteristics of the luminescence spectrum of Cr^{3+} ions in orthorhombic sites in Cr^{3+}: MgO. (*After Henry et al.*[47])

Zeeman Spectroscopy

The Zeeman effect is the splitting of optical lines by a static magnetic field due to the removal of the spin degeneracy of levels involved in the optical transitions. In many situations the splittings are not much larger than the optical linewidth of zero-phonon lines and much less than the width of vibronically broadened bands. The technique of optically detected magnetic resonance (ODMR) is then used to measure the Zeeman splittings. As we have already shown, ODMR also has the combined ability to link inextricably, an excited-state ESR spectrum with an absorption band and a luminescence band. The spectrum shown in Fig. 16 in Vol. I, Chap. 31 is an example of this unique power, which has been used in such diverse situations as color centers, transition-metal ions, rare-earth ions, phosphor- and laser-active ions (e.g., Ga^+, Tl°), as well as donor-acceptor and exciton recombination in semiconductors.[19] We now illustrate the relationship of the selection rules and polarization properties of the triplet-singlet transitions.

The *F*-center in calcium oxide consists of two electrons trapped in the Coulomb field of a negative-ion vacancy. The ground state is a spin singlet, $^1A_{1g}$, from which electric dipole absorption transitions are allowed into a $^1T_{1u}$ state derived from the $(1s2p)$ configuration. Such $^1A_{1g} \rightarrow {}^1T_{1u}$ transitions are signified by a strong optical absorption band centered at a wavelength $\lambda \simeq 400$ nm (Vol. I, Chap. 31, Fig. 16). Dexcitation of this $^1T_{1u}$ state does not proceed via $^1T_{1u} \rightarrow {}^1A_{1g}$ luminescence. Instead, there is an efficient nonradiative decay from $^1T_{1u}$ into the triplet $^3T_{1u}$ state also derived from the $(1s2p)$ configuration.[49] The spin-forbidden $^3T_{1u} \rightarrow {}^1A_{1g}$ transition gives rise to a striking orange fluorescence, which occurs with a radiative lifetime $\tau_R = 3.4$ ms at 4.2 K. The ODMR spectrum of the *F*-center and its absorption and emission spectral dependences are depicted in Fig. 16 in Vol. I, Chap. 31, other details are shown in Fig. 18. With the magnetic field at some general orientation in the (100) plane there are six lines. From the variation of the resonant fields with the orientation of the magnetic field in the crystal, Edel et al. (1972)[50] identified the spectrum with the $S = 1$ state of tetragonally distorted *F*-center. The measured orientation dependence gives $g_{||} \approx g_{\perp} = 1.999$ $D = 60.5\,\mathrm{m}T$.

Figure 18 shows the selection rules for emission of circularly polarized light by $S = 1$ states in axial crystal fields. We denote the populations of the $M_s = 0, \pm 1$ levels as N_0 and $N_{\pm 1}$. The low-field ESR line, corresponding to the $M_s = 0 \rightarrow M_s = +1$ transition, should be observed as an increase in σ_+-light because $N_0 > N_{+1}$ and ESR transitions enhance the $M_s = \pm 1$ level. However, the high-field line is observed as a change in intensity of σ_--light. If spin-lattice relaxation is efficient (i.e., $T_1 < \tau_R$), then the spin states are in thermal equilibrium, $N_0 < N_{-1}$, ESR transitions depopulate the $|M_s = -1\rangle$ level. Thus, the high-field ODMR line is seen as a decrease in the *F*-center in these crystals (viz., that

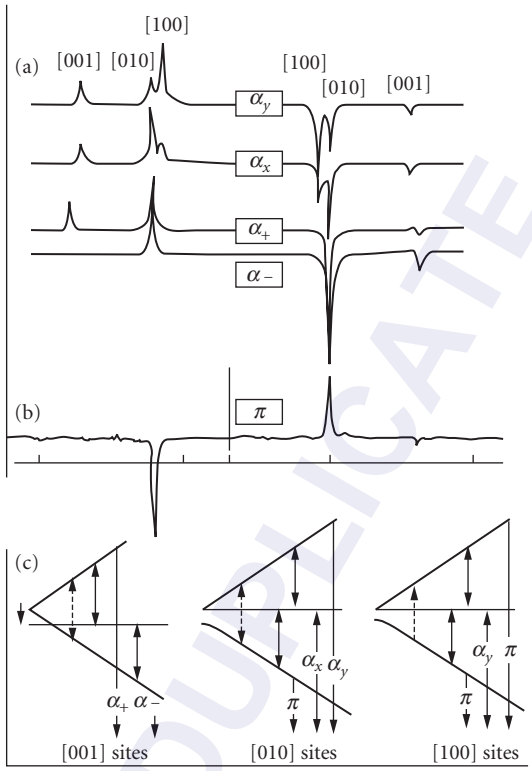

FIGURE 18 Polarization selection rules and the appropriately detected ODMR spectra of the ${}^3T_{1u} \rightarrow {}^1A_{1g}$ transition of *F*-centers in CaO. (*After Edel et al.*[50])

for the lowest ${}^3T_1$ state, D is positive and the spin states are in thermal equilibrium). It is worth noting that since the $|M_s = 0\rangle \rightarrow M_s = \pm 1\rangle$ ESR transitions occur at different values of the magnetic field, ODMR may be detected simply as a change in the emission intensity at resonance; it is not necessary to measure specifically the sense of polarization of the emitted light. The experimental data clearly establish the tetragonal symmetry of the *F*-center in calcuim oxide: the tetragonal distortion occurs in the excited ${}^3T_{1u}$ state due to vibronic coupling to modes of E_g symmetry resulting in a static Jahn-Teller effect.[50]

3.1 GLOSSARY

c	speed of light
C_n^2	atmospheric turbulence strength parameter
D	beam diameter
F	hypergeometric function
$g(\nu)$	optical absorption lineshape function
H	height above sea level
h	Planck's constant
I	Irradiance (intensity) of optical beam (W/m^2)
k	optical wave number
K	turbulent wave number
L	propagation path length
L_0	outer scale size of atmospheric turbulence
l_0	inner scale size of atmospheric turbulence
N	density or concentration of molecules
$p(I)$	probability density function of irradiance fluctuations
P_ν	Planck radiation function
R	gas constant

S	molecular absorption line intensity
T	temperature
v	wind speed
β	backscatter coefficient of the atmosphere
γ_p	pressure-broadened half-width of absorption line
κ	optical attenuation
λ	wavelength
ν	optical frequency (wave numbers)
ρ_0	phase coherence length
σ_I^2	variance of irradiance fluctuations
σ_R	Rayleigh scattering cross section

3.2 INTRODUCTION

Atmospheric optics involves the transmission, absorption, emission, refraction, and reflection of light by the atmosphere and is probably one of the most widely observed of all optical phenomena.[1–5] The atmosphere interacts with light due to the composition of the atmosphere, which under normal conditions, consists of a variety of different molecular species and small particles like aerosols, water droplets, and ice particles. This interaction of the atmosphere with light is observed to produce a wide variety of optical phenomena including the blue color of the sky, the red sunset, the optical absorption of specific wavelengths due to atmospheric molecules, the twinkling of stars at night, the greenish tint sometimes observed during a severe storm due to the high density of particles in the atmosphere, and is critical in determining the balance between incoming sunlight and outgoing infrared (IR) radiation and thus influencing the earth's climate.

One of the most basic optical phenomena of the atmosphere is the absorption of light. This absorption process can be depicted as in Fig. 1 which shows the transmission spectrum of the atmosphere as

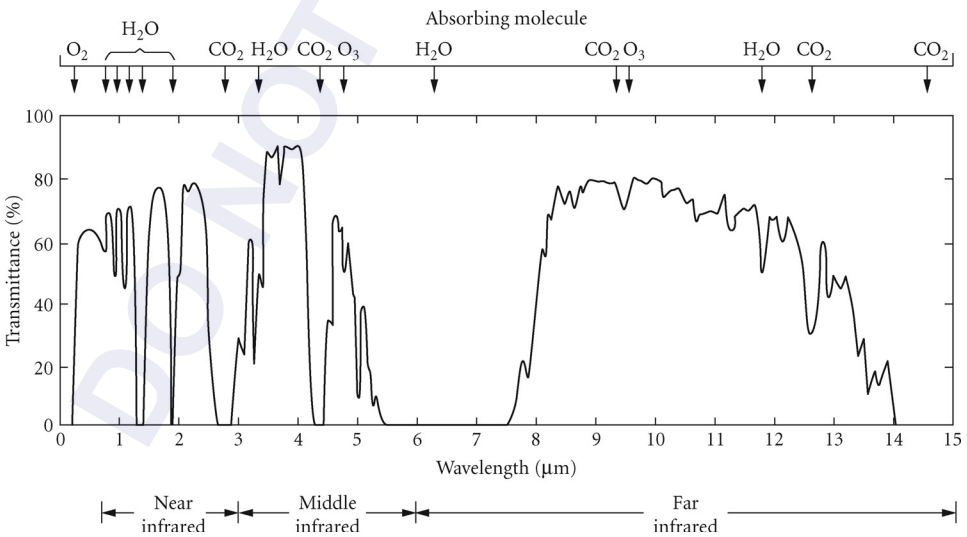

FIGURE 1 Transmittance through the earth's atmosphere as a function of wavelength taken with low spectral resolution (path length 1800 m). (*From Measures, Ref. 5.*)

a function of wavelength.[5] The transmission of the atmosphere is highly dependent upon the wavelength of the spectral radiation, and, as will be covered later in this chapter, upon the composition and specific optical properties of the constituents in the atmosphere. The prominent spectral features in the transmission spectrum in Fig. 1 are primarily due to absorption bands and individual absorption lines of the molecular gases in the atmosphere, while a portion of the slowly varying background transmission is due to aerosol extinction and continuum absorption.

This chapter presents a tutorial overview of some of the basic optical properties of the atmosphere, with an emphasis on those properties associated with optical propagation and transmission of light through the earth's atmosphere. The physical phenomena of optical absorption, scattering, emission, and refractive properties of the atmosphere will be covered for optical wavelengths from the ultraviolet (UV) to the far-infrared. The primary focus of this chapter is on *linear* optical properties associated with the transmission of light through the atmosphere. Historically, the study of atmospheric optics has centered on the radiance transfer function of the atmosphere, and the linear transmission spectrum and blackbody emission spectrum of the atmosphere. This emphasis was due to the large body of research associated with passive, electro-optical sensors which primarily use the transmission of ambient optical light or light from selected emission sources. During the past few decades, however, the use of lasers has added a new dimension to the study of atmospheric optics. In this case, not only is one interested in the transmission of light through the atmosphere, but also information regarding the optical properties of the backscattered optical radiation.

In this chapter, the standard linear optical interactions of an optical or laser beam with the atmosphere will be covered, with an emphasis placed on linear absorption and scattering interactions. It should be mentioned that the first edition of the OSA *Handbook of Optics* chapter on "Atmospheric Optics" had considerable nomographs and computational charts to aid the user in numerically calculating the transmission of the atmosphere.[2] Because of the present availability of a wide range of spectral databases and computer programs (such as the HITRAN Spectroscopy Database, LOWTRAN, MODTRAN, and FASCODE atmospheric transmission computer programs) that model and calculate the transmission of light through the atmosphere, these nomographs, while still useful, are not as vital. As a result, the emphasis on this edition of the "Atmospheric Optics" chapter is on the basic theory of the optical interactions, how this theory is used to model the optics of the atmosphere, the use of available computer programs and databases to calculate the optical properties of the atmosphere, and examples of instruments and meteorological phenomena related to optical or visual remote sensing of the atmosphere.

The overall organization of this chapter begins with a description of the natural, homogeneous atmosphere and the representation of its physical and chemical composition as a function of altitude. A brief survey is then made of the major linear optical interactions that can occur between a propagating optical beam and the naturally occurring constituents in the atmosphere. The next section covers several major computational programs (HITRAN, LOWTRAN, MODTRAN, and FASCODE) and U.S. Standard Atmospheric Models which are used to compute the optical transmission, scattering, and absorption properties of the atmosphere. The next major technical section presents an overview of the influence of atmospheric refractive turbulence on the statistical propagation of an optical beam or wavefront through the atmosphere. Finally, the last few sections of the chapter include a brief introduction to some optical and laser remote sensing experiments of the atmosphere, a brief introduction to the visually important field of meteorological optics, and references to the critical influence of atmospheric optics on global climate change.

It should be noted that the material contained within this chapter has been compiled from several recent overview/summary publications on the optical transmission and atmospheric composition of the atmosphere, as well as from a large number of technical reports and journal publications. These major overview references are (1) *Atmospheric Radiation,* (2) the previous edition of the *OSA Handbook of Optics* (chapter on "Optical Properties of the Atmosphere"), (3) *Handbook of Geophysics and the Space Environment* (chapter on "Optical and Infrared Properties of the Atmosphere"), (4) *The Infrared Handbook*, and (5) *Laser Remote Sensing.*[1–5] The interested reader is directed toward these comprehensive treatments as well as to the listed references therein for detailed information concerning the topics covered in this brief overview of atmospheric optics.

3.3 PHYSICAL AND CHEMICAL COMPOSITION OF THE STANDARD ATMOSPHERE

The atmosphere is a fluid composed of gases and particles whose physical and chemical properties vary as a function of time, altitude, and geographical location. Although these properties can be highly dependent upon local and regional conditions, many of the optical properties of the atmosphere can be described to an adequate level by looking at the composition of what one normally calls a *standard atmosphere.* This section will describe the background, homogeneous standard composition of the atmosphere. This will serve as a basis for the determination of the quantitative interaction of the molecular gases and particles in the atmosphere with a propagating optical wavefront.

Molecular Gas Concentration, Pressure, and Temperature

The majority of the atmosphere is composed of lightweight molecular gases. Table 1 lists the major gases and trace species of the terrestrial atmosphere, and their approximate concentration (volume fraction) at standard room temperature (296 K), altitude at sea level, and total pressure of 1 atm.[6] The major optically active molecular constituents of the atmosphere are N_2, O_2, H_2O, and CO_2, with a secondary grouping of CH_4, N_2O, CO, and O_3. The other species in the table are present in the atmosphere at trace-level concentrations (ppb, down to less than ppt by volume); however, the concentration may be increased by many orders of magnitude due to local emission sources of these gases.

The temperature of the atmosphere varies both with seasonal changes and altitude. Figure 2 shows the average temperature profile of the atmosphere as a function of altitude presented for the U.S. Standard Atmosphere.[7–9] The temperature decreases significantly with altitude until the level of the stratosphere is reached where the temperature profile has an inflection point. The U.S. Standard Atmosphere is one of six basic atmospheric models developed by the U.S. government; these different models furnish a good representation of the different atmospheric conditions which are often encountered. Figure 3 shows the temperature profile for the six atmospheric models.[7–9]

The pressure of the atmosphere decreases with altitude due to the gravitational pull of the earth and the hydrostatic equilibrium pressure of the atmospheric fluid. This is indicated in Fig. 4 which shows the total pressure of the atmosphere in millibars (1013 mb = 1 atm = 760 torr) as a function of altitude for the different atmospheric models.[7–9] The fractional or partial pressure of most of the major gases (N_2, O_2, CO_2, N_2O, CO, and CH_4) follows this profile and these gases are considered uniformly mixed. However, the concentration of water vapor is very temperature-dependent due to freezing and is not uniformly mixed in the atmosphere. Figure 5*a* shows the density of water vapor as a function of altitude; the units of density are in molecules/cm^3 and are related to 1 atm by the appropriate value of Loschmidts number (the number of molecules in 1 cm^3 of air) at a temperature of 296 K, which is 2.479×10^{19} molecules/cm^3.[7–9]

The partial pressure of ozone (O_3) also varies significantly with altitude because it is generated in the upper altitudes and near ground level by solar radiation, and is in chemical equilibrium with other gases in the atmosphere which themselves vary with altitude and time of day. Figure 5*b* shows the typical concentration of ozone as a function of altitude.[7–9] The ozone concentration peaks at an altitude of approximately 20 km and is one of the principle molecular optical absorbers in the atmosphere at that altitude. Further details of these atmospheric models under different atmospheric conditions are contained within the listed references and the reader is encouraged to consult these references for more detailed information.[3,7–9]

Aerosols, Water Droplets, and Ice Particles

The atmospheric propagation of optical radiation is influenced by particulate matter suspended in the air such as aerosols (e.g., dust, haze) and water (e.g., ice or liquid cloud droplets, precipitation). Figure 6 shows the basic characteristics of particles in the atmosphere as a function of altitude,[3] and Fig. 7 indicates the approximate size of common atmospheric particles.[5]

TABLE 1 List of Molecular Gases and Their Typical Concentration (Volume Fraction) for the Ambient U.S. Standard Atmosphere

Molecule	Concentration (Volume Fraction)
N_2	0.781
O_2	0.209
H_2O	0.0775 (variable)
CO_2	3.3×10^{-4} (higher now: 3.9×10^{-4}, or 390 ppm)
A (argon)	0.0093
CH_4	1.7×10^{-6}
N_2O	3.2×10^{-7}
CO	1.5×10^{-7}
O_3	2.66×10^{-8} (variable)
H_2CO	2.4×10^{-9}
C_2H_6	2×10^{-9}
HCl	1×10^{-9}
CH_3Cl	7×10^{-10}
OCS	6×10^{-10}
C_2H_2	3×10^{-10}
SO_2	3×10^{-10}
NO	3×10^{-10}
H_2O_2	2×10^{-10}
HCN	1.7×10^{-10}
HNO_3	5×10^{-11}
NH_3	5×10^{-11}
NO_2	2.3×10^{-11}
HOCl	7.7×10^{-12}
HI	3×10^{-12}
HBr	1.7×10^{-12}
OH	4.4×10^{-14}
HF	1×10^{-14}
ClO	1×10^{-14}
HCOOH	1×10^{-14}
COF_2	1×10^{-14}
SF_6	1×10^{-14}
H_2S	1×10^{-14}
PH_3	1×10^{-20}
HO_2	Trace
O (atom)	Trace
$ClONO_2$	Trace
NO^+	Trace
HOBr	Trace
C_2H_4	Trace
CH_3OH	Trace
CH_3Br	Trace
CH_3CN	Trace
CF_4	Trace

Note: The trace species have concentrations less than 1×10^{-9}, with a value that is variable and often dependent upon local emission sources.

Aerosols in the boundary layer (surface to 1 to 2 km altitude) are locally emitted, wind-driven particulates, and have the greatest variability in composition and concentration. Over land, the aerosols are mostly soil particles, dust, and organic particles from vegetation. Over the oceans, they are mostly sea salt particles. At times, however, long-range global winds are capable of transporting land particulates vast distances across the oceans or continents, especially those particulates associated with dust storms or large biomass fires, so that substantial mixing of the different particulate types may occur.

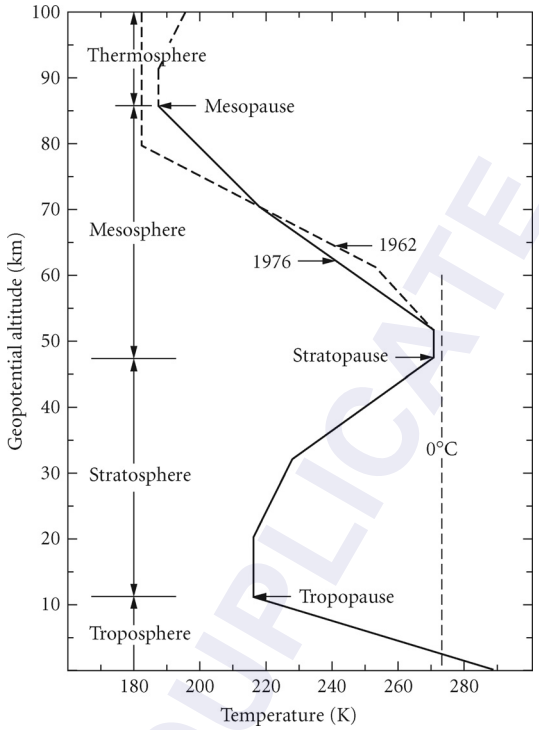

FIGURE 2 Temperature-height profile for U.S. Standard Atmosphere (0 to 86 km).

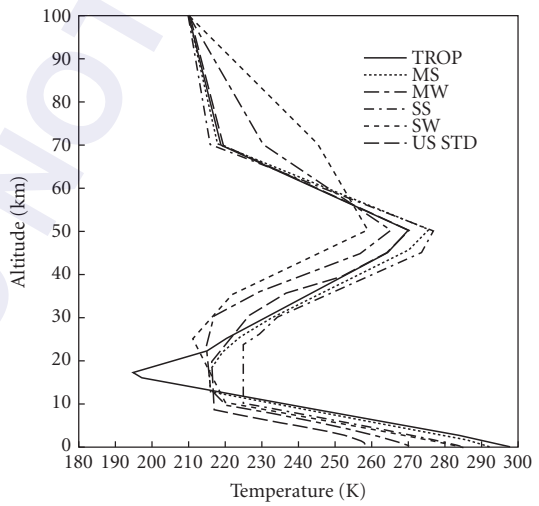

FIGURE 3 Temperature vs. altitude for the six model atmospheres: tropical (TROP), midlatitude summer (MS), midlatitude winter (MW), subarctic summer (SS), subarctic winter (SW), and U.S. standard (US STD).

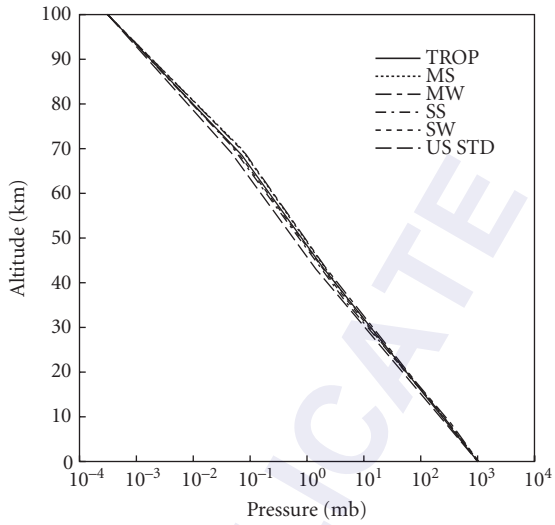

FIGURE 4 Pressure vs. altitude for the six model atmospheres.

In the troposphere above the boundary layer, the composition is less dependent upon local surface conditions and a more uniform, global distribution is observed. The aerosols observed in the troposphere are mostly due to the coagulation of gaseous compounds and fine dust. Above the troposphere, in the region of the stratosphere from 10 to 30 km, the background aerosols are mostly sulfate particles and are uniformly mixed globally. However, the concentration can be perturbed by several orders of magnitude due to the injection of dust and SO_2 by volcanic activity, such as the

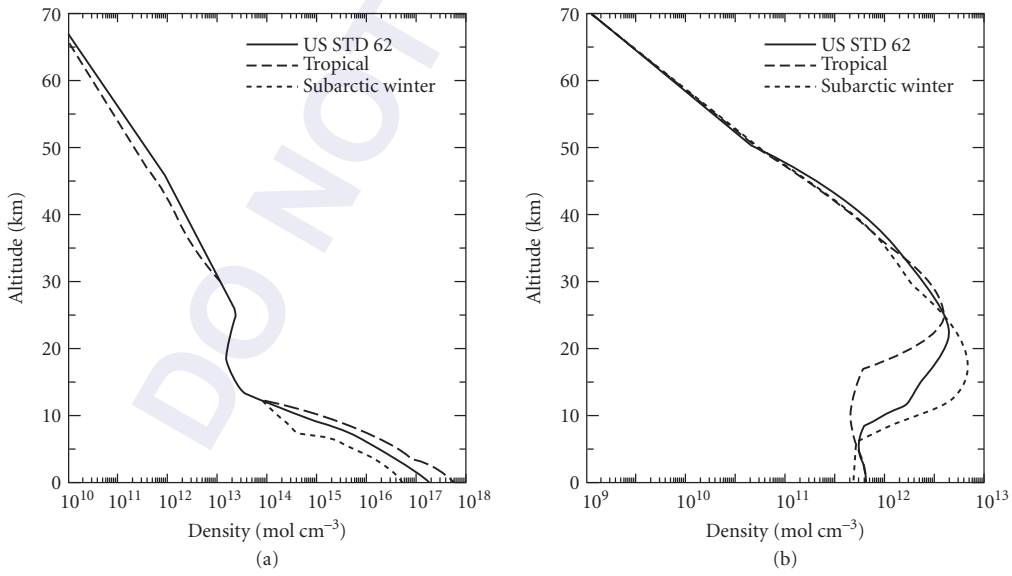

FIGURE 5 (*a*) Water vapor profile of several models and (*b*) ozone profile for several models; the U.S. standard model shown is the 1962 model.

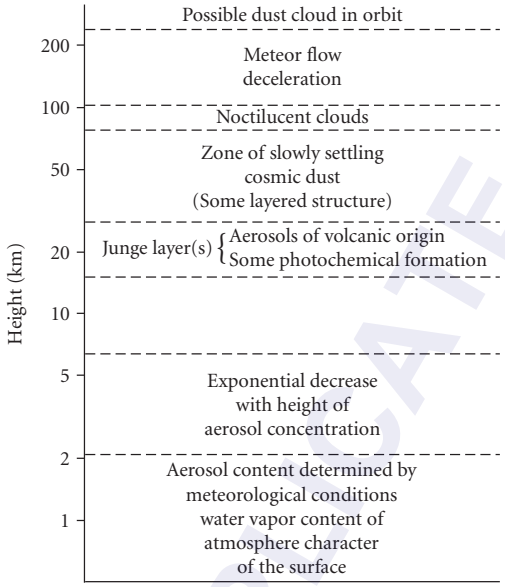

FIGURE 6 Physical characteristics of atmospheric aerosols.

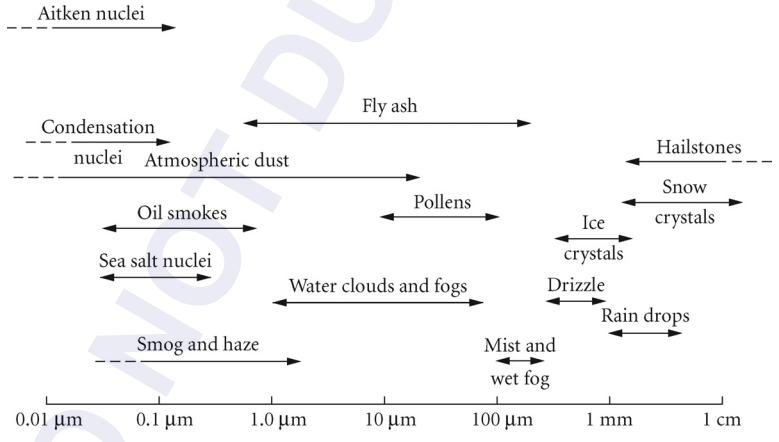

FIGURE 7 Representative diameters of common atmospheric particles. (*From Measures, Ref. 5.*)

recent eruption of Mt. Pinatubo.[10] Such increases in the aerosol concentration may persist for several years and significantly impact the global temperature of the earth.

Several models have been developed for the number density and size distribution of aerosols in the atmosphere.[7–9] Figures 8 and 9 show two aerosol distribution models appropriate for the rural environment and maritime environment, as a function of relative humidity;[7–9] the humidity influences the size distribution of the aerosol particles and their growth characteristics. The greatest number density (particles/cm^3) occurs near a size of 0.01 μm but a significant number of aerosols are still present even at the larger sizes near 1 to 2 μm. Finally, the optical characteristics of the aerosols can also be dependent upon water vapor concentration, with changes in surface, size, and growth

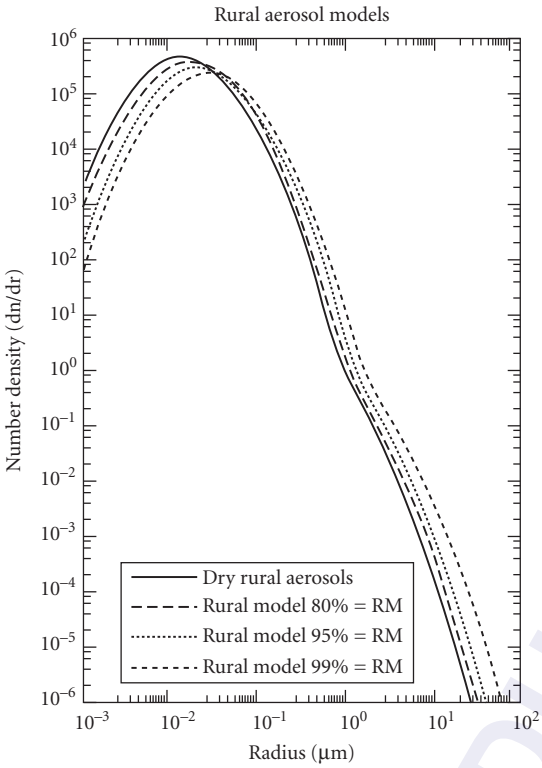

FIGURE 8 Aerosol number density distribution (cm^{-3} μm^{-1}) for the rural model at different relative humidities with total particle concentrations fixed at 15,000 cm^{-3}.

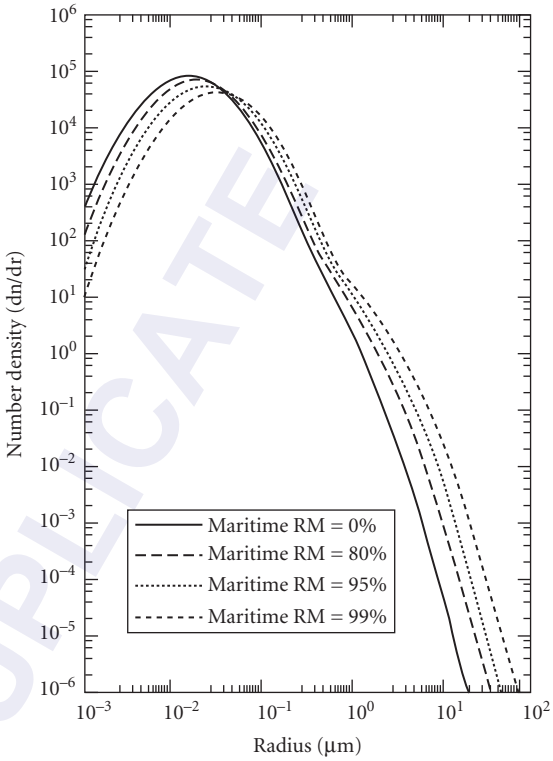

FIGURE 9 Aerosol number density distribution (cm^{-3} μm^{-1}) for the maritime model at different relative humidities with total particle concentrations fixed at 4000 cm^{-3}.

characteristics of the aerosols sometimes observed to be dependent upon the relative humidity. Such humidity changes can also influence the concentration of some pollutant gases (if these gases have been absorbed onto the surface of the aerosol particles).[7–9]

3.4 FUNDAMENTAL THEORY OF INTERACTION OF LIGHT WITH THE ATMOSPHERE

The propagation of light through the atmosphere depends upon several optical interaction phenomena and the physical composition of the atmosphere. In this section, we consider some of the basic interactions involved in the transmission, absorption, emission, and scattering of light as it passes through the atmosphere. Although all of these interactions can be described as part of an overall radiative transfer process, it is common to separate the interactions into distinct optical phenomena of molecular absorption, Rayleigh scattering, Mie or aerosol scattering, and molecular emission. Each of these basic phenomena is discussed in this section following a brief outline of the fundamental equations for the transmission of light in the atmosphere centered on the Beer-Lambert law.[1,2]

The linear transmission (or absorption) of monochromatic light by species in the atmosphere may be expressed approximately by the Beer-Lambert law as

$$I(\lambda, t', x) = I(\lambda, t, 0)e^{-\int_0^x \kappa(\lambda)N(x', t)dx'} \tag{1}$$

where $I(\lambda, t', x)$ is the intensity of the optical beam after passing through a path length of x, $\kappa(\lambda)$ is the optical attenuation or extinction coefficient of the species per unit of species density and length, and $N(x, t)$ is the spatial and temporal distribution of the species density that is producing the absorption; λ is the wavelength of the monochromatic light, and the parameter time t' is inserted to remind one of the potential propagation delay. Equation (1) contains the term $N(x, t)$ which explicitly indicates the spatial and temporal variability of the concentration of the attenuating species since in many experimental cases such variability may be a dominant feature.

It is common to write the attenuation coefficient in terms of coefficients that can describe the different phenomena that can cause the extinction of the optical beam. The most dominant interactions in the natural atmosphere are those due to Rayleigh (elastic) scattering, linear absorption, and Mie (aerosol/particulate) scattering; elastic means that the scattered light does not change in wavelength from that which was transmitted while inelastic infers a shift in the wavelength. In this case, one can write $\kappa(\lambda)$ as

$$\kappa(\lambda) = \kappa_a(\lambda) + \kappa_R(\lambda) + \kappa_M(\lambda) \tag{2}$$

where these terms represent the individual contributions due to absorption, Rayleigh scattering, and Mie scattering, respectively. The values for each of these extinction coefficients are described in the following sections along with the appropriate species density term $N(x, t)$. In some of these cases, the reemission of the optical radiation, possibly at a different wavelength, is also of importance. Rayleigh extinction will lead to Rayleigh backscatter, Raman extinction leads to spontaneous Raman scattering, absorption can lead to fluorescence emission or thermal heating of the molecule, and Mie extinction is defined primarily in terms of the scattering coefficient. Under idealized conditions, the scattering processes can be related directly to the value of the attenuation processes. However, if several complex optical processes occur simultaneously, such as in atmospheric propagation, the attenuation and scattering processes are not directly linked via a simple analytical equation. In this case, independent measurements of the scattering coefficient and the extinction coefficient have to be made, or approximation formulas are used to relate the two coefficients.[4,5]

Molecular Absorption

The absorption of optical radiation by molecules in the atmosphere is primarily associated with individual optical absorption transitions between the allowed quantized energy levels of the molecule. The energy levels of a molecule can usually be separated into those associated with rotational, vibrational, or electronic energy states. Absorption transitions between the rotational levels occur in the far-IR and microwave spectral region, transitions between vibrational levels occur in the near-IR (2 to 20 μm wavelength), and electronic transitions generally occur in the UV-visible region (0.3 to 0.7 μm). Transitions can occur which combine several of these categories, such as rotational-vibrational transitions or electronic-vibrational-rotational transitions.

Some of the most distinctive and identifiable absorption lines of many atmospheric molecules are the rotational-vibrational optical absorption lines in the infrared spectral region. These lines are often clustered together into vibrational bands according to the allowed quantum transitions of the molecule. In many cases, the individual lines are distinct and can be resolved if the spectral resolution of the measuring instrument is fine enough (i.e., <0.1 cm^{-1}). An example of such a region is the absorption feature near 2.04 μm in Fig. 1 which is actually composed of individual absorption lines if viewed under higher spectral resolution. Figure 10 is a computed high-resolution expansion of the atmospheric spectrum of Fig. 1 near 2.04 μm over a path length of 1800 m which shows these individual lines. In this case, the individual lines are well-separated and appear like a "picket fence" spectrum showing gaps between the absorption lines. Many of the atmospheric gaseous molecules listed earlier in Table 1 have similar spectral structure. These gases are relatively lightweight and have few (less than 5 or 6) atoms per molecule so that their moments of inertia are relatively small. The resulting energy spacing between the allowed rotational-vibrational absorption transitions is large and well-separated in wavelength.

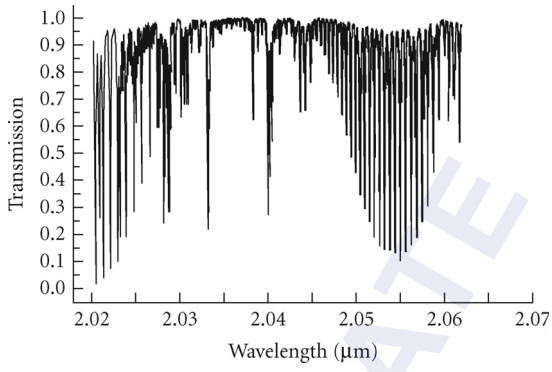

FIGURE 10 High-resolution transmission spectrum of the atmosphere for a horizontal path of 1800 m (similar to that in Fig. 1) for the spectral region near 2.04 μm. The individual rotational absorption lines due to CO_2 and H_2O are easily observed.

In other spectral regions, however, the individual lines overlap or are so strong or saturated that the transmission spectrum displays only broad spectral features; an example of such a spectral region is the strong absorption seen near 2.7 μm, 5 to 8 μm, and beyond 13 μm in Fig. 1. Finally, the molecular absorption observed in the UV is often due to optical transitions to an electronic energy level, molecular energy continuum or a predissociation energy level. In some cases, such as that for O_3 or SO_2, this results in broad absorption bands that extend throughout the UV region (250 to 350 nm).

More complex, heavier molecules, such as benzene or chlorofluorocarbons, have absorption spectra which are blended or merged together into band spectra due to the complexity and overlap of the rotational-vibrational transitions of these molecules. Figure 11 shows a transmission spectrum of Freon-12 (CCl_2F_2) which has a complex spectrum near 11 μm. As seen, the individual rotational lines are merged into a band spectrum. The band spectrum is unique for each gas and can be used to identify the chemical composition of the gas. Heavy molecules in the atmosphere are not normally part of the natural atmosphere and are usually the result of pollution or gaseous plumes injected into the atmosphere.

The overall transmission or absorption of the atmosphere due to an individual molecular absorption line can be given quantitatively as[1,2]

$$\kappa_a(\lambda)N(x, t) = Sg(\nu - \nu_0)NP_a \tag{3}$$

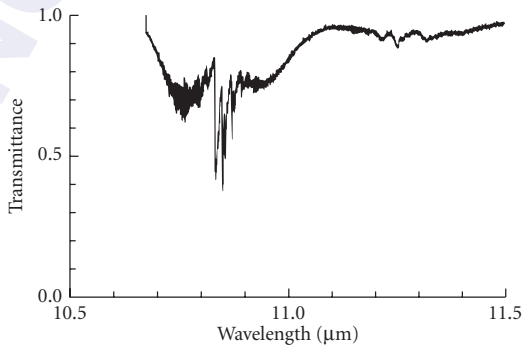

FIGURE 11 High-resolution absorption spectrum of Freon-12 gas showing complex band structure typical of heavy, complex molecules in the atmosphere (path of 100 m with 1 ppm concentration).

where S is the molecular transition line intensity (units of cm/molecule), $g(\nu - \nu_0)$ is the normalized lineshape function (units of cm or $1/\text{cm}^{-1}$), N is the number of molecules of absorbing species per cm^3 per atm, and P_a is the partial pressure of the absorbing gas in atm. The value of N is equal to the value of Loschmidt's number, which is 2.479×10^{19} molecules cm^{-3} atm^{-1} at a temperature of 296 K; the value of N is inversely proportional to temperature due to the change in gas concentration as a function of temperature for 1 atm of pressure. As will be seen later, the definition of S as given in Eq. (3) is that used in the HITRAN database.[11–13] In this case, S contains the Boltzmann population factor and isotope fraction (natural abundance) as well as the stimulated emission term due to finite population in the upper energy states of the molecule.[11,12] In Eq. (3), $Sg(\nu - \nu_0)$ is the absorption cross section per molecule (cm^2/molecule) and NP_a is the number of absorbing molecules in units of molecules/cm^3.

The lineshape function can be described by several different models. The two most prevalent are the Lorentzian lineshape associated with pressure broadening and the Gaussian lineshape associated with Doppler broadening which becomes important at elevated temperatures or low pressures.

The Lorentzian/pressure-broadened profile is given by

$$g_L(\nu - \nu_0) = (\gamma_P/\pi)/\left[(\nu - \nu_0)^2 + \gamma_P^2\right] \tag{4}$$

where γ_p is the pressure-broadened half-width at half-maximum (HWHM) in wave numbers (cm^{-1}). The pressure-broadened half-width is obtained from the air-broadened half-width parameter g as $\gamma_p = gP_t$, where P_t is the total background atmospheric pressure. Under ambient atmospheric conditions, g is approximately 0.05 cm^{-1} (i.e., 1.5 GHz) for many molecules in the atmosphere.

It should be noted that under very low pressure conditions, where the time between collisions with other molecules is relatively long, the intrinsic radiative lifetime of the molecule will determine the lineshape profile. Under these conditions, the linewidth is called the natural linewidth. The natural linewidth of many molecules is on the order of a few MHz (i.e., approximately 0.0001 cm^{-1}) or less.

The Gaussian or Doppler line profile is expressed as

$$g_D(\nu - \nu_0) = (1/\gamma_D)(\ln 2/\pi)1/2\left[-\ln 2(\nu - \nu_0)^2/\gamma_D^2\right] \tag{5}$$

where γ_D is the Doppler linewidth (HWHM in cm^{-1}) given by

$$\gamma_D = (\nu_0/c)[2RT \ln 2/M]^{1/2} \tag{6}$$

where R is the gas constant, T is the temperature in Kelvin, and M is the molecular weight of the molecule.

The value for the lineshape at the peak (line center) is equal to $1/(\pi\gamma_p) = 0.318/\gamma_p$ for the pressure-broadened case. For the Doppler peak, the maximum value is $(\ln 2/\pi)^{1/2}/\gamma_D = 0.469/\gamma_D$. Under ambient atmospheric conditions, the Doppler linewidth is usually much smaller than the pressure-broadened linewidth.

For those cases where both Lorentzian and Doppler broadening are present in approximately equal amounts, a convolution of the Doppler and Lorentzian profile must be used. This convolution of a Doppler and Lorentzian is called a Voigt profile and involves a double integral for an exact calculation. Fortunately, several numerical approximations are available for the computation of the Voigt profile and lineshape parameters.[14–16] The Voigt profile is important in the spectroscopy of molecules in the upper atmosphere where the ambient pressure is low and the Doppler and pressure-broadened linewidths are of the same order of magnitude. Recent advances in remote-sensing experiments have suggested that further refinements to the description of the line shape in the atmosphere are required. These phenomena include line coupling, speed-dependent corrections, collision-induced narrowing, and other effects on the lineshape.[17]

Finally, the large number of transition lines of water vapor and other gases in the atmosphere can produce a significant level of background "quasi-continuum" absorption in the atmosphere. This phenomenon is primarily due to the additive contribution from the wings of the absorption lines even at wavelengths far removed (>25 cm^{-1}) from the line centers. Such an effect has been studied by Burch and by Clough et al. for water vapor due to strong self-broadening interactions.[18] Figure 12

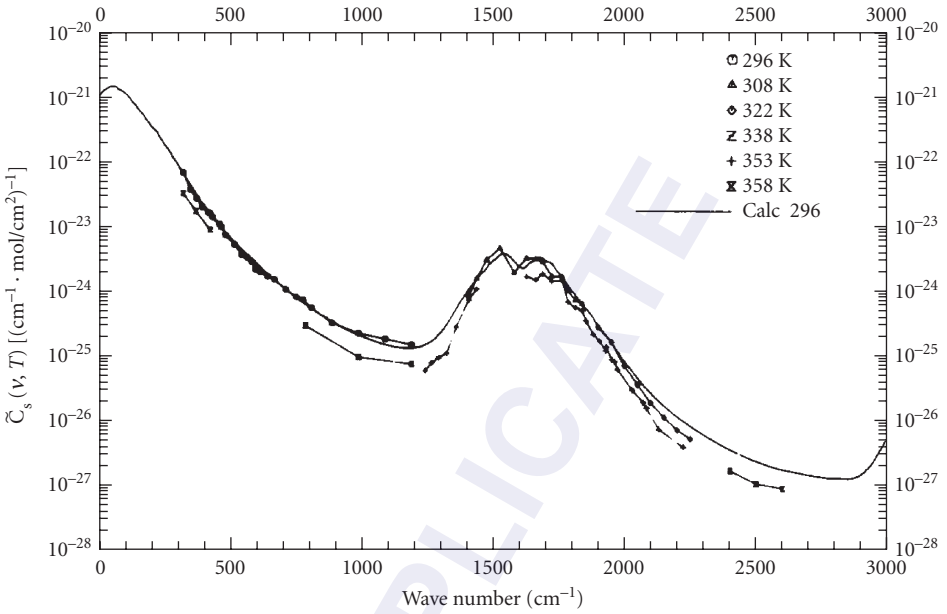

FIGURE 12 Self-density absorption continuum values C_s for water vapor as a function of wave number. The experimental values were measured by Burch. (*From Ref. 3.*)

shows a plot of the relative continuum coefficient for water vapor as a function of wave number. Good agreement with the experimental data and model calculations is shown. Models for water vapor and nitrogen continuum absorption are contained within many of the major atmospheric transmission programs (such as FASCODE). The typical value for the continuum absorption is negligible in the visible to the near-IR, but can be significant at wavelengths in the range of 5 to 20 μm.

Molecular Rayleigh Scattering

Rayleigh scattering is elastic scattering of the optical radiation due to the displacement of the weakly bound electronic cloud surrounding the gaseous molecule which is perturbed by the incoming electromagnetic (optical) field. This phenomenon is associated with optical scattering where the wavelength of light is much larger than the physical size of the scatterers (i.e., atmospheric molecules). Rayleigh scattering, which makes the color of the sky blue and the setting or rising sun red, was first described by Lord Rayleigh in 1871. The Rayleigh differential scattering cross section for polarized, monochromatic light is given by[5]

$$d\sigma_R/d\Omega = [\pi^2(n^2 - 1^2)/N^2\lambda^4][\cos^2\phi\cos^2\theta + \sin^2\phi] \tag{7}$$

where n is the index of refraction of the atmosphere, N is the density of molecules, λ is the wavelength of the optical radiation, and ϕ and θ are the spherical coordinate angles of the scattered polarized light referenced to the direction of the incident light. As seen from Eq. (7), shorter-wavelength light (i.e., blue) is more strongly scattered out from a propagating beam than the longer wavelengths (i.e., red), which is consistent with the preceding comments regarding the color of the sky or the sunset. A typical value for $d\sigma_R/d\Omega$, at a wavelength of 700 nm in the atmosphere (STP) is approximately 2×10^{-28} cm^2 sr^{-1}.[3] This value depends upon the molecule and has been tabulated for many of the major gases in the atmosphere.[14–19]

The total Rayleigh scattering cross section can be determined from Eq. (7) by integrating over 4π steradians to yield

$$\sigma_R(\text{total}) = [8/3][\pi^2(n^2-1)^2/N^2\lambda^4] \tag{8}$$

At sea level (and room temperature, $T = 296$ K) where $N = 2.5 \times 10^{19}$ molecules/cm^3, Eq. (8) can be multiplied by N to yield the total Rayleigh scattering extinction coefficient as

$$\kappa_R(\lambda)N(x, t) = N\sigma_R(\text{total}) = 1.18 \times 10^{-8}\ [550\ \text{nm}/\lambda(\text{nm})]^4\ \text{cm}^{-1} \tag{9}$$

The neglect of the effect of dispersion of the atmosphere (variation of the index of refraction n with wavelength) results in an error of less than 3 percent in Eq. (9) in the visible wavelength range.[5]

The molecular Rayleigh backscatter ($\theta = \pi$) cross section for the atmosphere has been given by Collins and Russell for polarized incident light (and received scattered light of the same polarization) as[19]

$$\sigma_R = 5.45 \times 10^{-28}\ [550\ \text{nm}/\lambda\ (\text{nm})]^4\ \text{cm}^2\ \text{sr}^{-1} \tag{10}$$

At sea level where $N = 2.47 \times 10^{19}$ molecules/cm^3, the atmospheric volume backscatter coefficient, β_R, is thus given by

$$\beta_R = N\sigma_R = 1.39 \times 10^{-8}\ [550\ \text{nm}/\lambda(\text{nm})]^4\ \text{cm}^{-1}\ \text{sr}^{-1} \tag{11}$$

The backscatter coefficient for the reflectivity of a laser beam due to Rayleigh backscatter is determined by multiplying β_R by the range resolution or length of the optical interaction being considered.

For unpolarized incident light, the Rayleigh scattered light has a depolarization factor δ which is the ratio of the two orthogonal polarized backscatter intensities. δ is usually defined as the ratio of the perpendicular and parallel polarization components measured relative to the direction of the incident polarization. Values of δ depend upon the anisotropy of the molecules or scatters, and typical values range from 0.02 to 0.11.[20] Depolarization also occurs for multiple scattering and is of considerable interest in laser or optical transmission through dense aerosols or clouds.[21] The depolarization factor can sometimes be used to determine the physical and chemical composition of the cloud constituents, such as the relative ratio of water vapor or ice crystals in a cloud.

Mie Scattering: Aerosols, Water Droplets, and Ice Particles

Mie scattering is similar to Rayleigh scattering, except the size of the scattering sites is on the same order of magnitude as the wavelength of the incident light, and is, thus, due to aerosols and fine particulates in the atmosphere. The scattered radiation is the same wavelength as the incident light but experiences a more complex functional dependence upon the interplay of the optical wavelength and particle size distribution than that seen for Rayleigh scattering.

In 1908, Mie investigated the scattering of light by dielectric spheres of size comparable to the wavelength of the incident light.[22] His analysis indicated the clear asymmetry between the forward and backward directions, where for large particle sizes the forward-directed scattering dominates. Complete treatments of Mie scattering can be found in several excellent works by Deirmendjian and others, which take into account the complex index of refraction and size distribution of the particles.[23,24] These calculations are also influenced by the asymmetry of the aerosols or particulates which may not be spherical in shape.

The effect of Mie scattering in the atmosphere can be described as in the following figures. Figure 13 shows the aerosol Mie extinction coefficient as a function of wavelength for several atmospheric models, along with a typical Rayleigh scattering curve for comparison.[25] Figure 14 shows similar values for the volume Mie backscatter coefficient as a function of wavelength.[25] Extinction and backscatter coefficient values are highly dependent upon the wavelength and particulate composition.

Figures 15 and 16 show the calculated extinction coefficient for the rural and maritime aerosol models described in Sec. 3.3 as a function of relative humidity and wavelength.[3] Significant changes in the backscatter can be produced by relatively small changes in the humidity.

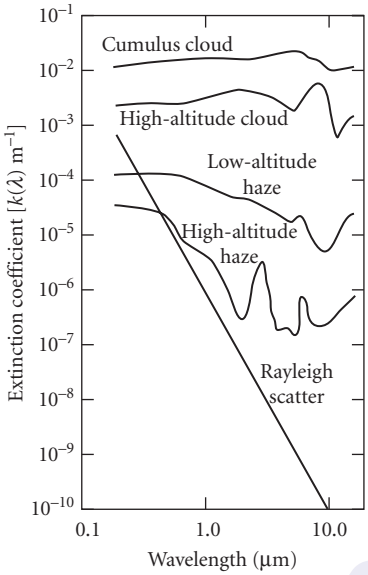

FIGURE 13 Aerosol extinction coefficient as a function of wavelength. (*From Measures, Ref. 5.*)

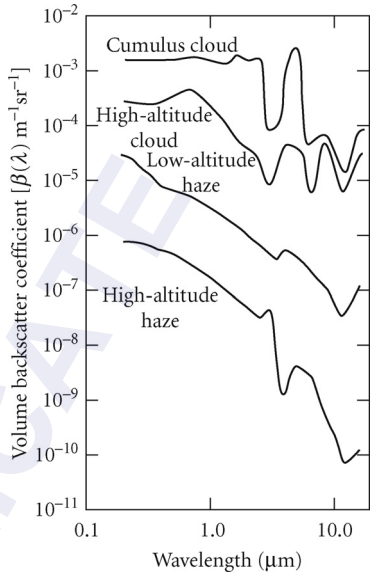

FIGURE 14 Aerosol volume backscattering coefficient as a function of wavelength. (*From Measures, Ref. 5.*)

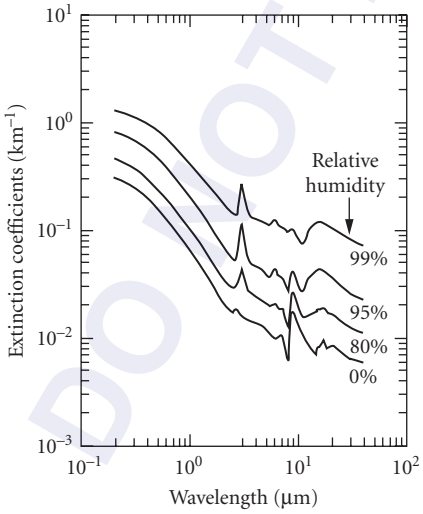

FIGURE 15 Extinction coefficients vs. wavelength for the rural aerosol model for different relative humidities and constant number density of particles.

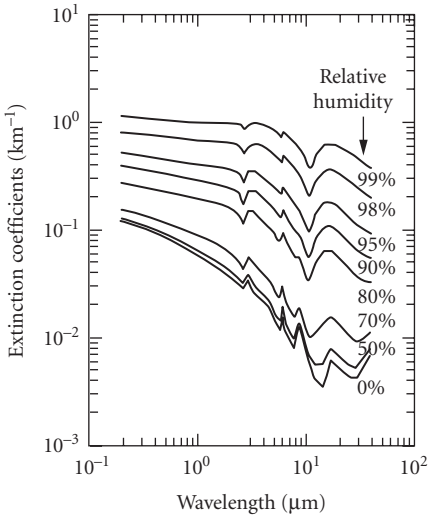

FIGURE 16 Extinction coefficients vs. wavelength for the maritime aerosol model for different relative humidities and constant number density of particles.

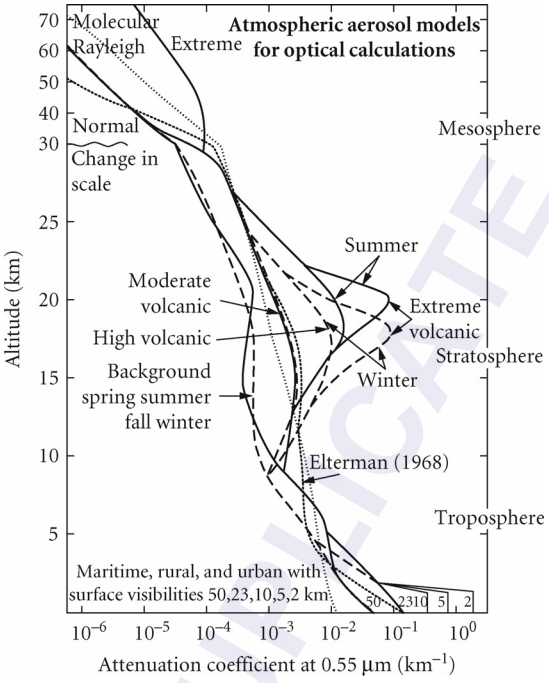

FIGURE 17 The vertical distribution of the aerosol extinction coefficient (at 0.55-μm wavelength) for the different atmospheric models. Also shown for comparison are the Rayleigh profile (dotted line). Between 2 and 30 km, where the distinction on a seasonal basis is made, the spring-summer conditions are indicated with a solid line and fall-winter conditions are indicated by a dashed line. (*From Ref. 3.*)

The extinction coefficient is also a function of altitude, following the dependence of the composition of the aerosols. Figure 17 shows an atmospheric aerosol extinction model as a function of altitude for a wavelength of 0.55 μm.[3,10] The influence of the visibility (in km) at ground level dominates the extinction value at the lower altitudes and the composition and density of volcanic particulate dominates the upper altitude regions. The dependence of the extinction on the volcanic composition at the upper altitudes is shown in Fig. 18 which shows these values as a function of wavelength and of composition.[3,10]

The variation of the backscatter coefficient as a function of altitude is shown in Fig. 19 which displays atmospheric backscatter data obtained by McCormick using a 1.06-μm Nd:YAG Lidar.[26] The boundary layer aerosols dominate at the lower levels and the decrease in the atmospheric particulate density determines the overall slope with altitude. Of interest is the increased value near 20 km due to the presence of volcanic aerosols in the atmosphere due to the eruption of Mt. Pinatubo in 1991.

Molecular Emission and Thermal Spectral Radiance

The same optical molecular transitions that cause absorption also emit light when they are thermally excited. Since the molecules have a finite temperature T, they will act as blackbody radiators with optical emission given by the Planck radiation law. The allowed transitions of the molecules

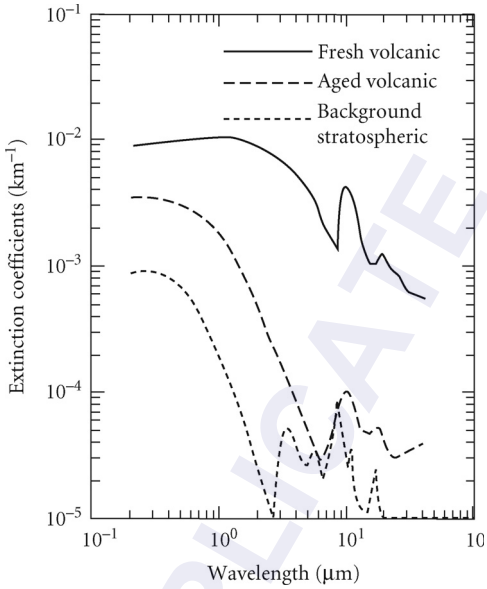

FIGURE 18 Extinction coefficients for the different stratospheric aerosol models (background, volcanic, and fresh volcanic). The extinction coefficients have been normalized to values around peak levels for these models.

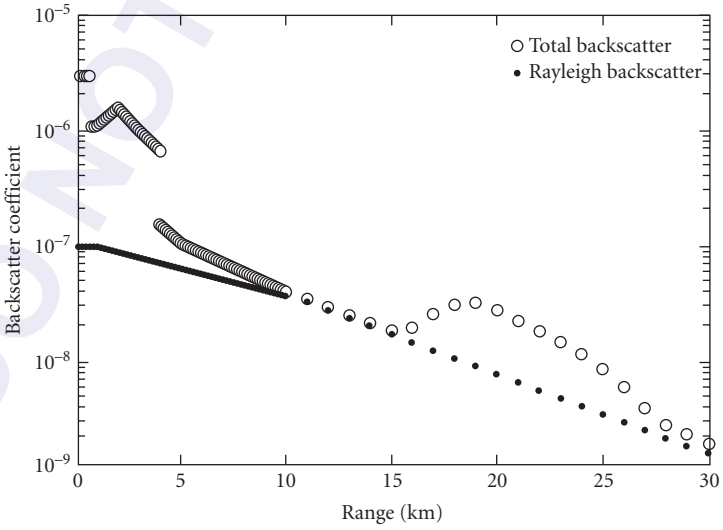

FIGURE 19 1.06-μm lidar backscatter coefficient measurements as a function of vertical altitude. (*From McCormick and Winker, Ref. 26.*)

will modify the radiance distribution of the radiation due to emission of the radiation according to the thermal distribution of the population within the energy levels of the molecule; it should be noted that the Boltzmann thermal population distribution is essentially the same as that which is described by the Planck radiation law for local thermodynamic equilibrium conditions. As such, the molecular emission spectrum of the radiation is similar to that for absorption. The thermal radiance from the clear atmosphere involves the calculation of the blackbody radiation emitted by each elemental volume of air multiplied by the absorption spectral distribution of the molecular absorption lines, $\kappa_a(s)$ and then this emission spectrum is attenuated by the rest of the atmosphere as the emission propagates toward the viewer. This may be expressed as

$$I_\nu = \int_0^s \kappa_a(s) P_\nu(s) \exp\left[-\int_0^s \kappa_a(s')ds'\right] ds \tag{12}$$

where the exponential term is Beer's law, and $P_\nu(s)$ is the Planck function given by

$$P_\nu(s) = 2h\nu^3/[c^2 \exp([h\nu/kT(s)] - 1)] \tag{13}$$

In these equations, s is the distance from the receiver along the optical propagation path, ν is the optical frequency, h is Planck's constant, c is the speed of light, k is Boltzmann's constant, and $T(s)$ is the temperature at position s along the path. As seen in Eq. (12), each volume element emits thermal radiation of $\kappa_a(s)P_\nu(s)$, which is then attenuated by Beer's law. The total emission spectral density is obtained by summing or integrating over all the emission volume elements and calculating the appropriate absorption along the optical path for each element.

As an example, Fig. 20 shows a plot of the spectral radiance measured on a clear day with 1 cm^{-1} spectral resolution. Note that the regions of strong absorption produce more radiance as the foregoing equation suggests, and that regions of little absorption correspond to little radiance. In the 800- to 1200-wave number spectral region (i.e., 8.3- to 12.5-μm wavelength region), the radiance is relatively low. This is consistent with the fact that the spectral region from 8 to 12 μm is a transmission window of the atmosphere with relatively little absorption of radiation.

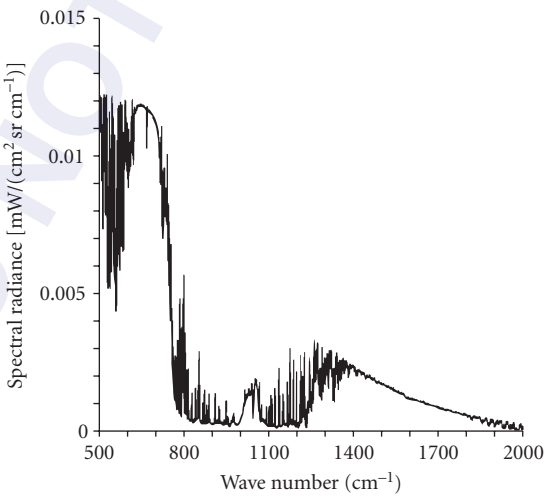

FIGURE 20 Spectral radiance (molecular thermal emission) measured on a clear day showing the relatively low value of radiance near 1000 cm^{-1} (i.e., 10-μm wavelength). (*Provided by Churnside.*)

Surface Reflectivity and Multiple Scattering

The spectral intensity of naturally occurring light at the earth's surface is primarily due to the incident intensity from the sun in the visible to mid-IR wavelength range, and due to thermal emission from the atmosphere and background radiance in the mid-IR. In both cases, the optical radiation is affected by the reflectance characteristics of the clouds and surface layers. For instance, the fraction of light that falls on the earth's surface and is reflected back into the atmosphere is dependent upon the reflectivity of the surface, the incident solar radiation (polarization and spectral density), and the absorption of the atmosphere.

The reflectivity of a surface, such as the earth's surface, is often characterized using the bidirectional reflectance function (BDRF). This function accounts for the nonspecular reflection of light from common rough surfaces and describes the changes in the reflectivity of a surface as a function of the angle which the incident beam makes with the surface. In addition, the reflectivity of a surface is usually a function of wavelength. This latter effect can be seen in Fig. 21 which shows the reflectance of several common substances for normal incident radiation.[2] As seen in Fig. 21, the reflectivity of these surfaces is a strong function of wavelength.

The effect of multiple scattering sometimes must be considered when the scattered light undergoes more than one scatter event, and is rescattered on other particles or molecules. These multiple scattering events increase with increasing optical thickness and produce deviations from the Beer-Lambert law. Extensive analyses of the scattering processes for multiple scattering have been conducted and have shown some success in predicting the overall penetration of light through a thick dense cloud. Different computational techniques have been used including the Gauss-Seidel Iterative Method, Layer Adding Method, and Monte-Carlo Techniques.[3,5]

Additional Optical Interactions

In some optical experiments on the atmosphere, a laser beam is used to excite the molecules in the atmosphere to emit inelastic radiation. Two important inelastic optical processes for atmospheric remote sensing are fluorescence and Raman scattering.[5,27]

For the case of laser-induced fluorescence, the molecules are excited to an upper energy state and the reemitted photons are detected. In these experiments, the inelastic fluorescence emission is red-shifted in wavelength and can be distinguished in wavelength from the elastic scattered Rayleigh or Mie backscatter. Laser-induced fluorescence is mostly used in the UV to visible spectral region; collisional quenching is quite high in the infrared so that the fluorescence efficiency is higher in the UV-visible than in the IR. Laser-induced fluorescence is sometimes reduced by saturation effects due to stimulated emission from the upper energy levels. However, in those cases where laser-induced fluorescence can be successfully used, it is one of the most sensitive optical techniques for the detection of atomic or molecular species in the atmosphere.

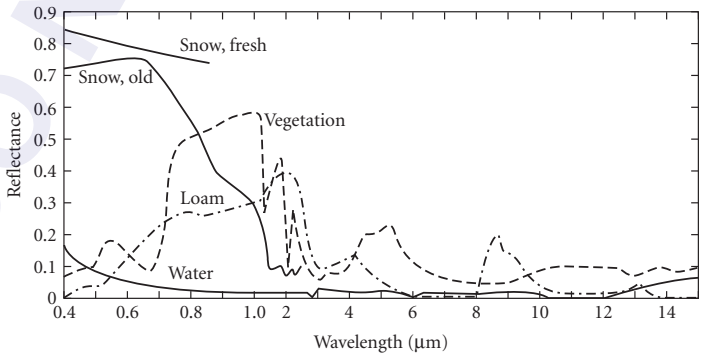

FIGURE 21 Typical reflectance of water surface, snow, dry soil, and vegetation. (*From Ref. 2.*)

Laser-induced Raman scattering of the atmosphere is a useful probe of the composition and temperature of concentrated species in the atmosphere. The Raman-shifted emitted light is often weak due to the relatively small cross section for Raman scattering. However, for those cases where the distance is short from the laser to the measurement cloud, or where the concentration of the species is high, it offers significant information concerning the composition of the gaseous atmosphere.

The use of an intense laser beam can also bring about nonlinear optical interactions as the laser beam propagates through the atmosphere. The most important of these are stimulated Raman scattering, thermal blooming, dielectric breakdown, and harmonic conversion. Each of these processes requires a tightly focused laser beam to initiate the nonlinear optical process.[28,29]

3.5 PREDICTION OF ATMOSPHERIC OPTICAL TRANSMISSION: COMPUTER PROGRAMS AND DATABASES

During the past three decades, several computer programs and databases have been developed which are very useful for the determination of the optical properties of the atmosphere. Many of these are based upon programs originally developed at the U.S. Air Force Cambridge Research Laboratories. The latest versions of these programs and databases are the HITRAN database,[13] FASCODE computer program,[30–32] and the LOWTRAN or MODTRAN computer code.[33,34] In addition, several PC (personal computer) versions of these database/computer programs have recently become available so that the user can easily use these computational aids.

Molecular Absorption Line Database: HITRAN

The HITRAN database contains optical spectral data on most of the major molecules contributing to absorption or radiance in the atmosphere; details of HITRAN are covered in several recent journal articles.[11–13] The 40 molecules contained in HITRAN are given in Table 1, and cover over a million individual absorption lines in the spectral range from 0.000001 cm^{-1} to 25,233 cm^{-1} (i.e., 0.3963 to 10^{10} μm). A free copy of this database can be obtained by filling out a request form in the HITRAN Web site.[35] Each line in the database contains 19 molecular data items that consist of the molecule formula code, isotopologue type, transition frequency (cm^{-1}), line intensity S in cm/molecule, Einstein A-coefficient (s^{-1}), air-broadened half-width (cm^{-1}/atm), self-broadened half-width (cm^{-1}/atm), lower state energy (cm^{-1}), temperature coefficient for air-broadened linewidth, air-pressure induced line shift (cm^{-1} atm^{-1}), upper-state global quanta index, lower-state global quanta index, upper- and lower-state quanta, uncertainty codes, reference numbers, a flag for line coupling if necessary, and upper- and lower-level statistical weights. The density of the lines of the 2004 HITRAN database is shown in Fig. 22. The recently released 2008 HITRAN database has been expanded to 42 molecules.

FIGURE 23 Example of data contained within the HITRAN database showing individual absorption lines, frequency, line intensity, and other spectroscopic parameters.

Figure 23 shows an output from a computer program that was used to search the HITRAN database and display some of the pertinent information.[36] The data in HITRAN are in sequential order by transition frequency in wave numbers, and list the molecular name, isotope, absorption line strength S, transition probability R, air-pressure-broadened linewidth γ_g, lower energy state E'', and upper/lower quanta for the different molecules and isotopic species in the atmosphere.

Line-by-Line Transmission Program: FASCODE

FASCODE is a large, sophisticated computer program that uses molecular absorption equations (similar to those under "Molecular Absorption") and the HITRAN database to calculate the high-resolution spectra of the atmosphere. It uses efficient algorithms to speed the computations of the spectral transmission, emission, and radiance of the atmosphere at a spectral resolution that can be set to better than the natural linewidth,[32] and includes the effects of Rayleigh and aerosol scattering and the continuum molecular extinction. FASCODE also calculates the radiance and transmittance of atmospheric slant paths, and can calculate the integrated transmittance through the atmosphere from the ground up to higher altitudes. Voigt lineshape profiles are also used to handle the transition from pressure-broadened lineshapes near ground level to the Doppler-dominated lineshapes at very high altitudes. Several representative models of the atmosphere are contained within FASCODE, so that the user can specify different seasonal and geographical models. Figure 24 shows a sample output generated from data produced from the FASCODE program and a comparison with experimental data obtained by J. Dowling at NRL.[30,31] As can be seen, the agreement is very good. There are also several other line-by-line codes available for specialized applications; examples include GENLN2 developed by D.P. Edwards at NCAR (National Center for Atmospheric Research/Boulder), and LBLRTM (Atmospheric and Environmental Research, Inc.).

Broadband Transmission: LOWTRAN and MODTRAN

The LOWTRAN computer program does not use the HITRAN database directly, but uses absorption band models based on degrading spectral calculations based on HITRAN to calculate the moderate resolution (20 cm^{-1}) transmission spectrum of the atmosphere. LOWTRAN uses extensive

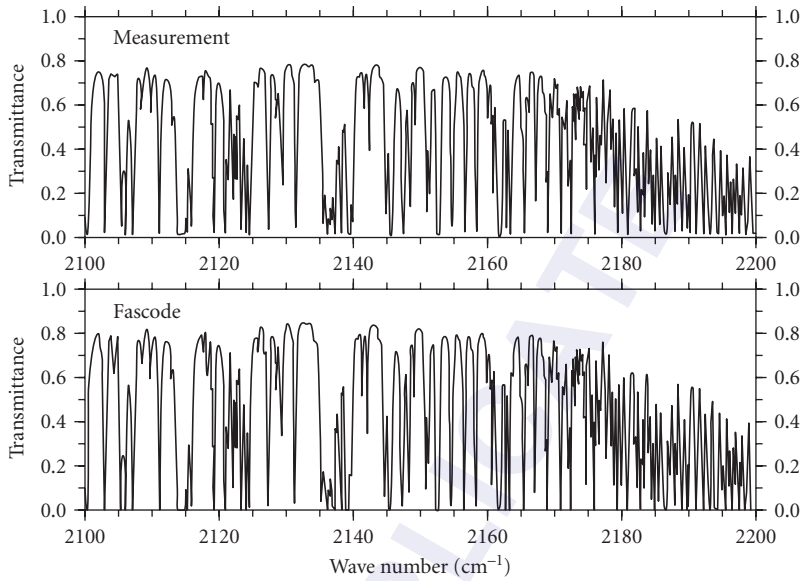

FIGURE 24 Comparison of an FASCOD2 transmittance calculation with an experimental atmospheric measurement (from NRL) over a 6.4-km path at the ground. (*Courtesy of Clough, Ref. 30.*)

band-model calculations to speed up the computations, and provides an accurate and rapid means of estimating the transmittance and background radiance of the earth's atmosphere over the spectral interval of 350 cm^{-1} to 40,000 cm^{-1} (i.e., 250-nm–28-μm wavelength). The spectral range of the LOWTRAN program extends into the UV. In the LOWTRAN program, the total transmittance at a given wavelength is given as the product of the transmittances due to molecular band absorption, molecular scattering, aerosol extinction, and molecular continuum absorption. The molecular band absorption is composed of four components of water vapor, ozone, nitric acid, and the uniformly mixed gases (CO_2, N_2O, CH_4, CO, O_2, and N_2).

The latest version of LOWTRAN(7) contains models treating solar and lunar scattered radiation, spherical refractive geometry, slant-path geometry, wind-dependent maritime aerosols, vertical structure aerosols, standard seasonal and geographic atmospheric models (e.g., mid-latitude summer), cirrus cloud model, and a rain model.[34] As an example, Fig. 25 shows a ground-level solar radiance model used by LOWTRAN, and Fig. 26 shows an example of a rain-rate model and its effect upon the transmission of the atmosphere as a function of rain rate in mm of water per hour.[34]

Extensive experimental measurements have been made to verify LOWTRAN calculations. Figure 27 shows a composite plot of the LOWTRAN-predicted transmittance and experimental data for a path length of 1.3 km at sea level.[3] As can be seen, the agreement is quite good. It is estimated that the LOWTRAN calculations are good to about 10 percent.[3] It should be added that the molecular absorption portion of the preceding LOWTRAN (moderate-resolution) spectra can also be generated using the high-resolution FASCODE/HITRAN program and then spectrally smoothing (i.e., degrading) the spectra to match that of the LOWTRAN spectra.

The most recent extension of the LOWTRAN program is the MODTRAN program. MODTRAN is similar to LOWTRAN but has increased spectral resolution. At present, the resolution for the latest version of MODTRAN, called MODTRAN(5), can be specified by the user between 0.1 and 20 cm^{-1}.

Programs and Databases for Use on Personal Computers

The preceding databases and computer programs have been converted or modified to run on different kinds of personal computers.[35,36] The HITRAN database has been available on CD-ROMs for the past decade, but is now available via the internet. Several related programs are available, ranging from a complete copy of the FASCODE and LOWTRAN programs[35] to a simpler molecular transmission program of the atmosphere.[36] These programs calculate the transmission spectrum of the atmosphere and some show the overlay spectra of known laser lines. As an example, Fig. 28 shows the transmission spectrum produced by the HITRAN-PC program[36] for a horizontal path of 300 m (U.S. Standard Atmosphere) over the wavelength range of 250 nm (40,000 cm-1) to 20 μm (500 cm^{-1}); the transmission spectrum includes water, nitrogen, and CO_2 continuum and urban aerosol attenuation, and was smoothed to a spectral resolution of 1 cm^{-1} to better display the overall transmission features of the atmosphere.

While these PC versions of the HITRAN database and transmission programs have become available only recently, they have already made a significant impact in the fields of atmospheric optics and optical remote sensing. They allow quick and easy access to atmospheric spectral data which was previously only available on a mainframe computer. It should be added that other computer programs are available which allow one to add or subtract different spectra generated by these HITRAN-based programs, from spectroscopic instrumentation such as FT-IR spectrometers or from other IR gas spectra databases. In the latter case, for example, the U.S. National Institute of Standards and Technology (NIST) has compiled a computer database of the qualitative IR absorption spectra of over 5200 different gases (toxic and other hydrocarbon compounds) with a spectral resolution of 4 cm^{-1}.[37] The Pacific Northwest National Laboratory also offers absorption cross-section files of numerous gases.[38] In addition, higher-resolution quantitative spectra for a limited group of gases can be obtained from several commercial companies.[39]

3.6 ATMOSPHERIC OPTICAL TURBULENCE

The most familiar effects of refractive turbulence in the atmosphere are the twinkling of stars and the shimmering of the horizon on a hot day. The first of these is a random fluctuation of the amplitude of light also known as scintillation. The second is a random fluctuation of the phase front that

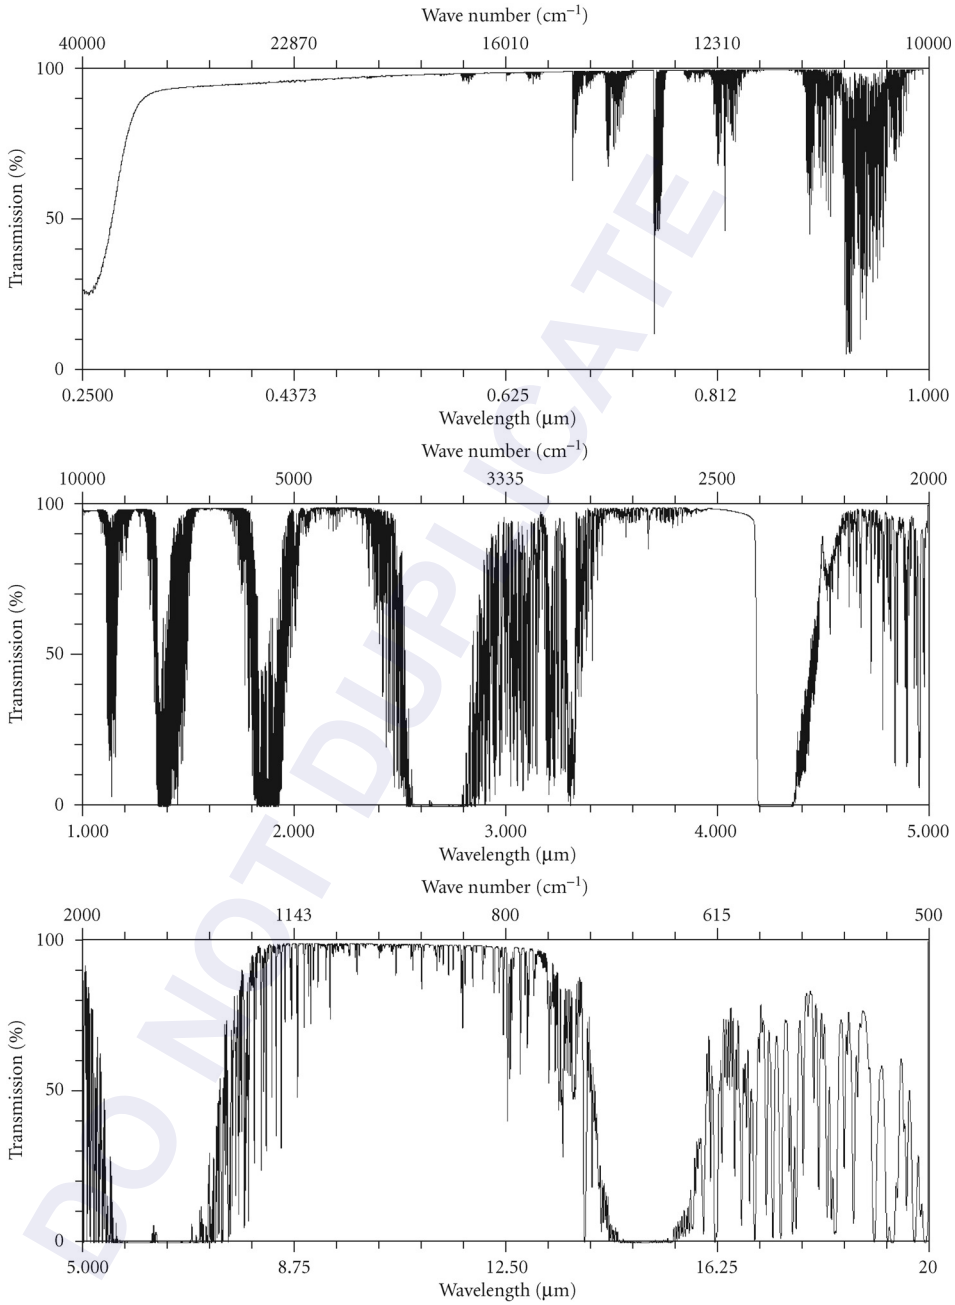

FIGURE 28 Example of generated atmospheric transmission spectrum of the atmosphere for a horizontal path of 300 m for the wavelength range from UV (250 nm or 40,000 cm^{-1}) to the IR (20 μm or 500 cm^{-1}); the spectrum includes water, nitrogen, and CO_2 continuum, urban ozone and NO_2, and urban aerosol attenuation, and has been smoothed to a resolution of 0.5 cm^{-1} to better show the absorption and transmission windows of the atmosphere. (*From Ref. 36 and D. Pliutau.*)

leads to a reduction in the resolution of an image. Other effects include the wander and break-up of an optical beam. A detailed discussion of all of these effects and the implications for various applications can be found in Ref. 40.

In the visible and near-IR region of the spectrum, the fluctuations of the refractive index in the atmosphere are determined by fluctuations of the temperature. These temperature fluctuations are caused by turbulent mixing of air of different temperatures. In the far-IR region, humidity fluctuations also contribute.

Turbulence Characteristics

Refractive turbulence in the atmosphere can be characterized by three parameters. The outer scale L_0 is the length of the largest scales of turbulent eddies. The inner scale l_0 is the length of the smallest scales. For eddies in the inertial subrange (sizes between the inner and outer scale), the refractive index fluctuations are best described by the structure function. This function is defined by

$$D_n(r_1, r_2) = \left\langle [n(r_1) - n(r_2)]^2 \right\rangle \tag{14}$$

where $n(r_1)$ is the index of refraction at point r_1 and the angle brackets denote an ensemble average. For homogeneous and isotropic turbulence it depends only on the distance between the two points r and is given by

$$D_n(r) = C_n^2 r^{2/3} \tag{15}$$

where C_n^2 is a measure of the strength of turbulence and is defined by this equation.

The power spectrum of turbulence is the Fourier transform of the correlation function, which is contained in the cross term of the structure function. For scales within the inertial subrange, it is given by the Kolmogorov spectrum:

$$\Phi_n(K) = 0.033 C_n^2 K^{-11/3} \tag{16}$$

For scales larger than the outer scale, the spectrum actually approaches a constant value, and the result can be approximated by the von Kármán spectrum:

$$\Phi_n(K) = 0.033 C_n^2 (K^2 + K_o^2)^{-11/6} \tag{17}$$

where K_0 is the wave number corresponding to the outer scale. For scales near the inner scale, there is a small increase over the Kolmogorov spectrum, with a large decrease at smaller scales.[41] The resulting spectrum can be approximated by a rather simple function.[42,43]

In the boundary layer (the lowest few hundred meters of the atmosphere), turbulence is generated by radiative heating and cooling of the ground. During the day, solar heating of the ground drives convective plumes. Refractive turbulence is generated by the mixing of these warm plumes with the cooler air surrounding them. At night, the ground is cooled by radiation and the cooler air near the ground is mixed with warmer air higher up by winds. A period of extremely low turbulence exists at dawn and at dusk when there is no temperature gradient in the lower atmosphere. Turbulence levels are also very low when the sky is overcast and solar heating and radiative cooling rates are low. Measured values of turbulence strength near the ground vary from less than 10^{-17} to greater than 10^{-12} $m^{-2/3}$ at heights of 2 to 2.5 m.[44,45]

Figure 29 illustrates typical summertime values near Boulder, Colorado. This is a 24-hour plot of 15-minute averages of C_n^2 measured at a height of about 1.5 m on August 22, 1991. At night, the sky was clear, and C_n^2 was a few parts times 10^{-13}. The dawn minimum is seen as a very short period of low turbulence just after 6:00. After sunrise, C_n^2 increases rapidly to over 10^{-12}. Just before noon, cumulus clouds developed, and C_n^2 became lower with large fluctuations. At about 18:00, the clouds dissipated,

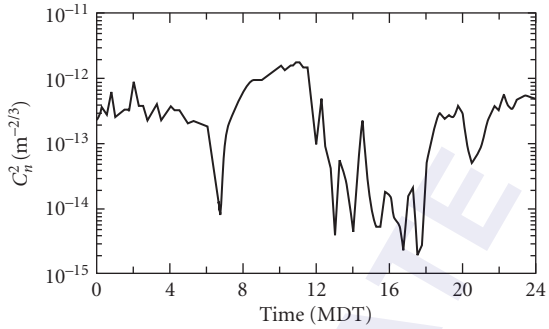

FIGURE 29 Plot of refractive-turbulence structure parameter C_n^2 for a typical summer day near Boulder, Colorado. (*Courtesy G. R. Ochs, NOAA WPL.*)

and turbulence levels increased. The dusk minimum is evident just after 20:00, and then turbulence strength returns to typical nighttime levels.

From a theory introduced by Monin and Obukhov,[46] a theoretical dependence of turbulence strength on height in the boundary layer above flat ground can be derived.[47,48] During periods of convection C_n^2 decreases as the −4/3 power of height. At other times (night or overcast days), the power is more nearly −2/3. These height dependencies have been verified by a number of experiments over relatively flat terrain.[49–53] However, values measured in mountainous regions are closer to the −1/3 power of height day or night.[54] Under certain conditions, the turbulence strength can be predicted from meteorological parameters and characteristics of the underlying surface.[55–57]

Farther from the ground, no theory for the turbulence profile exists. Measurements have been made from aircraft[44,49] and with balloons.[58–60] Profiles of C_n^2 have also been measured remotely from the ground using acoustic sounders,[61–63] radar,[49,50,64–69] and optical techniques.[59,70–73] The measurements show large variations in refractive turbulence strength. They all exhibit a sharply layered structure in which the turbulence appears in layers of the order of 100 m thick with relatively calm air in between. In some cases these layers can be associated with orographic features; that is, the turbulence can be attributed to mountain lee waves. Generally, as height increases, the turbulence decreases to a minimum value that occurs at a height of about 3 to 5 km. The turbulence level then increases to a maximum at about the tropopause (10 km). Turbulence levels decrease rapidly above the tropopause.

Model turbulence profiles have evolved from this type of measurement. Perhaps the best available model for altitudes of 3 to 20 km is the Hufnagel model:[74,75]

$$C_n^2 = \left\{\left[(2.2\times 10^{-53})H^{10}\left(\frac{W}{27}\right)^2\right]\exp\left(-\frac{H}{1000}\right) + 10^{-16}\exp\left(-\frac{H}{1500}\right)\right\}\exp[u(H,t)] \tag{18}$$

where H is the height above sea level in meters, W is the vertical average of the square of the wind speed, and u is a random variable that allows the random nature of the profiles to be modeled. W is defined by

$$W^2 = \frac{1}{1500}\int_{5000}^{20{,}000} v^2(H)\,dH \tag{19}$$

where $v(H)$ is the wind speed at height H. In data taken over Maryland, W was normally distributed with a mean value of 27 m/s and a standard deviation of 9 m/s. The random variable u is assumed to be a zero-mean, Gaussian variable with a covariance function given by

$$\langle u(H,t)u(H+\delta H, t+\delta t)\rangle = A(\delta H/100)\exp(-\delta t/5) + A(\delta H/2000)\exp(-\delta t/80) \tag{20}$$

where

$$A(\delta H/L) = 1 - |\delta H/L| \qquad \text{for } |H| < L \tag{21}$$

and equals 0 otherwise.

The time interval δt is measured in minutes. The average C_n^2 profile can be found by recognizing that $\langle \exp(u) \rangle = \exp(1)$. To extend the model to local ground level, one should add the surface layer dependence (e.g., $H^{-4/3}$ for daytime).

Another attempt to extend the model to ground level is the Hufnagel-Valley model.[76] This is given by

$$C_n^2 = 0.00594\left(\frac{W}{27}\right)^2 (H \times 10^{-5})^{10} \exp\left(-\frac{H}{1000}\right) + 2.7 \times 10^{-16} \exp\left(-\frac{H}{1500}\right) + A\exp\left(-\frac{H}{100}\right) \tag{22}$$

where W is commonly set to 21 and A to 1.7×10^{-14}. This specific model is referred to as the $HV_{5/7}$ model because it produces a coherence diameter r_0 of about 5 cm and an isoplanatic angle of about 7 μrad for a wavelength of 0.5 μm. Although this is not as accurate for modeling turbulence near the ground, it has the advantage that the moments of the turbulence profile important to propagation can be evaluated analytically.[76]

The $HV_{5/7}$ model is plotted as a function of height in the dashed line in Fig. 30. The solid line in the figure is a balloon measurement taken in College Station, Pennsylvania. The data were reported with 20-m vertical resolution and smoothed with a Gaussian filter with a 100-m exp (−1) full-width. This particular data set was chosen because it has a coherence diameter of about 5 cm and an isoplanatic angle of about 7 μrad. The layered structure of the real atmosphere is clear in the data. Note also the difference between the model atmosphere and the real atmosphere even when the coherence diameter and the isoplanatic angle are similar.

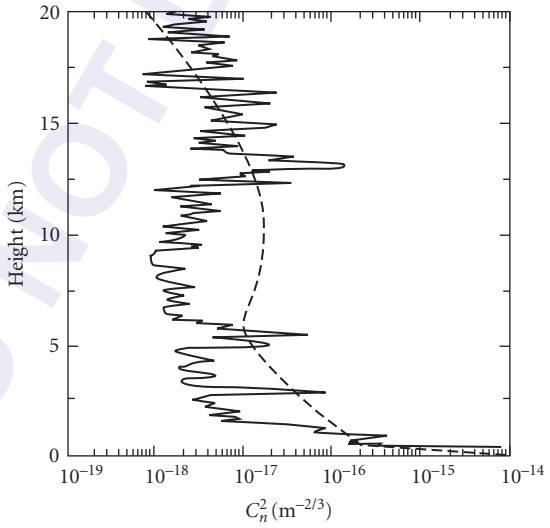

FIGURE 30 Turbulence strength C_n^2 as a function of height. The solid line is a balloon measurement made in College Station, Pennsylvania, and the dashed line is the $HV_{5/7}$ model. (*Courtesy R. R. Beland, Geophysics Directorate, Phillips Laboratory, U.S. Air Force.*)

Less is known about the vertical profiles of inner and outer scales. Near the ground (1 to 2 m) we typically observe inner scales of 5 to 10 mm over flat grassland in Colorado. Calculations of inner scale from measured values of Kolmogorov microscale range from 0.5 to 9 mm at similar heights.[77] Aircraft measurements of dissipation rate were used along with a viscosity profile calculated from typical profiles of temperature and pressure to estimate a profile of microscale.[78] Values increase monotonically to about 4 cm at a height of 10 km and to about 8 cm at 20 km.

Near the ground, the outer scale can be estimated using Monin-Obukhov similarity theory.[46] The outer scale can be defined as that separation at which the structure function of temperature fluctuations is equal to twice the variance. Using typical surface layer scaling relationships[79] we see that

$$L_0 = \begin{cases} 7.04H(1-7S_{\mathrm{MO}})(1-16S_{\mathrm{MO}})^{-32} & \text{for} \quad -2 < S_{\mathrm{MO}} \\ 7.04H(1+S_{\mathrm{MO}})^{-3}(1+2.75S_{\mathrm{MO}}^{2/3})^{-32} & \text{for} \quad 0 < S_{\mathrm{MO}} < \end{cases} \tag{23}$$

where S_{MO} is the Monin-Obukhov stability parameter. For typical daytime conditions ($S_{\mathrm{MO}} < 0$), L_0 is generally between $H/2$ and H.

Above the boundary layer, the situation is more complex. Barat and Bertin[80] measured outer scale values of 10 to 100 m in a turbulent layer using a balloonborne instrument. Some recent optical data[81,82] suggest that the outer scale is generally between 10 and 40 m.

Beam Wander

The first effect of refractive turbulence to consider is the wander of an optical beam in the atmosphere. The deviations of the centroid of a beam in each of the two orthogonal transverse axes will be independent of Gaussian random variables. This wander is generally characterized statistically by the variance of the angular displacement. In isotropic turbulence, the variances in the two axes are equal and the magnitude of the displacement is a Rayleigh random variable with a variance that is twice that of the displacement in a single axis. Both the single-axis and the magnitude variances are reported in the literature.

Three main approaches to the calculation of beam-wander variance have been used: (1) If diffraction effects are negligible and if the path-integrated turbulence is small enough, the geometric optics approximation[83–86] can be used. Diffraction effects are negligible when the aperture diameter is greater than the Fresnel zone size.[86] The other condition requires that the product of the transverse coherence of the field and the aperture diameter is greater than the square of the Fresnel zone size.[86] (2) If diffraction must be considered, the Huygens-Fresnel approximation[87–90] can be used. (3) The most complete theory uses the Markov random process approximation to the moment equation.[91–93] In the two types of calculation that include diffraction, beams with a Gaussian irradiance profile are generally assumed.

In the geometric optics approximation, the variance of the angular displacement in a single axis is given by[86]

$$\sigma_d^2 = 2.92D^{-1/3}\int_0^L dz C_n^2(z)\frac{\left(1-\dfrac{z}{L}\right)^2}{\left|1-\dfrac{z}{F}\right|^{1/3}} \tag{24}$$

where D is the diameter of the initial beam, z is position along the path, L is the propagation path length, and F is the geometric focal range of the initial beam (negative for a diverging beam). For homogeneous turbulence and a beam that does not come to a focus between the transmitter and observation plane, Eq. (24) reduces to

$$\sigma_d^2 = 0.97C_n^2D^{-1/3}L_2F_1\left(\frac{1}{3}, 1; 4; \frac{L}{F}\right) \tag{25}$$

where ${}_2F_1$ is the hypergeometric function. The hypergeometric function is 1 for a collimated beam and 1.125 for a focused beam.

In the Markov approximation, the single-axis variance is given by[91]

$$\sigma_d^2 = 4\pi^2 \int_0^L dz \left(1 - \frac{z}{L}\right)^2 \int_0^\infty dK K^3 \Phi_n(K, z) \times \exp\left\{-\frac{K^2 D^2}{8}\left[\left(1 - \frac{z}{F}\right)^2 + \frac{16z^2}{K^2 D^2}\right] - \pi D_\Psi\left(\frac{Kz}{k}\right)\right. \tag{26}$$

where $\Phi_n(K, z)$ is the path-dependent refractive index spectrum, K is the wave number of turbulence, D is the exp (-1) irradiance diameter of the initial beam, k is the optical wave number, and $D_\Psi(r)$ is the wave structure function for separation r of a spherical wave. The structure function is given by

$$D_\Psi(r) = 8\pi^2 k^2 \int_0^z dz' \int_0^\infty dK' K' \Phi_n(K', z')[1 - J_0(K' r z'/z)] \tag{27}$$

where J_0 is the zero-order Bessel function of the first kind. The last term in the exponential of Eq. (26) is a correction term for strong turbulence. The middle term includes the effects of diffraction.

Beam Spreading

The next effect of refractive turbulence to consider is the spread of an optical beam as it propagates through the atmosphere. There are two types of beam spread denoted as long term and short term. The long-term beam spread is defined as the turbulence-induced beam spread observed over a long time average. It includes the effects of the slow wander of the entire beam. The short-term beam spread is defined as the beam spread observed at an instant of time. It does not include the effects of beam wander and is often approximated by the long-term beam spread with the effects of wander removed, although the two are not identical.

We can consider beam wander to be caused by turbulent eddies that are larger than the beam. Short-term beam spread is caused by turbulent eddies that are smaller than the beam. There are more small eddies than large in the beam at any time which implies that the beam spread at any instant is averaged over more eddies. As a result, the fluctuations of short-term beam spread are much smaller than those of beam wander and are typically neglected. The primary effect of short-term beam spread is to spread the average energy over a larger area. Thus, the average value of the on-axis irradiance is reduced, and the average value of the irradiance at large angles is increased.

The extended Huygens-Fresnel principle can be used to calculate the long-term spread of a Gaussian beam in refractive turbulence.[94–98] The exp (-1) irradiance radius of a Gaussian beam is

$$p_1 = \left[\frac{4}{k^2 D^2} + \frac{D^2}{4}\left(1 - \frac{L}{F}\right)^2 + \frac{4}{k^2 \rho_0^2}\right]^{1/2} \tag{28}$$

where D is the exp (-1) irradiance diameter of the source and ρ_0 is the phase coherence length that would be observed for a point source propagating from the receiver to the transmitter. The first term in this equation is the diffraction beam spread, the second is the geometrical optics projection of the transmitter aperture, and the final term is the total turbulence-induced spread.

The phase coherence length is defined as the transverse separation at which the coherence of the field is reduced to exp (-1). If the coherence length ρ_0 is much larger than the inner scale, the structure function is given by $D_\Psi(r) = 2(r/\rho_0)^{5/3}$ and

$$\rho_0 = \left[1.46 k^2 \int_0^L dz \left(\frac{z}{L}\right)^{5/3} C_n^2(z)\right]^{-3/5} \tag{29}$$

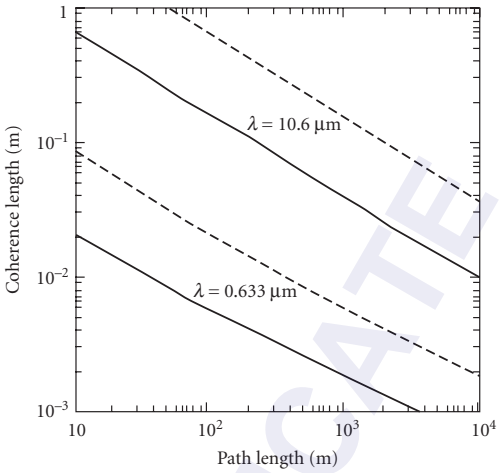

FIGURE 31 Coherence length ρ_0 as a function of path length for two common laser wavelengths. An inner scale of 1 cm, and values of 10^{-12} (solid lines) and 10^{-13} (dashed lines) were used in the calculations.

If the coherence length is much smaller than the inner scale, then $D_\Psi(r) = 2(r/\rho_0)^2$ and

$$\rho_0 = \left[1.86k^2 \int_0^L dz \left(\frac{z}{L}\right)^2 C_n^2(z) l_0^{-1/3}(z)\right]^{-1/2} \tag{30}$$

Typical values of ρ_0 for spherical-wave propagation through homogeneous turbulence are presented in Fig. 31. In these plots there is a slope change from $L^{-3/5}$ to $L^{-1/2}$, where ρ_0 is about equal to the inner scale of 1 cm. This small change is nearly imperceptible in the figure.

The extended Huygens-Fresnel principle has been used to calculate the short-term beam spread by explicitly subtracting the beam wander.[99–102] If ρ_0 and l_0 are much smaller than D, then the short-term beam spread is approximately given by

$$p_s = \left\{\frac{4}{k^2D^2} + \frac{D^2}{4L^2}\left(1 - \frac{L}{F}\right)^2 + \frac{4}{k^2\rho_0^2}\left[1 - 0.62\left(\frac{\rho_0}{D}\right)^{1/3}\right]^{6/5}\right\}^{1/2} \tag{31}$$

If ρ_0 is much greater than D, the turbulence-induced component of beam spreading can be neglected.

If inner scale and outer scale effects are included, more complicated integral expressions result.[103] Numerical calculations were performed for truncated Gaussian beams with central obscurations.[104] The following approximation was obtained by a curve fit to the results:

$$\begin{aligned} p_s &= \left(1 + 0.182\frac{D_{\text{eff}}^2}{r_0^2}\right)^{1/2} p_d \qquad \text{for} \qquad \frac{D_{\text{eff}}}{r_0} < 3 \\ p_s &= \left[1 + \left(\frac{D_{\text{eff}}}{r_0}\right)^2 - 1.18\left(\frac{D_{\text{eff}}}{r_0}\right)^{-5/3}\right]^{1/2} p_d \qquad \text{for} \qquad 3 < \frac{D_{\text{eff}}}{r_0} < \end{aligned} \tag{32}$$

where D_{eff} is the effective diameter of the truncated aperture, $r_0 = 2.099\, p_0$, and p_d is the diffraction-limited value. These expressions agree fairly well with available data.[87,105,106]

Imaging and Heterodyne Detection

The problem of imaging through the turbulent atmosphere is similar to the problem of beam propagation through the atmosphere. The dancing of an image in the focal plane of an imaging system is mathematically equivalent to the wander of a beam focused at the object by the same optical system. The resolution of the short-exposure image is equivalent to the short-term beam spread of the same focused beam. The resolution for a long exposure is related to the long-term beam spread.

Thus, the position of the image of a point object will drift in each axis in the focal plane. The variance of that drift is given by[107]

$$\sigma_i^2 = 1.10 C_n^2 D^{-1/3} L F^2 \tag{33}$$

where D is the aperture diameter of the imaging system, F is its focal length, and L is the distance to the object.

Fried[108] used the idea of tilt correction to calculate the average image resolution for a short-exposure image in the turbulent atmosphere. This problem is mathematically equivalent to the propagation of a beam in the opposite direction if the imaging aperture replaces the beam width. These results were refined by Lutomirski et al.[109] and applied to a space-to-ground path by Valley.[103]

Image resolution is also related to the signal-to-noise ratio of an optical heterodyne receiver. The long-exposure resolution is equivalent to a staring receiver. The short-exposure resolution is equivalent to a receiver that employs tilt-correction of the signal or of the local oscillator.[108,110–112]

Scintillation

The refractive index inhomogeneities that distort the optical phase front also produce amplitude scintillation at some distance. The first cases to be considered were plane-wave and spherical-wave propagation through weak path-integrated turbulence where the weak-turbulence condition requires that fluctuations of irradiance be much less than the mean value. Tatarskii[113] used a perturbation approach to the wave equation. Lee and Harp[114] used a physical approach to arrive at the same results. These results are summarized in a number of good reviews.[101,102,115,116]

We will first consider the weak-turbulence results. For propagation from space to the ground, the plane wave formula is generally valid. The variance of irradiance fluctuations (normalized by the mean irradiance value) is given by[115]

$$\sigma_r^2 = k^{7/6} \sec^{11/6}\theta \int_0^\infty dH H^{5/6} C_n^2(H) \tag{34}$$

where k is the optical wave number, θ is the zenith angle, and H is the height of the receiver above the ground. This expression is valid as long as the path-integrated turbulence is weak enough that the variance is much less than unity. This condition is usually met for near-zenith propagation.

For propagation of diverging waves near the ground, the spherical-wave approximation is often valid. Assuming constant turbulence along the path, the weak-turbulence variance in this case is given by[115]

$$\begin{aligned} \sigma_r^2 &= \exp\left[0.5 k^{7/6} L^{11/6} C_n^2\right] - 1 \qquad \text{for} \qquad l_0 < \surd \\ \sigma_r^2 &= \exp\left[1.28 L^3 l_o^{-7/3} C_n^2\right] - 1 \qquad \text{for} \qquad l_0 > \surd \end{aligned} \tag{35}$$

where L is the path length and l_0 is the inner scale of turbulence.

For narrow-beam propagation, the effects of the finite beam must be considered. Kon and Tatarskii[117] calculated the amplitude fluctuations of a collimated beam using the perturbation technique. Schmeltzer[118] extended these results to include focused beams. These results were used to obtain numerical values for a variety of propagation conditions.[119–121] Ishimaru[122–124] used a spectral representation to obtain similar results. Under certain conditions, one sees a reduction in the variance on the optical axis[119,120,125,126] and an increase off of the optical axis.[127]

The spatial scale of weak scintillations is about equal to the larger of either the Fresnel zone size $(L/k)^{1/2}$ or the inner scale.[115] Scintillation will be reduced if an aperture larger than the scale size is used to collect the light. If the aperture diameter D is much larger than the scale size, the reduction factor can be expressed as[128,129]

$$A = C\left(\frac{D}{D_0}\right)^{-7/3} \tag{36}$$

where D_0 is $(\lambda L)^{1/2}$ and C is 4.71 for a plane wave and 23.5 for a spherical wave when the inner scale is much smaller than the Fresnel zone. If the inner scale is much larger than the Fresnel zone, D_0 is the inner scale and C is 0.45 for a plane wave and 9.17 for a spherical wave.

It is generally accepted that the probability density function for weak scintillation is log normal.[101,113,115,130] This density function has the form

$$p(I) = \frac{1}{\sqrt{2\pi}\sigma_I I}\exp\left[-\frac{1}{2\sigma_r^2}\left(\ln I + 0.5\sigma_r^2\right)^2\right] \tag{37}$$

The weak-turbulence theory is, in essence, a single-scattering theory. As the path-integrated turbulence becomes larger, multiple-scattering effects become important, and this theory breaks down. Actual observed values of irradiance variance are smaller than predicted in this region as shown in Fig. 32. The circles in this figure are 1-minute averages of irradiance variance for 488-nm laser light propagated across 1200 m of flat grassland. The solid line is the weak-turbulence approximation.

In these and other experiments, variance values reach a peak value of between 3 and 5 for a spherical wave and they begin to decrease with increasing turbulence strength.[131–134] In the limit of infinite path-integrated turbulence, the normalized variance of irradiance is predicted to approach unity.[135,136] In the intermediate region near the peak irradiance, numerical evaluation of currently available theories is impractical, and variance values are most easily obtained through numerical simulation.[137–140]

In very strong turbulence two distinct spatial scales are evident in the scintillation pattern.[136,141–144] The smaller scale is about the size of the coherence length ρ_0 discussed under "Beam Spreading." The larger scale is the size of the scattering disk which is the ratio of the square of the Fresnel zone to the coherence length $(L/k\rho_0)$. As turbulence increases, the small scale becomes smaller and the large scale becomes larger. The strength of the small-scale fluctuations is constant in this regime and contributes a value of unity to the variance. The large-scale fluctuations contribute the rest of the variance and become weaker with increasing turbulence strength.

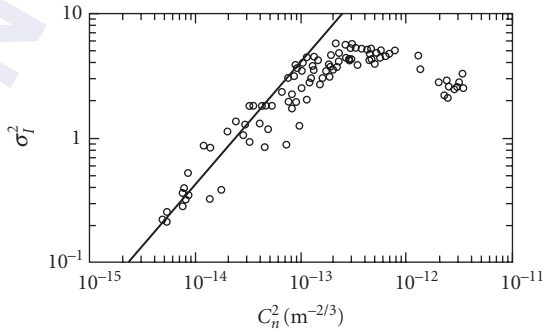

FIGURE 32 Plot of normalized variance of irradiance σ_1^2 as a function of turbulence strength. C_n^2 circles are data taken with a 488-nm wavelength laser over a 1200-m path, and the line is the corresponding weak-turbulence theory.

The two-scale nature of the irradiance fluctuations suggests a two-scale probability density function. The log-normally modulated Rician density function has been shown to agree with experimental data[130] and simulations.[145] It has the form

$$p(I) = \int_0^\infty dz \frac{(1+r)}{z} \exp\left(-r - \frac{1+r}{z} I\right) I_0 \left\{2\left[\frac{(1+r)r}{z}\right]^{1/2} I\right\} \frac{1}{(2\pi)^{1/2}\sigma_z z} \exp\left[-\frac{\left(\ln z + \frac{1}{2}\sigma_z^2\right)^2}{2\sigma_z^2}\right] \tag{38}$$

where r is a coherence parameter that decreases with increasing turbulence, I_0 is the 0-order modified Bessel function of the first kind, and σ_z^2 is the variance of the logarithm of the modulation factor z. For $r >> 1$ this function reduces to the lognormal; for $r << 1$, it reduces to a log-normally modulated exponential:[134,146]

$$p(I) = \frac{1}{\sqrt{2\pi}\sigma_z} \int_0^\infty \frac{dz}{z^2} \exp\left[-\frac{I}{z} - \frac{\left(\ln z + \frac{1}{2}\sigma_z^2\right)^2}{2\sigma_z^2}\right] \tag{39}$$

where the parameter σ_z^2 is related to the irradiance variance by the relationship

$$\sigma_I^2 = 2\exp(\sigma_z^2) - 1 \tag{40}$$

As this model suggests, the density function of the fluctuations approaches a lognormal, even in strong turbulence, if an aperture $>> \rho_0$ is used.[147]

If the fluctuations at both large and small scales are approximated by gamma distributions, the resulting integral can be evaluated analytically to get the gamma-gamma density function:[148]

$$p(I) = \frac{2(\alpha\beta)^{0.5(\alpha+\beta)}}{\Gamma(\alpha)\Gamma(\beta)} I^{0.5(\alpha+\beta)-1} \mathrm{K}_{\alpha-\beta}(2\sqrt{\alpha\beta I}) \tag{41}$$

where α and β are related to the variances at the two scales, Γ is the gamma function, and K is the modified Bessel function of the second kind.

3.7 EXAMPLES OF ATMOSPHERIC OPTICAL REMOTE SENSING

One of the more important applications of atmospheric optics is optical remote sensing. Atmospheric optical remote sensing concerns the use of an optical or laser beam to remotely sense information about the atmosphere or a distant target. Optical remote sensing measurements are diverse in nature and include the use of a spectral radiometer aboard a satellite for the detection of trace species in the upper atmosphere, the use of spectral emission and absorption from the earth for the detection of the concentration of water vapor in the atmosphere, the use of lasers to measure the range-resolved distribution of several molecules including ozone in the atmosphere, and Doppler wind measurements. In this section, some typical optical remote sensing experiments will be presented in order to give a flavor of the wide variety of atmospheric optical measurements that are currently being conducted. More in-depth references can be found in several current journal papers, books, and conference proceedings.[149–156]

The Upper Atmospheric Research Satellite (UARS) was placed into orbit in September 1991 as part of the Earth Observing System. One of the optical remote sensing instruments aboard UARS is the High Resolution Doppler Imager (HRDI) developed by P. Hays' and V. Abreu's group while at the University of Michigan.[157,158] The HRDI is a triple etalon Fabry-Perot Interferometer designed to measure Doppler shifts of molecular absorption and emission lines in the earth's atmosphere in order to determine the wind velocity of the atmosphere. A wind velocity of 10 m/s causes a Doppler shift of 2×10^{-5} nm for the oxygen lines detected near a wavelength of 600 to 800 nm. A schematic of the instrument is given in Fig. 33*a* which shows the telescope, triple Fabry-Perots, and unique imaging Photo-Multiplier tubes to detect the Fabry-Perot patterns of the spectral absorption lines. The HRDI instrument is a passive remote sensing system and uses the reflected or scattered sunlight as its illumination source. Figure 33*b* shows the wind field measured by UARS (HRDI) for an altitude of 90 km.

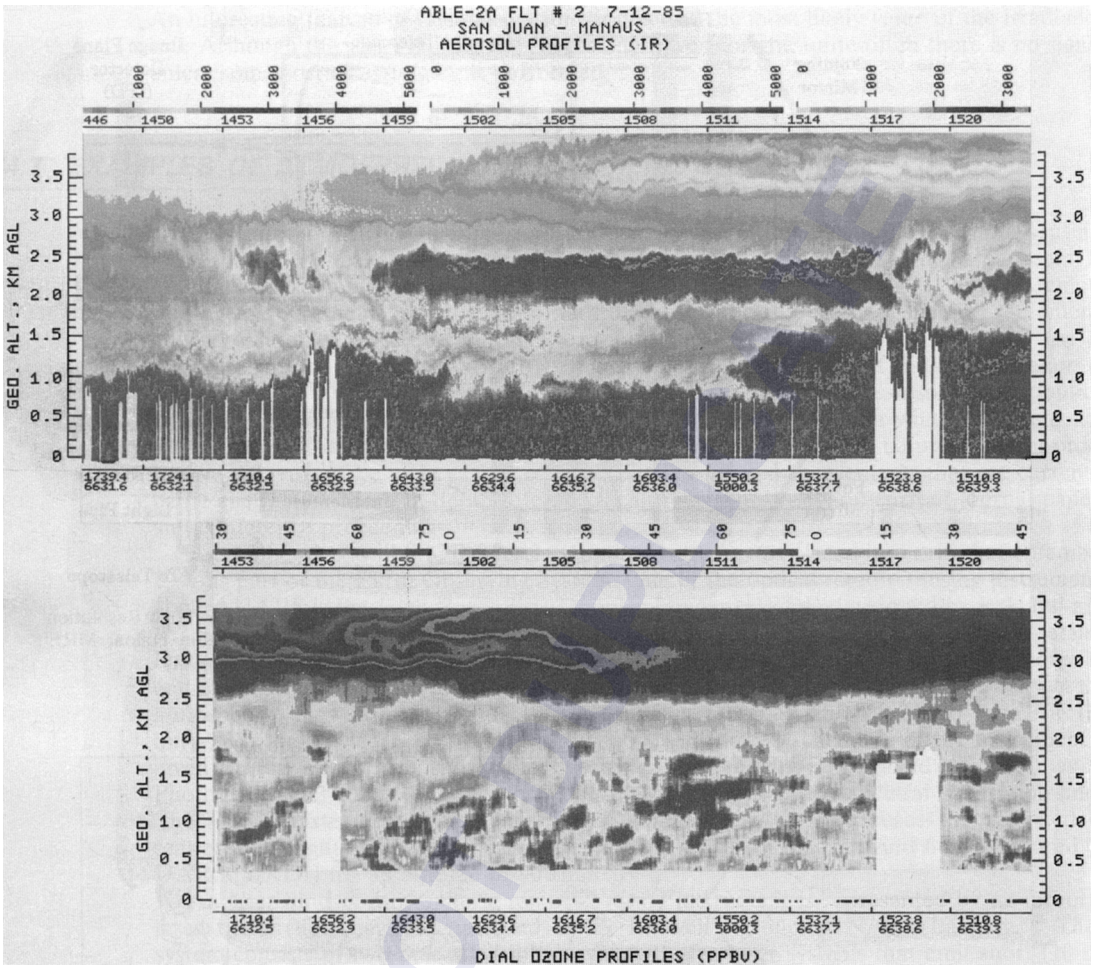

FIGURE 34 Range-resolved lidar measurements of atmospheric aerosols and ozone density. (*From Browell, Ref. 159.*)

Another kind of atmospheric remote sensing instrument is represented by an airborne laser radar (lidar) system operated by E. Browell's group at NASA/Langley.[159] Their system consists of two pulsed, visible-wavelength dye laser systems that emit short (10 ns) pulses of tunable optical radiation that can be directed toward aerosol clouds in the atmosphere. By the proper tuning of the wavelength of these lasers, the difference in the absorption due to ozone, water vapor, or oxygen in the atmosphere can be measured. Because the laser pulse is short, the timing out to the aerosol scatterers can be determined and range-resolved lidar measurements can be made. Figure 34 shows range-resolved lidar backscatter profiles obtained as a function of the lidar aircraft ground position. The variation in the atmospheric density and ozone distribution as a function of altitude and distance is readily observed.

A Coherent Doppler lidar is one which is able to measure the Doppler shift of the backscattered lidar returns from the atmosphere. Several Doppler lidar systems have been developed which can determine wind speed with an accuracy of 0.1 m/s at ranges of up to 15 km. One such system is operated by M. Hardesty's group at NOAA/WPL for the mapping of winds near airports and for meteorological studies.[160,161] Figure 35 shows a two-dimensional plot of the measured wind velocity obtained during the approach of a wind gust front associated with colliding thunderstorms; the upper

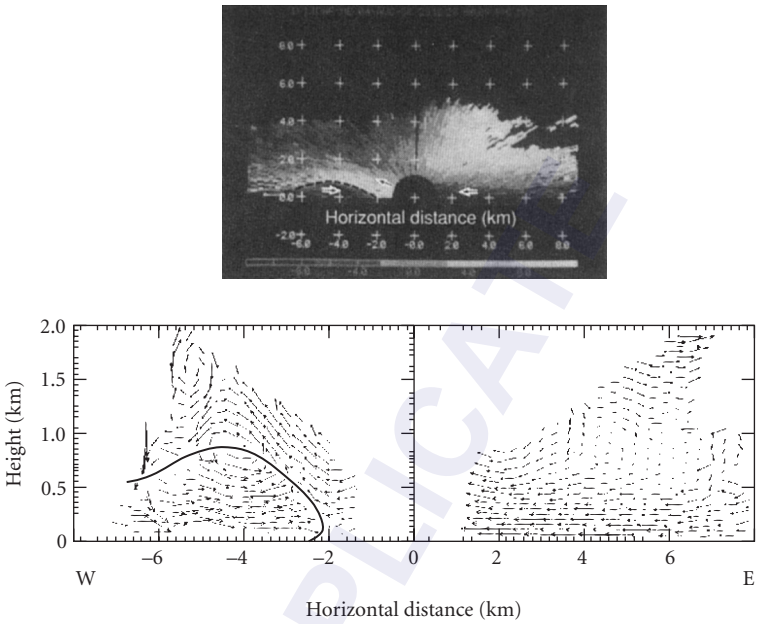

FIGURE 35 Coherent Doppler lidar measurements of atmospheric winds showing velocity profile of gust front. Upper plot is real-time display of Doppler signal and lower plot is range-resolved wind field. (*From Hardesty, Ref. 160.*)

figure shows the real-time Doppler lidar display of the measured radial wind velocity, and the lower plot shows the computed wind velocity. As seen, a Doppler lidar system is able to remotely measure the wind speed with spatial resolution on the order of 100 m. A similar Doppler lidar system is being considered for the early detection of windshear in front of commercial aircraft.

A further example of atmospheric optical remote sensing is that of the remote measurement of the global concentration and distribution of atmospheric aerosols. P. McCormick's group at NASA/Langley and Hampton University has developed the SAGE II satellite system which is part of a package of instruments to detect global aerosol and selected species concentrations in the atmosphere.[162] This system measures the difference in the optical radiation emitted from the earth's surface and the differential absorption due to known absorption lines or spectral bands of several species in the atmosphere, including ozone. The instrument also provides for the spatial mapping of the concentration of aerosols in the atmosphere, and an example of such a measurement is shown in Fig. 36. This figure shows the measured concentration of aerosols after the eruption of Mt. Pinatubo and demonstrates the global circulation and transport of the injected material into the earth's atmosphere.

More recently, this capability has been refined by David Winker's group at NASA that developed the laser based CALIPSO lidar satellite which has produced continuous high-resolution 3D maps of global cloud and aerosol distributions since its launch in 2006.

There are several ongoing optical remote sensing programs to map and measure the global concentration of CO_2 and other green house gases in the atmosphere. For example, the spaceborne Atmospheric Infrared Sounder (AIRS) from JPL has measured the CO_2 concentration at the mid-troposphere (8 km altitude) beginning in 2003, and the NASA Orbiting Carbon Observatory (OCO) to be launched in 2008 will be the first dedicated spaceborne instrument to measure the sources and sinks of CO_2 globally. Both of these instruments use optical spectroscopy of atmospheric CO_2 lines to measure the concentration of CO_2 in the atmosphere.

Finally, there are related nonlinear optical processes that can also be used for remote sensing. For example, laser-induced-breakdown spectroscopy (LIBS) has been used recently in a lidar system for the remote detection of chemical species by focusing a pulsed laser beam at a remote target, producing a plasma spark at the

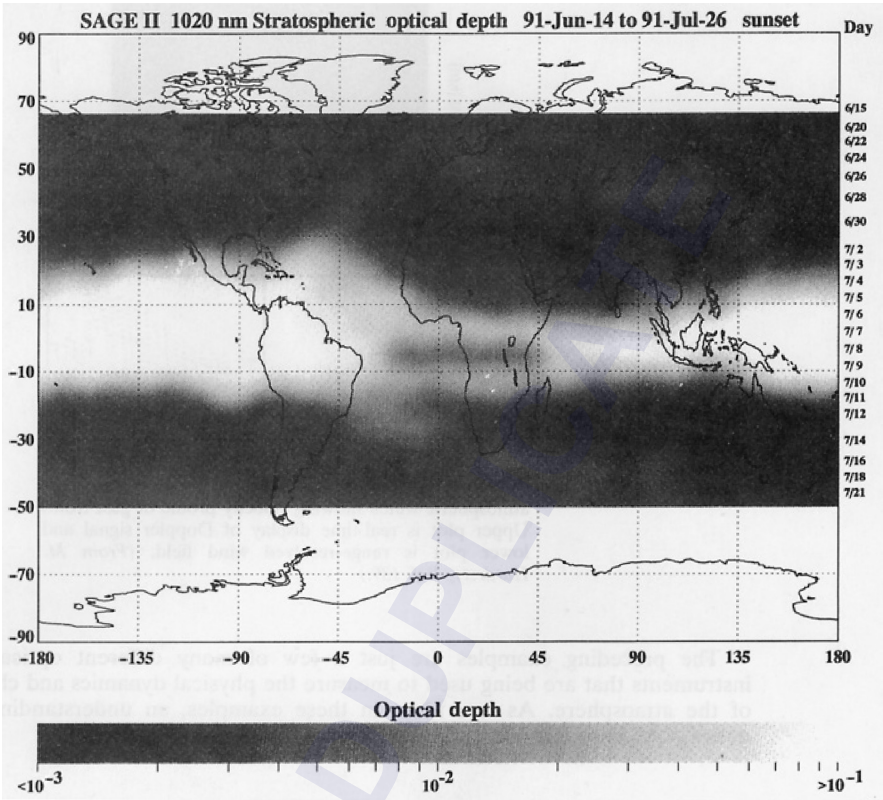

FIGURE 36 Measurement of global aerosol concentration using SAGE II satellite following eruption of Mt. Pinatubo. (*From McCormick, Ref. 162.*)

target, and analyzing the emitted spectral light after being transmitted back through the atmosphere.[163,164] Another technique is the use of a high-power femtosecond pulse-length laser to produce a dielectric breakdown (spark) in air that self focuses into a long filament of several 100s of meters in length. The channeling of the laser filament has been used to remotely detect distant targets and atmospheric gases.[165]

The preceding examples are just a few of many different optical remote sensing instruments that are being used to measure the physical dynamics and chemical properties of the atmosphere. As is evident in these examples, an understanding of atmospheric optics plays an important and integral part in these measurements.

3.8 METEOROLOGICAL OPTICS

One of the most colorful aspects of atmospheric optics is that associated with meteorological optics. Meteorological optics involves the interplay of light with the atmosphere and the physical origin of the observed optical phenomena. Several excellent books have been written about this subject, and the reader should consult these and the contained references.[166,167] While it is beyond the scope of this chapter to present an overview of meteorological optics, some specific optical phenomena will be described to give the reader a sampling of some of the interesting effects involved in naturally occurring atmospheric and meteorological optics.

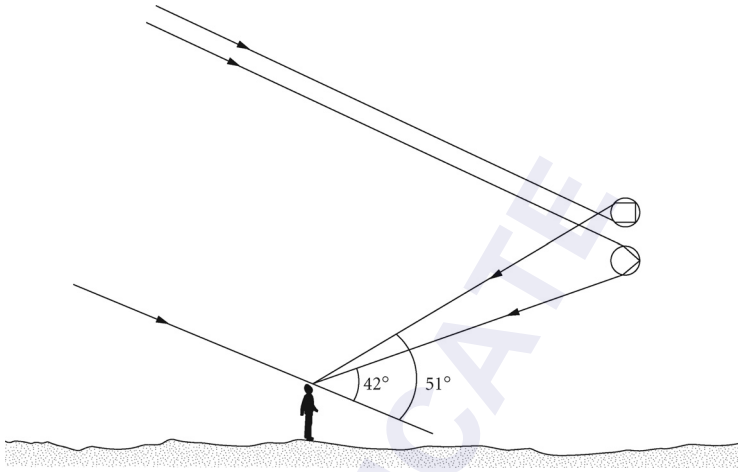

FIGURE 37 Different raindrops contribute to the primary and to the larger, secondary rainbow. (*From Greenler, Ref. 167.*)

Some of the more common and interesting meteorological optical phenomena involve rainbows, ice-crystal halos, and mirages. The rainbow in the atmosphere is caused by internal reflection and refraction of sunlight by water droplets in the atmosphere. Figure 37 shows the geometry involved in the formation of a rainbow, including both the primary and larger secondary rainbow. Because of the dispersion of light within the water droplet, the colors or wavelengths are separated in the backscattered image. Although rainbows are commonly observed in the visible spectrum, such refraction also occurs in the infrared spectrum. As an example, Fig. 38 shows a natural rainbow in the atmosphere photographed with IR-sensitive film by R. Greenler.[167]

FIGURE 38 A natural infrared rainbow. (*From Greenler, Ref. 167.*)

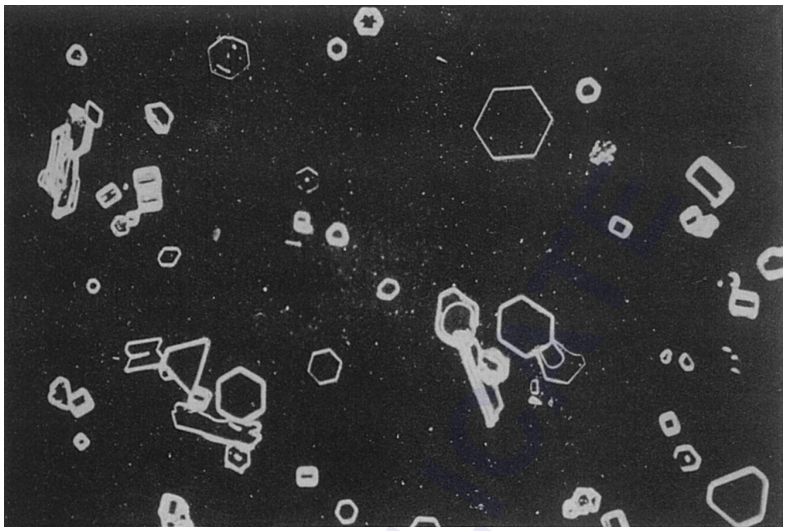

FIGURE 39 Photograph of magnified small ice crystals collected as they fell from the sky. (*From Greenler, Ref. 167.*)

The phenomena of halos, arcs, and spots are due to the refraction of light by ice crystals suspended in the atmosphere. Figure 39 shows a photograph of collected ice crystals as they fell from the sky. The geometrical shapes, especially the hexagonal (six-sided) crystals, play an important role in the formation of halos and arcs in the atmosphere.

The common optical phenomenon of the mirage is caused by variation in the temperature and thus, the density of the air as a function of altitude or transverse geometrical distance. As an example, Fig. 40 shows the geometry of light-ray paths for a case where the air temperature decreases with height

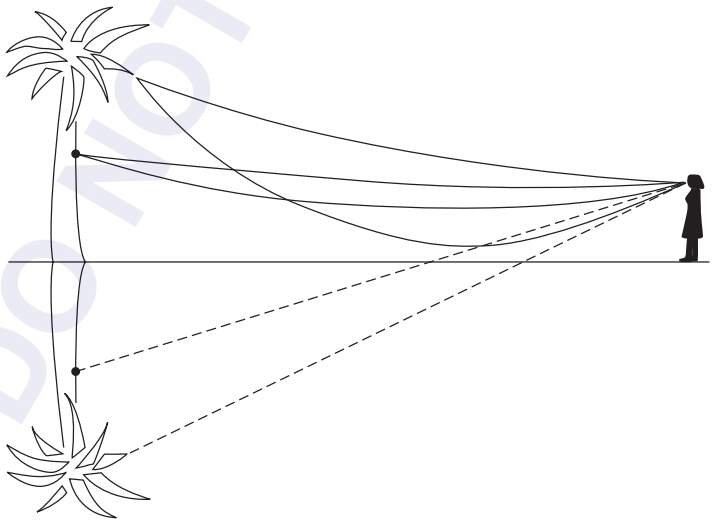

FIGURE 40 The origin of the inverted image in the desert mirage. (*From Greenler, Ref. 167.*)

FIGURE 41 The desert (or hot-road) mirage. In the inverted part of the image you can see the apparent reflection of motocycles, cars, painted stripes on the road, and the grassy road edge. (*From Greenler, Ref. 167.*)

to a sufficient extent over the viewing angle that the difference in the index of refraction can cause a refraction of the image similar to total internal reflection. The heated air (less dense) near the ground can thus act like a mirror, and reflect the light upward toward the viewer. As an example, Fig. 41 shows a photograph taken by Greenler of motorcycles on a hot road surface. The reflected image of the motorcycles "within" the road surface is evident. There are many manifestations of mirages dependent upon the local temperature gradient and geometry of the situation. In many cases, partial and distorted images are observed leading to the almost surreal connotation often associated with mirages.

Finally, another atmospheric meteorological optical phenomenon is that of the green flash. A green flash is observed under certain conditions just as the sun is setting below the horizon. This phenomenon is easily understood as being due to the different relative displacement of each different wavelength or color in the sun's image due to spatially distributed refraction of the atmosphere.[167] As the sun sets, the last image to be observed is the shortest wavelength color, blue. However, most of the blue light has been Rayleigh scattered from the image seen by the observer so that the last image observed is closer to a green color. Under extremely clear atmospheric conditions when the Rayleigh scattering is not as preferential in scattering the blue light, the flash has been reported as blue in color. Lastly, one of the authors (DK) has observed several occurrences of the green flash and noticed that the green flash seems to be seen more often from sunsets over water than over land, suggesting that a form of water vapor layer induced ducting of the optical beam along the water's surface may be involved in enhancing the absorption and scattering process.

3.9 ATMOSPHERIC OPTICS AND GLOBAL CLIMATE CHANGE

Of importance, atmospheric optics largely determines the earth's climate because incoming sunlight (optical energy) is scattered and absorbed and outgoing thermal radiation is absorbed and reemitted by the atmosphere. This net energy flux, either incoming or outgoing, determines if the earth's

climate will warm or cool, and is directly related to the radiative transfer calculations mentioned in Sec. 3.4. A convenient way to express changes in this energy balance is in terms of the radiative forcing, which is defined as the change in the incoming and outgoing radiative flux at the top of the troposphere. To a good approximation, individual forcing terms add linearly to produce a linear surface-temperature response at regional to global scales. Reference 168 by the Intergovernmental Panel on Climate Change (2007) provides a detailed description of radiative forcing and the scientific basis for these findings.

As an example, Fig. 42 shows that the major radiative forcing mechanisms for changes between the years of 1750 and 2005 are the result of anthropogenic changes to the atmosphere.[168] As can be seen, the largest effect is that of infrared absorption by the greenhouse gases, principally CO_2. This is the reason that the measurement of the global concentration of CO_2 is important for accurate predictions for future warming or cooling trends of the earth. Other forcing effects are also shown in Fig. 42. Water vapor remains the largest absorber of infrared radiation, but changes in water vapor caused

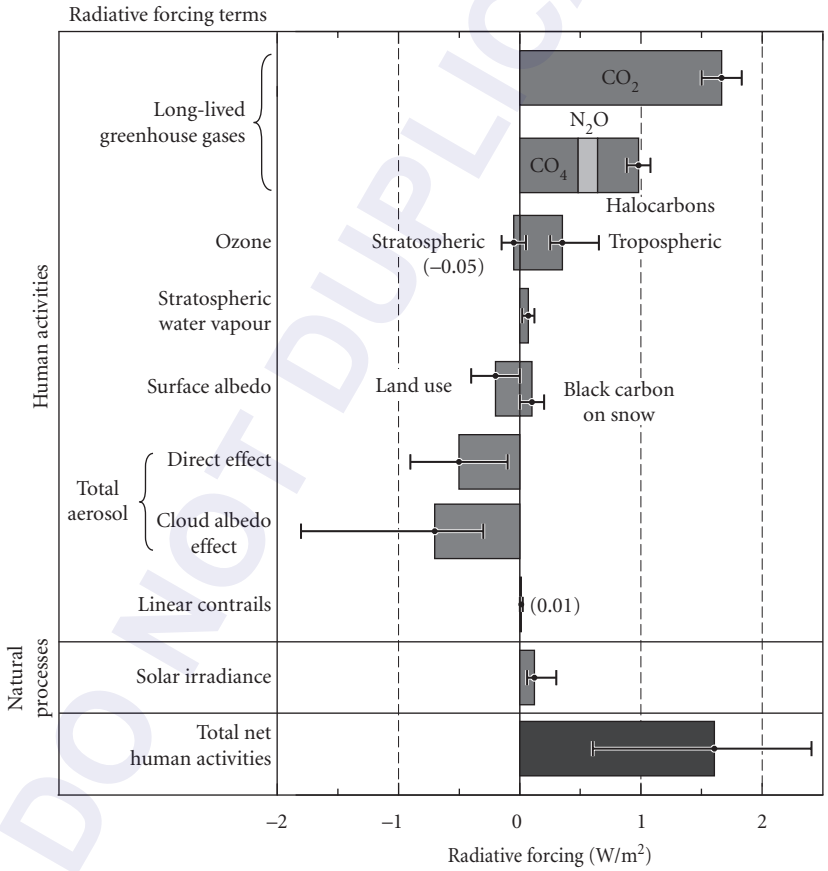

FIGURE 42 Effect of atmospheric optics on global climate change represented by the radiative forcing terms between the years of 1750 and 2005. The change in the energy (W/m^2) balance for the earth over this time period is shown resulting in a net positive energy flow onto the earth, with a potential warming effect. Contributions due to individual terms, such as changes in the CO_2 gas concentration or changes in land use, are shown. (*Reprinted with permission from Ref. 168.*)

by climate changes are considered a response rather than a forcing term. The exception is a small increase in stratospheric water vapor produced by methane emissions. Similarly, the effects of clouds are part of a climate response, except for the increase in cloudiness that is a direct result of increases in atmospheric aerosols. The linearity of climate response to radiative forcing implies that the most efficient radiative transfer calculations for each term can be used. For example, a high resolution spectral absorption calculation is not needed to calculate the radiative transfer through clouds, and a multiple-scattering calculation is not needed to calculate the effects of absorption by gases.

In summary, Fig. 42 shows the important contributions of radiative forcing effects that contribute to changes in the heat balance of the earth's atmosphere. All of the noted terms are influenced by the optical properties of the atmosphere whether due to absorption of sunlight by the line or band spectrum of molecules in the air, the reflection of light by the earth's surface or oceans, or reabsorption of thermal radiation by greenhouse gases. The interested reader is encouraged to study Ref. 168 for more information, and references therein.

3.10 ACKNOWLEDGMENTS

We would like to acknowledge the contributions and help received in the preparation of this chapter and in the delineation of the authors' work. The authors divided the writing of the chapter sections as follows: D. K. Killinger served as lead author and wrote Secs. 3.2 through 3.4 and Secs. 3.7 and 3.8 on atmospheric interactions with light, remote sensing, and meteorological optics. L. S. Rothman wrote and provided the extensive background information on HITRAN, FASCODE, and LOWTRAN in Sec. 3.5. The comprehensive Secs. 3.6 and 3.9 were written by J. H. Churnside. The data of Fig. 29 were provided by G. R. Ochs of NOAA/WPL and the data in Fig. 30 were provided by R. R. Beland of the Geophysics Directorate, Phillips Laboratory. We wish to thank Prof. Robert Greenler for providing original photographs of the meteorological optics phenomena; Paul Hays, Vincent Abreu, and Wilbert Skinner for information on the HRDI instrument; P. McCormick and D. Winker for SAGE II data; Mike Hardesty for Doppler lidar wind profiles; and Ed Browell for lidar ozone mapping data. We want to thank A. Jursa for providing a copy of the *Handbook of Geophysics*. R. Measures for permission to use diagrams from his book *Laser Remote Sensing*, and M. Thomas and D. Duncan for providing a copy of their chapter on atmospheric optics from *The Infrared Handbook*.

Finally, we wish to thank many of our colleagues who have suggested topics and technical items added to this work. We hope that the reader will gain an overall feeling of atmospheric optics from reading this chapter, and we encourage the reader to use the references cited for further in-depth study.

ABSTRACT

In this chapter, how the random aberrations introduced by atmospheric turbulence degrade the image formed by a ground-based telescope with an annular pupil is considered. The results for imaging with a circular pupil are obtained as a special case of the annular pupil. Both the long- and short-exposure images are discussed in terms of their Strehl ratio, point-spread function (PSF), and transfer function. The discussion given is equally applicable to laser beams propagating through turbulence. An atmospheric coherence length is defined and it is shown that, for fixed power of a beam and regardless of the size of its diameter, the central irradiance in the focal plane is smaller than the corresponding aberration-free value for a beam of diameter equal to that of the coherence length. The aberration function is decomposed into Zernike annular polynomials and the autocorrelation and crosscorrelations of the expansion coefficients are given for Kolmogorov turbulence. It is shown that the aberration variance increases with the obscuration ratio of the annular pupil. The angle of arrival is also discussed, both in terms of the wavefront tilt as well as the centroid of the aberrated PSF. It is shown that the difference between the two is small, and the obscuration has only a second-order effect.

4.1 GLOSSARY

a	outer radius of the pupil
a_j	expansion coefficients
$A_L(\vec{r}_p)$	amplitude function of the lens (or imaging system) at a pupil point with position vector $\vec{r}_p$
C_n^2	refractive index structure parameter
$\mathcal{D}$	structure function ($\mathcal{D}_w$—wave, $\mathcal{D}_\Phi$—phase, $\mathcal{D}_l$—log amplitude, $\mathcal{D}_n$—refractive index)
D	diameter of exit pupil or aperture
F	focal ratio of the image-forming light cone $(F = R/D)$

*The author is also an adjunct professor at the College of Optical Sciences at the University of Arizona, Tucson and the Department of Optics and Photonics, National Central University, Chung Li, Taiwan.

$I_i(\vec{r}_i)$	irradiance at a point $\vec{r}_i$ in the image plane
$I(r)$	normalized irradiance in the image plane such that its aberration-free central value is $I(0) = 1$
$\langle I_0 \rangle$	time-averaged irradiance at the exit pupil
j	Zernike aberration mode number
J	number of Zernike aberration modes
$l(\vec{r}_p)$	log-amplitude function introduced by atmospheric turbulence
L	path length through atmosphere or from source to receiver
$n(\vec{r})$	fluctuating part of refractive index $N(\vec{r})$
$P(r_c)$	encircled power in a circle of radius r_c in the image plane
P_{ex}	power in the exit pupil
$P_L(\vec{r}_p)$	lens pupil function
$P_R(\vec{r}_p)$	complex amplitude variation introduced by atmospheric turbulence
r_0	Fried's atmospheric coherence length
R	radius of curvature of the reference sphere with respect to which the aberration is defined
$R_n^m(\rho)$	Zernike circle radial polynomial of degree n and azimuthal frequency m
$\langle S \rangle$	time-averaged Strehl ratio
S_a	coherent area $\pi r_0^2/4$ of atmospheric turbulence
$\langle S_t \rangle$	tilt-corrected time-averaged Strehl ratio
S_{ex}	area of exit pupil
$Z_n^m(\rho, \theta)$	Zernike circle polynomial of degree n and azimuthal frequency m
ϵ	obscuration ratio of an annular pupil
Δ_J	phase aberration variance after correcting $J = j$ aberration modes
η	central irradiance in the image plane normalized by the aberration-free value for a pupil with area S_a but containing the same total power
λ	wavelength of object radiation
$\vec{\nu}_i$	spatial frequency vector in the image plane
$\vec{\nu}$	normalized spatial frequency vector
ϑ_0	isoplanatic angle of turbulence
σ_α, σ_β	tip and tilt angle standard deviations
σ_Φ^2	phase aberration variance
$\tau(\vec{\nu})$	optical transfer function
ρ	radial variable normalized by the pupil radius a
$\tau_a(\nu)$	long-exposure (LE) atmospheric MTF reduction factor
$\Phi(\vec{r}_p)$	phase aberration
$\Phi_R(\vec{r}_p)$	random phase aberration introduced by atmospheric turbulence

4.2 INTRODUCTION

The resolution of a telescope forming an aberration-free image is determined by its diameter D; larger the diameter, better the resolution. However, in ground-based astronomy, the resolution is degraded considerably because of the aberrations introduced by atmospheric turbulence. A plane wave of uniform amplitude and phase representing the light from a star propagating through the atmosphere undergoes both amplitude and phase variations due to the random inhomogeneities

in its refractive index. The amplitude variations, called scintillations, result in the twinkling of stars. The purpose of a large ground-based telescope has therefore generally not been better resolution but to collect more light so that dim objects may be observed. Of course, with the advent of adaptive optics,[1–3] the resolution can be improved by correcting the phase aberrations with a deformable mirror. The amplitude variations are negligible in near-field imaging, that is, when the far-field distance $D^2/\lambda >> L$ or $D >> \sqrt{\lambda L}$, where λ is the wavelength of the starlight and L is the propagation path length through the turbulence.[4] In principle, a diffraction-limited image can be obtained if the aberrations are corrected completely in real time by the deformable mirror. However, in far-field imaging, that is, when $D^2/\lambda << L$ or $D << \sqrt{\lambda L}$, significant amplitude variations are introduced in addition to the phase variations. Since the amplitude variations cannot be corrected by adaptive optics, even a complete correction of the phase errors does not yield a diffraction-limited image.

In this chapter, we consider the effect of random aberrations introduced by atmospheric turbulence on the image quality. The discussion given is applicable equally to laser beams propagating through turbulence. First, we derive expressions for the degraded time-averaged point-spread function (PSF) and optical transfer function (OTF). The pupil function of the overall imaging system is written as the product of the pupil function of the optical system and a complex amplitude factor introduced by turbulence. As a result, the time-averaged OTF of the overall system is also equal to the product of the OTF of the optical system and an OTF reduction factor representing the mutual coherence function of the wave propagating through the turbulent atmosphere. The time-averaged images thus obtained are referred to as the *long-exposure images*.[4] The exposure time may be 1 to 10 s.

Next, the structure functions for refractive index and phase fluctuations are given for the *Kolmogorov turbulence*. We introduce the notion of *atmospheric coherence length* r_0, and show that it limits the resolution of the image regardless of how large the telescope diameter is.[4] Since large telescopes have annular pupils, we consider systems with such pupils and describe the Strehl ratio, PSF, and encircled power as a function of the ratio of the pupil diameter and the coherence length. The phase aberration introduced by Kolmogorov turbulence is expanded in terms of the Zernike annular polynomials,[5–8] and autocorrelation and crosscorrelation of the expansion coefficients are given.[9] It is shown that atmospheric turbulence dominates the degradation of the system modulation transfer function (MTF), Strehl ratio, or the angle of arrival; the effect of the pupil obscuration is small even for weak turbulence. The piston-removed aberration variance increases monotonically as the obscuration of the pupil increases. A large portion (87 percent for a circular pupil and somewhat larger for an annular pupil) of the aberration variance is a random wavefront tilt, resulting in a random displacement of the image over a long exposure. Hence, a better quality image is obtained if the exposure time is short enough so that the image does not wander. Such an image is referred to as a *short-exposure image*.[4] The exposure time may be 0.1 s or less. The location of such an image is random which is not relevant in astronomy. The image wander, sometimes referred to as the *angle of arrival*, is considered in terms of the wavefront tilt (called the Z-tilt) or the *centroid* of the image (called the G-tilt), and expressions are given for their standard deviations.

The fluctuating image can be stabilized if the tilt is corrected in real time with a steering mirror. A tilt-corrected image is equivalent to a time-averaged short-exposure image. The characteristics of such an image are considered and compared with those of a long-exposure image. The angular resolution of the system for a long-exposure image is about λ/r_0 compared to the diffraction-limited resolution λ/D. For a short-exposure image the resolution is substantially better than that for a long-exposure image. When the coherence length is much smaller than the pupil diameter, the image breaks up into small spots, called *speckles*, whose size depends on the latter, while the overall size of the image is determined by the former. An example of a speckled short-exposure image of a point object is illustrated and compared with the corresponding aberration-free image.

4.3 LONG-EXPOSURE IMAGE

When the medium between an object and the optical system imaging it is homogeneous, a spherical wavefront of uniform amplitude centered on an object point is incident on the entrance pupil of the system. If the system is aberration free and has uniform transmittance, a spherical wavefront of

uniform amplitude centered at the Gaussian image point emerges from its exit pupil. However, if the system is aberrated and has nonuniform transmittance, then the emerging wavefront is distorted with a nonuniform amplitude. Let $\mathbf{\Phi}_L(\vec{r}_p)$ and $A_L(\vec{r}_p)$ be the phase and amplitude transmittance corresponding to a point $\vec{r}_p$ on the exit pupil. A dimensionless pupil function of the system may be written

$$P_L(\vec{r}_p) = A_L(\vec{r}_p)\exp\left[i\mathbf{\Phi}_L(\vec{r}_p)\right] \tag{1}$$

When the medium between the object and the imaging system is inhomogeneous as in ground-based astronomy, it introduces random phase and amplitude variations across the wavefront propagating through it. Let $\mathbf{\Phi}_R(\vec{r}_{\text{en}})$ and $\ell(\vec{r}_{\text{en}})$ be the random phase and (dimensionless) log amplitude introduced by atmospheric turbulence at a point $\vec{r}_{\text{en}}$ on the entrance pupil. As the wave propagates through the imaging system, it undergoes additional phase and amplitude variations. The total phase aberration at a point $\vec{r}_p$ on the exit pupil may be written

$$\mathbf{\Phi}(\vec{r}_p) = \mathbf{\Phi}_L(\vec{r}_p) + \mathbf{\Phi}_R(\vec{r}_p) \tag{2}$$

where the position vector $\vec{r}_p$ is related to the position vector $\vec{r}_{\text{en}}$ by the pupil magnification m_p (i.e., $\vec{r}_p = m_p\vec{r}_{\text{en}}$). The pupil function of the overall system (i.e., including the effects of atmospheric turbulence) representing the wavefront at the exit pupil may be written

$$P(\vec{r}_p) = P_L(\vec{r}_p)P_R(\vec{r}_p) \tag{3}$$

where

$$P_R(\vec{r}_p) = \exp\left[\ell(\vec{r}_p) + i\mathbf{\Phi}_R(\vec{r}_p)\right] \tag{4}$$

is truncated by the pupil function $P_L(\vec{r}_p)$ and represents the complex amplitude variation introduced by turbulence.

The instantaneous irradiance distribution of the star image formed by the overall system is given by[10,11]

$$I_i(\vec{r}_i) = \frac{P_{\text{ex}}}{S_{\text{ex}}\lambda^2R^2}\left|\int P(\vec{r}_p)\exp\left(-\frac{2\pi i}{\lambda R}\vec{r}_p\cdot\vec{r}_i\right)d\vec{r}_p\right|^2 \tag{5}$$

where $\vec{r}_i$ is the position vector of a point in the image plane, P_{ex} is the total power in the image, S_{ex} is the area of the exit pupil, λ is the wavelength of object radiation, and R is the radius of curvature of the reference sphere with respect to which the aberration is defined.

Substituting Eq. (3) into Eq. (5), the time-averaged distribution, representing a long-exposure image, may be written

$$\langle I_i(\vec{r}_i)\rangle = \frac{\langle P_{\text{ex}}\rangle}{S_{\text{ex}}\lambda^2R^2}\iint P_L(\vec{r}_p)P_L^*(\vec{r}_p')\langle P_R(\vec{r}_p)P_R^*(\vec{r}_p')\rangle \times \exp\left[-\frac{2\pi i}{\lambda R}(\vec{r}_p - \vec{r}_p')\cdot\vec{r}_i\right]d\vec{r}_p d\vec{r}_p' \tag{6}$$

where $*$ denotes a complex conjugate. Thus, considering Eq. (4), we may write the *mutual coherence function* (MCF) of the wave incident on the system, using abbreviated notation

$$\langle P_R(\vec{r}_p)P_R^*(\vec{r}_p')\rangle \equiv \langle P_1P_2^*\rangle = \langle\exp[(\ell_1+\ell_2) + i(\mathbf{\Phi}_1 - \mathbf{\Phi}_2)]\rangle \tag{7}$$

If the refractive index fluctuations are statistically stationary, that is, they are statistically homogeneous and isotropic, then so are the fluctuations in ℓ and Φ which they generate. Therefore,

$$\langle(\ell_1+\ell_2)\,(\Phi_1-\Phi_2)\rangle = (\langle\ell_1\Phi_1\rangle - \langle\ell_2\Phi_2\rangle) + (\langle\ell_2\Phi_1\rangle - \langle\ell_1\Phi_2\rangle) \tag{8a}$$

$$= 0 \tag{8b}$$

where the two averaged quantities in the first term on the right-hand side of Eq. (8*a*) cancel each other due to homogeneity of turbulence, and those in the second term cancel due to its isotropy. Thus, $\ell_1+\ell_2$ and $\Phi_1-\Phi_2$ are uncorrelated random variables. Hence, Eq. (7) may be written

$$\langle P_R(\vec{r}_p)P_R^*(\vec{r}_p')\rangle = \langle\exp(\ell_1+\ell_2)\rangle\langle\exp[i(\Phi_1-\Phi_2)]\rangle \tag{9}$$

For a Gaussian random variable x with a mean value of $\langle x\rangle$ and a standard deviation of σ, it is easy to show that

$$\langle\exp(bx)\rangle = \frac{1}{2\pi\sigma}\int_{-\infty}^{\infty}\exp(bx)\exp[-(x-\langle x\rangle)^2/2\sigma^2]dx$$

$$= \exp\left[\frac{1}{2}b^2\langle(x-\langle x\rangle)^2\rangle + b\langle x\rangle\right] \tag{10}$$

where b is an arbitrary constant. As the wave propagates through the random atmosphere, it accumulates randomly both phase and amplitude variations. Each of these two random variables can be expressed as an integral along the propagation path. Since the atmospheric path length is much longer than the correlation length of these variable, the accumulation consists of a sum of a large number of terms that are statistically independent. By the central limit theorem, we can infer that they obey Gaussian statistics. Letting both ℓ and Φ_R be Gaussian random variables where Φ_R has a mean value of zero, it can be shown from conservation of power, that[4,11]

$$\langle\exp(\ell_1+\ell_2)\rangle = \exp\left[-\frac{1}{2}\mathcal{D}_\ell(|\vec{r}_p-\vec{r}_p'|)\right] \tag{11}$$

where

$$\mathcal{D}_\ell(|\vec{r}_p-\vec{r}_p'|) = \langle[\ell(\vec{r}_p)-\ell(\vec{r}_p')]^2\rangle \tag{12}$$

is the *log-amplitude structure function*.

Since Φ_1 and Φ_2 are Gaussian random variables with zero mean values, $\Phi_1-\Phi_2$ is also a Gaussian random variable. Hence, following Eq. (10), we obtain

$$\langle\exp[i(\Phi_1-\Phi_2)]\rangle = \exp\left[-\frac{1}{2}\langle(\Phi_1-\Phi_2)^2\rangle\right]$$

$$= \exp\left[-\frac{1}{2}\mathcal{D}_\Phi(|\vec{r}_p-\vec{r}_p'|)\right] \tag{13}$$

where

$$\mathcal{D}_\Phi(|\vec{r}_p-\vec{r}_p'|) = \langle[\Phi(\vec{r}_p)-\Phi(\vec{r}_p')]^2\rangle \tag{14}$$

is the *phase structure function* of turbulence. Substituting Eqs. (11) and (13) into Eq. (9), we may write the MCF

$$\langle P_R(\vec{r}_p)P_R^*(\vec{r}_p')\rangle = \exp\left[-\frac{1}{2}\mathcal{D}_w(|\vec{r}_p-\vec{r}_p'|)\right] \tag{15}$$

where

$$\mathcal{D}_w(|\vec{r}_p - \vec{r}'_p|) = \mathcal{D}_\ell(|\vec{r}_p - \vec{r}'_p|) + \mathcal{D}_\Phi(|\vec{r}_p - \vec{r}'_p|) \tag{16}$$

is called the *wave structure function* of turbulence.

Substituting Eq. (15) into Eq. (6), we obtain

$$\langle I_i(\vec{r}_i)\rangle = \frac{\langle P_{ex}\rangle}{S_{ex}\lambda^2 R^2}\iint P_L(\vec{r}_p)P_L^*(\vec{r}'_p)\exp\left[-\frac{1}{2}\mathcal{D}_w(|\vec{r}_p - \vec{r}'_p|)\right] \times \exp\left[-\frac{2\pi i}{\lambda R}(\vec{r}_p - \vec{r}'_p)\cdot\vec{r}_i\right]d\vec{r}_p d\vec{r}'_p \tag{17}$$

Because of a Fourier transform relationship between the PSF and the OTF, we identify $(\vec{r}_p - \vec{r}'_p)/\lambda R$ with a spatial frequency $\vec{v}_i$. Thus, we let

$$\vec{r}_p - \vec{r}'_p = \lambda R\vec{v}_i \tag{18}$$

Substituting Eq. (18) into Eq. (17) and carrying out the integration over $\vec{r}_p$, we may write

$$\langle I_i(\vec{r}_i)\rangle = \langle P_{ex}\rangle\int \tau_L(\vec{v}_i)\exp\left[-\frac{1}{2}\mathcal{D}_w(\lambda R v_i)\right]\exp(-2\pi i\vec{v}_i\cdot\vec{r}_i)d\vec{v}_i \tag{19}$$

where

$$\tau_L(\vec{v}_i) = S_{ex}^{-1}\int P_L(\vec{r}_p)P_L^*(\vec{r}_p - \lambda R\vec{v}_i)d\vec{r}_p \tag{20}$$

is the OTF of the (turbulence-free) optical system and $v_i = |\vec{v}_i|$. Now, we introduce normalized quantities

$$I(r) = I_i(\vec{r}_i)/I(0) \tag{21a}$$

$$\vec{r} = \vec{r}_i/\lambda F \tag{21b}$$

and

$$\vec{v} = \vec{v}_i/(1/\lambda F) \tag{21c}$$

where

$$I(0) = \frac{\langle P_{ex}\rangle S_{ex}}{\lambda^2 R^2} \tag{22}$$

is the aberration-free central irradiance for a uniform-amplitude wavefront with a total power $\langle P_{ex}\rangle$ and $1/\lambda F$ is the cutoff spatial frequency of the optical system. Here, $F = R/D$ is the focal ratio of the image-forming light cone. In terms of the normalized quantities, Eq. (19) for the time-averaged PSF may be written

$$\langle I(\vec{r})\rangle = (4/\pi)\int\langle\tau(\vec{v})\rangle\exp(-2\pi i\vec{v}\cdot\vec{r})d\vec{v} \tag{23}$$

where

$$\langle \tau(\vec{\nu}) \rangle = \tau_L(\vec{\nu}) \exp\left[-\frac{1}{2}\mathcal{D}_w(\nu D)\right] \tag{24}$$

is the time-averaged OTF. This OTF being equal to the product of the OTF of the optical system and the MCF associated with atmospheric turbulence is a consequence of the fact that the pupil function of the overall system is equal to the product of the pupil function of the optical system and the complex amplitude variation introduced by turbulence. It should be evident that, since $\nu D = \nu_i \lambda R$, the modification of the system OTF due to turbulence is independent of the diameter D of the exit pupil of the system. The MCF acts as a *reduction factor* for the OTF of the overall system.[11] It may also be referred to as the Hopkins ratio of the image if $\tau_L(\vec{\nu})$ is the aberration-free OTF. [11]

4.4 KOLMOGOROV TURBULENCE AND ATMOSPHERIC COHERENCE LENGTH

The refractive index $N(\vec{r})$ of the turbulent atmosphere at a point $\vec{r}$ in space fluctuates due to fluctuations of its temperature. It can be written as the sum of its mean value $\langle N(\vec{r}) \rangle$ at a point $\vec{r}$ and a fluctuating part $n(\vec{r})$ at that point, in the form

$$N(\vec{r}) = \langle N(\vec{r}) \rangle + n(\vec{r}) \tag{25}$$

Whereas $\langle N(\vec{r}) \rangle \simeq 1$, $n(\vec{r})$ is only on the order of 10^{-6}. It should be evident that $n(\vec{r})$ has a mean value $\langle n(\vec{r}) \rangle = 0$. The structure function $\mathcal{D}_n(\vec{r}_1, \vec{r}_2)$ of the refractive index fluctuations represents the mean square value of the difference of refractive index at two points $\vec{r}_1$ and $\vec{r}_2$, that is,

$$\mathcal{D}_n(\vec{r}_1, \vec{r}_2) = \langle [n(\vec{r}_1) - n(\vec{r}_2)]^2 \rangle \tag{26}$$

The turbulent atmosphere consists of packets of air called *eddies* each with a characteristic value of its refractive index. For Kolmogorov turbulence, the structural function is given by

$$\mathcal{D}_n(r) = C_n^2 r^{2/3}, \ \ell_0 << r << L_0 \tag{27}$$

where $r = |\vec{r}_2 - \vec{r}_1|$ and C_n^2 (in units of $\mathrm{m}^{-2/3}$) is called the *refractive index structure parameter*. The quantities ℓ_0 and L_0 are called the *inner* and *outer scales of turbulence* representing the smallest and the largest eddies, respectively. Typical values of C_n^2 vary from 10^{-13} $\mathrm{m}^{-2/3}$ for strong turbulence to 10^{-17} $\mathrm{m}^{-2/3}$ for weak turbulence. Values of ℓ_0 are on the order of a few millimeters, and those of L_0 vary from 1 to 100 m.

The wave structure function for a spherical wave propagating through Kolmogorov turbulence is given by[12]

$$\mathcal{D}_w(r) = 2.914 k^2 r^{5/3} \int_0^L C_n^2(z)(z/L)^{5/3} dz \tag{28}$$

where $k = 2\pi/\lambda$ and z varies along the atmospheric path of total length L from a value of zero at the source (or the object plane) to a value of L at the receiver (or the image plane). The wave structure function can also be written in the form[4,12]

$$\mathcal{D}_w(r) = 6.88(r/r_0)^{5/3} \tag{29}$$

where, for a spherical wave,

$$r_0 = 0.185 \lambda^{6/5} \left\{ \int_0^L C_n^2(z)(z/L)^{5/3} \, dz \right\}^{-3/5} \tag{30}$$

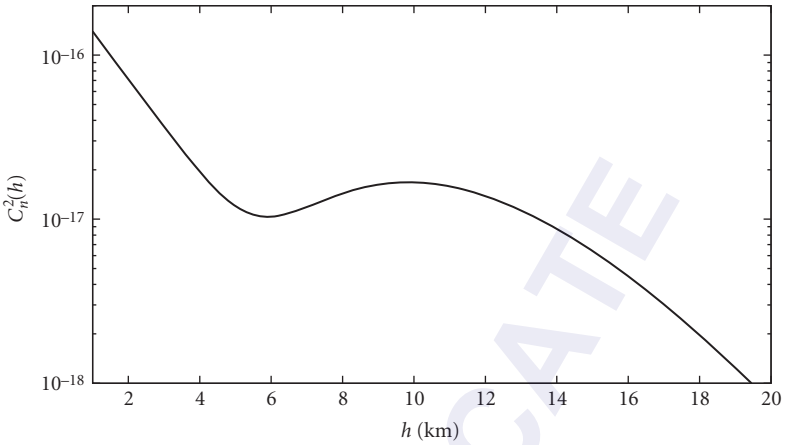

FIGURE 1 Variation of the refractive index structure parameter $C_n^2(h)$ with the altitude h for the Hufnagle-Valley model $H-V_{5/7}$ of Eq. (31).

is a characteristic length of Kolmogorov turbulence called its *coherence length* or *diameter*, often referred to as *Fried's coherence length*. We note that r_0 varies with the optical wavelength as $\lambda^{6/5}$. If the line of sight makes an angle θ with the zenith, then the path length L and the integral in Eq. (30) are increased by sec θ, or r_0 decreases by a factor of $(\sec\theta)^{3/5}$.

A commonly used model for the $C_n^2(z)$ variation is the Hufnagle-Valley model, often referred to as the $H-V_{5/7}$ model, given by[13]

$$C_n^2(h) = 8.2\times10^{-26}W^2h^{10}e^{-h} + 2.7\times10^{-16}e^{-h/1.5} + Ae^{-10h} \tag{31}$$

where h is the height from ground in kilometers, $A=1.7\times10^{-14}$, and $W=21$ m/s is the wind speed. Its variation with h is shown in Fig. 1. It decreases rapidly for the first few kilometers, dips at about 5.9 km, rises slightly due to turbulence in the jet stream peaking at about 9.8 km, and decreases monotonically to negligible values beyond about 20 km.

For a point source on the ground observed by an observer on an aircraft, space shuttle, or a satellite, light propagates upward in a manner similar to the $C_n^2(h)$ profile of increasing height h. The observer looks at the point source down through the atmosphere.[14] Substituting Eq. (31) into Eq. (30) with h replaced by z (keeping in mind that C_n^2 is in units of $m^{-2/3}$), we obtain the value of r_0 in the plane of the observer as a function of his/her height L, as shown in Fig. 2 by the solid curve. The observation is assumed to be along the zenith at a wavelength of $\lambda = 0.5$ μm. We note that r_0 increases slowly, goes through a peak at about 7.2 km and a valley at about 13.7 km, and then increases linearly with L beyond a height of about 20 km above which there is very little atmosphere.

For a ground observer looking up at a point source on an aircraft, space shuttle, or a satellite, z increases downward with a value of zero at the source and L on the ground. To determine r_0 from Eq. (30) using the $C_n^2(h)$ profile such as given by Eq. (31), we must either replace h by L-z, or replace z/L by $1-z/L$ as may be seen by a change of variable. Thus, Eq. (30) in this case is replaced by

$$r_0 = 0.185\lambda^{6/5}\left[\int_0^L C_n^2(L-z)(z/L)^{5/3}dz\right]^{-3/5}$$

$$= 0.185\lambda^{6/5}\left[\int_0^L C_n^2(z)\left(1-\frac{z}{L}\right)^{5/3}dz\right]^{-3/5} \tag{32}$$

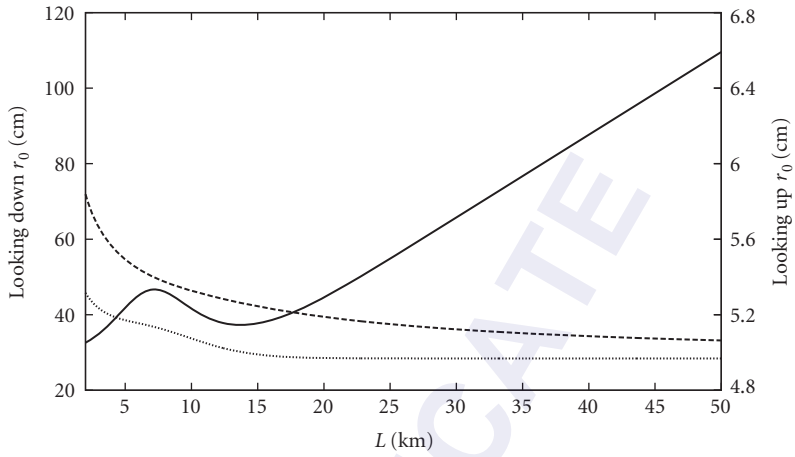

FIGURE 2 Variation of r_0 in the plane of the observer with the path length L from the source to the observer. The propagation of light is along the zenith at a wavelength $\lambda = 0.5\,\mu$m. The solid curve is for a point source on ground such that the spherical wave propagates upward to a space observer looking down directly at the source. The dashed curve is for a point source in space so that a spherical wave propagates down and an observer on ground looks at it directly above. The dotted curve is for plane wave propagation with an observer on ground (or in space) looking up (or down) at a space (or ground) object.

As shown in Fig. 2 by the dashed curve, the value of r_0 in the plane of the observer on ground does not change very much with the height L of the point source.

For a plane wave propagating up or down through the atmosphere, the factor z/L in Eq. (28) and in turn, in Eq. (30), is replaced by unity. It is easy to see this for starlight observed from ground. A plane wave can be thought of as a spherical wave originating at an infinite distance and traveling through a uniform medium for which $C_n^2 = 0$, except for the propagation path through the atmosphere. The value of z/L in the region for which $C_n^2 \neq 0$ is infinitesimally different from unity. Hence, the starlight propagation in ground-based astronomy can be considered as a plane wave propagation with $(z/L)^{5/3}$ in Eq. (30) replaced by unity, or a spherical wave propagating an infinite distance to reach the earth's atmosphere with nonzero C_n^2 value only near the end of its path for which z/L is negligibly different from unity. The variation of r_0 with the separation L of the plane-wave source and the observer is also shown in Fig. 2 by the dotted curve. We note that the variation is small and occurs for small values of L. For large values of L, approaching infinity as in ground-based astronomy, the value of r_0 is close to 5 cm. Moreover, the value of r_0 for a ground observer looking up through the atmosphere at an incoming plane wave is smaller than its value for a corresponding spherical wave, as expected from the smaller factor of $1 - z/L$ compared to z/L in Eq. (32).

We also note that r_0 is smaller when a satellite is observed from ground compared to when a ground object is observed from a satellite. As an observer moves to a higher altitude above the atmosphere, the value of r_0 increases linearly with the altitude L. Consequently, the image degradation is much smaller when a ground object is observed from space than when a space object is observed from ground. In the first case, the object is near the region of turbulence and it is observed from far away. In the second case, the object is away from the region of turbulence, but it is observed from nearby. The fact that the image quality is superior in the first case is similar to when an object behind a diffuse shower glass is observed. One can see some detail in the object when it is in contact with the shower glass. However, as soon as the object is moved slightly away from the shower glass, it appears only as a halo, illustrating complete loss of image resolution. This does not, however, mean that *reciprocity* of wave propagation does not hold. For example, if the wavefront errors of a wave from a point source

in space propagating downward are measured on ground and a conjugate correction is introduced in a beam transmitted upward with a deformable mirror, the beam focus in space will be diffraction limited (neglecting any measurement or correction error), illustrating that the atmosphere introduces the same wavefront errors whether a beam is propagating up or down through it.

Neglecting the variation of C_n^2 for horizontal propagation, we obtain

$$\mathcal{D}_w(r) = \begin{cases} 2.91C_n^2Lk^2r^{5/3} & \text{Plane wave} \quad (33a) \\ (3/8)2.91C_n^2Lk^2r^{5/3} & \text{Spherical wave} \quad (33b) \end{cases}$$

and

$$r_0 = \begin{cases} 1.68\left(C_n^2Lk^2\right)^{-3/5} & \text{Plane wave} \quad (34a) \\ 3.02\left(C_n^2Lk^2\right)^{-3/5} & \text{Spherical wave} \quad (34b) \end{cases}$$

In the *near field* ($L << D^2/\lambda$), the amplitude variations are negligible and, therefore, $\mathcal{D}_\Phi(r) = \mathcal{D}_w(r)$. In the *far field* ($L >> D^2/\lambda$), $\mathcal{D}_\Phi(r) = (1/2)\mathcal{D}_w(r)$. For in-between ranges, the multiplying factor between the two structure functions varies smoothly between 1 and 1/2.

Substituting Eq. (29) into Eq. (24), we may write the time-averaged OTF

$$\langle \tau(\vec{\nu}; D/r_0) \rangle = \tau_L(\vec{\nu}) M(\nu; D/r_0) \tag{35}$$

where

$$M(\nu; D/r_0) = \exp[-3.44(\nu D/r_0)^{5/3}] \tag{36}$$

is the *long-exposure MCF*. Since $\nu D = \nu_i \lambda R$ and r_0 varies as $\lambda^{6/5}$, the factor in the exponent in Eq. (36) varies with wavelength as $\lambda^{-1/3}$.

Since $\exp(-3.44) \simeq 0.03$, atmospheric turbulence reduces the overall system MTF corresponding to a spatial frequency $\nu = r_0/D$ by a factor of 0.03. From Eqs. (15) and (29), we find that r_0 represents a correlation length such that the correlation of complex amplitudes at two points on a wave separated by a distance r_0 is 0.03. Moreover, by definition, the MCF represents the *degree of spatial coherence* of the wave at the receiver, and thus the visibility of the fringes formed in a two-pinhole experiment and observed in the vicinity of a point that is equidistant from the two pinholes. Note that because of the random nature of atmospheric turbulence, the time-averaged irradiances at the two pinholes are equal to each other. Hence, r_0 represents a *partial coherence length* of the wave so that its degree of coherence corresponding to two points on it separated by r_0 is only 0.03, or that the visibility of the fringes formed by the secondary waves from these points is 0.03. The value of r_0 on a mountain site may vary from 5 to 10 cm in the visible region of the spectrum, and increases with wavelength as $\lambda^{6/5}$.

4.5 APPLICATION TO SYSTEMS WITH ANNULAR PUPILS

Now we apply Eq. (23) to a system with an annular pupil of outer radius $a = D/2$ and inner radius $a\epsilon$, and thus an obscuration ratio ϵ and an area $S_{ex}(\epsilon) = \pi(1 - \epsilon^2)a^2$ (see Fig. 3). For simplicity, we assume that the system is aberration free. Accordingly, its OTF is given by[11,16]

$$\tau(\nu; \epsilon) = \frac{1}{1 - \epsilon^2}[\tau(\nu) + \epsilon^2\tau(\nu/\epsilon) - \tau_{12}(\nu; \epsilon)], \quad 0 \le \nu \le 1 \tag{37}$$

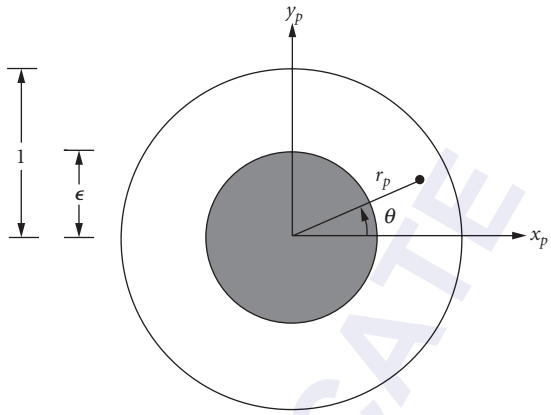

FIGURE 3 Annular pupil of obscuration ratio ϵ, representing the ratio of the inner and outer radii of the pupil.

where $\tau(\nu)$ is given by

$$\begin{aligned}\tau(\nu) &= (2/\pi)[\cos^{-1}\nu - \nu(1-\nu^2)^{1/2}],\ 0 \le \nu \le 1 \\ &= 0, \text{ otherwise}\end{aligned} \tag{38}$$

and represents the OTF of a corresponding system without any obscuration (i.e., for a circular pupil) and

$$\tau_{12}(\nu;\epsilon) = 2\epsilon^2,\ 0 \le \nu \le (1-\epsilon)/2 \tag{39a}$$

$$= (2/\pi)(\theta_1 + \epsilon^2\theta_2 - 2\nu\sin\theta_1),\ (1-\epsilon)/2 \le \nu \le (1+\epsilon)/2 \tag{39b}$$

$$= 0, \text{ otherwise} \tag{39c}$$

In Eq. (39*b*), θ_1 and θ_2 are given by

$$\cos\theta_1 = \frac{4\nu^2 + 1 - \epsilon^2}{4\nu} \tag{39d}$$

and

$$\cos\theta_2 = \frac{4\nu^2 - 1 + \epsilon^2}{4\epsilon\nu} \tag{39e}$$

respectively. Since the OTF is equal to the autocorrelation of the pupil function,[10,11,17] the cutoff frequency, which corresponds to the separation of two pupils by their diameter, is independent of ϵ. From Eq. (37)

$$\frac{\tau(\nu;\epsilon)}{\tau(\nu)} = \frac{1}{1-\epsilon^2} \tag{40}$$

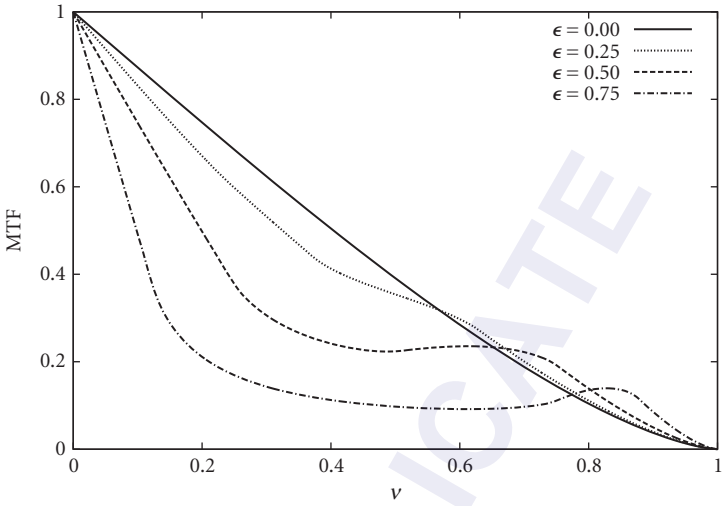

FIGURE 4 Aberration-free OTF $\tau(\nu;\epsilon)$ of an annular pupil illustrating the effect of its obscuration.

for spatial frequencies in the range $(1+\epsilon)/2 < \nu < 1$. The overlap area of two annular pupils displaced from each other by an amount corresponding to a frequency in this frequency range is independent of ϵ, but the fractional area is larger owing to the smaller area of the obscured exit pupil.[11]

How $\tau(\nu;\epsilon)$ varies with ν is shown in Fig. 4 for various values of ϵ, including zero. It is evident that the OTF of an annular pupil is significantly lower at low frequencies but somewhat higher at high frequencies, compared to that for a corresponding circular ($\epsilon = 0$) pupil. The slope of the OTF for an annular pupil at the origin is given by

$$\tau'(0;\epsilon) = -4/\pi(1-\epsilon) \tag{41}$$

This slope does not change when aberrations are introduced.[11] Moreover,

$$\int_0^1 \tau(\nu;\epsilon)\nu d\nu = (1-\epsilon^2)/8 \tag{42}$$

The time-averaged irradiance distribution and encircled power (in a circle of radius r_c in units of λF) of the image of a point object are given by

$$\langle I(r;\epsilon;D/r_0)\rangle = \frac{8}{1-\epsilon^2}\int_0^1 \langle \tau(\nu;\epsilon;D/r_0)\rangle J_0(2\pi r\nu)\nu d\nu \tag{43}$$

and

$$\langle P(r_c;\epsilon;D/r_0)\rangle = 2\pi r_c \int_0^1 \langle \tau(\nu;\epsilon;D/r_0)\rangle J_1(2\pi r_c\nu)d\nu \tag{44}$$

where

$$\langle \tau(\nu;\epsilon;D/r_0)\rangle = \tau(\nu;\epsilon)\exp\left[-3.44(\nu D/r_0)^{5/3}\right] \tag{45}$$

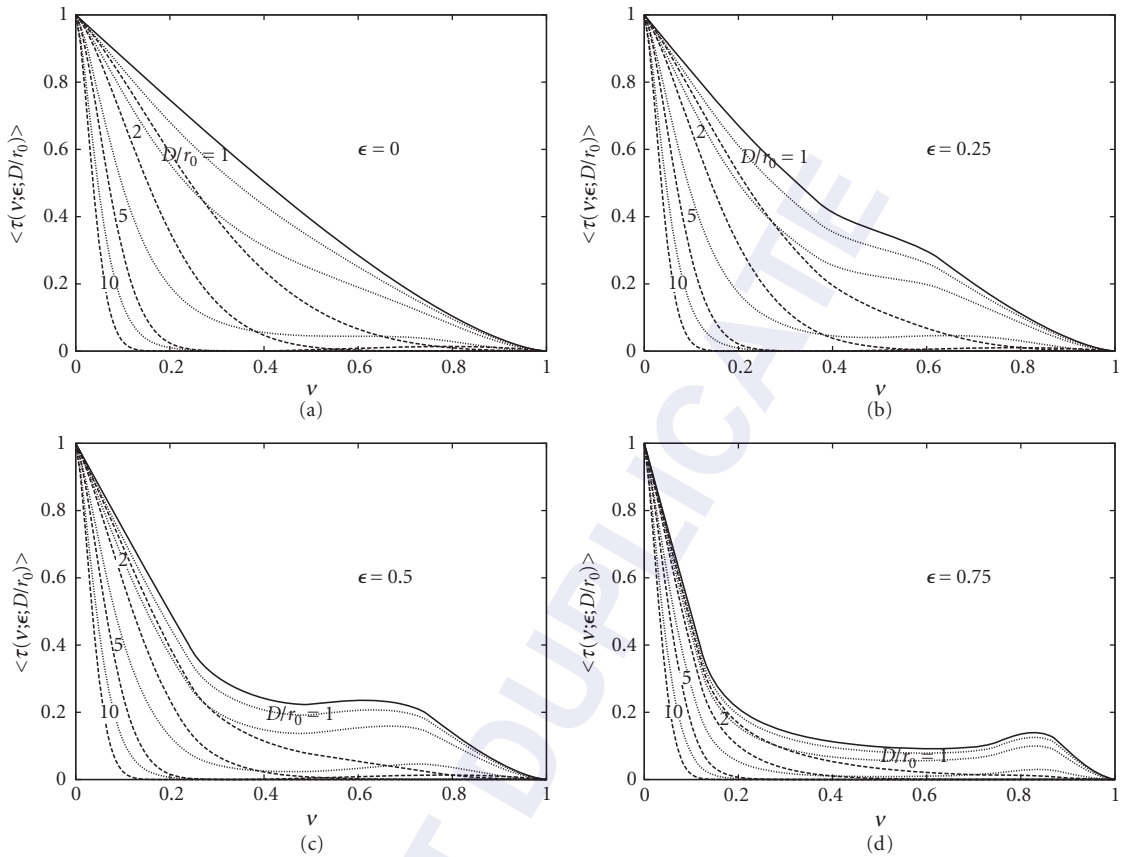

FIGURE 5 Time-averaged OTF for various values of ϵ and D/r_0. The solid curves represent the aberration-free OTF, and the dashed and dotted curves represent the corresponding long- and short-exposure OTFs.

is the OTF of the system degraded by atmospheric turbulence. The irradiance is normalized by the aberration-free central irradiance $\langle P_{ex}\rangle S_{ex}(\epsilon)/\lambda^2 R^2$ and the encircled power is normalized by the total power $\langle P_{ex}\rangle$. Figure 5 shows the time-averaged OTF for several values of D/r_0. The OTF gain at high frequencies disappears even for weak turbulence, as is evident from Fig. 5*b* for $D/r_0 = 1$. The turbulence dominates the OTF for large values of D/r_0, and the effect of obscuration becomes small, as illustrated in Fig. 5*c*. Not only is the MTF at any frequency reduced, but the effective cutoff frequency is also reduced, for example, from a value of 1 to about 0.1 when $D/r_0 = 10$.

Letting $r = 0$ in Eq. (43) yields the Strehl ratio of the image

$$\langle S(\epsilon; D/r_0)\rangle \equiv \langle I(0;\epsilon; D/r_0)\rangle$$

$$= \frac{8}{1-\epsilon^2}\int_0^1 \langle \tau(\nu;\epsilon; D/r_0)\rangle \nu d\nu \tag{46}$$

Figure 6 shows how the time-averaged Strehl ratio varies with D/r_0 for several values of ϵ. The Strehl ratio decreases monotonically as D/r_0 increases. It is slightly lower for an annular pupil for values of $D/r_0 \lesssim 3$ and somewhat higher for $D/r_0 \gtrsim 3$. As shown in Fig. 6*b*, it decreases monotonically with increasing

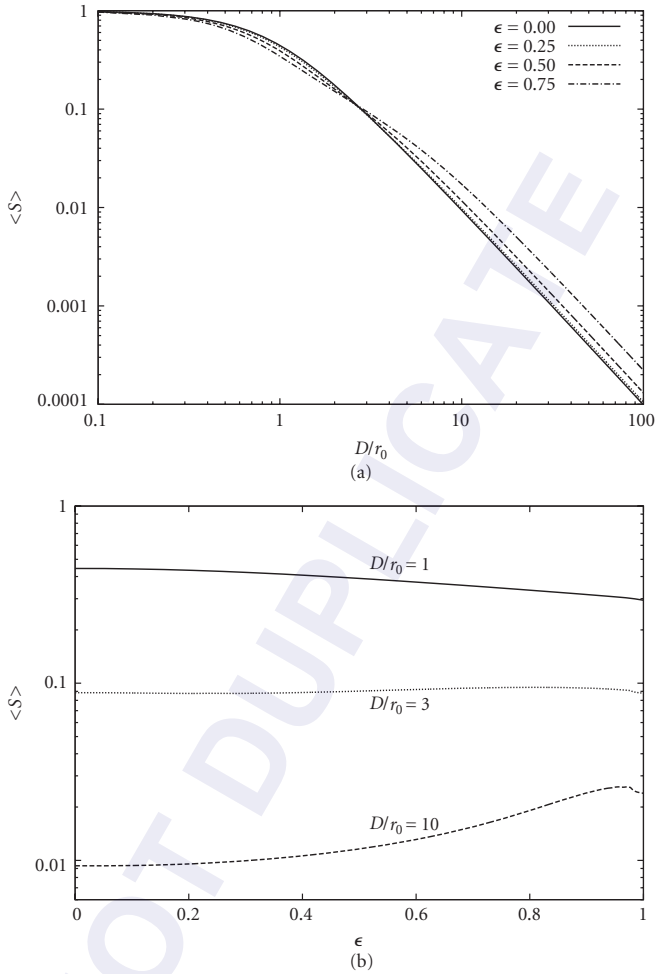

FIGURE 6 Variation of time-averaged long-exposure Strehl ratio $\langle S(\epsilon; D/r_0)\rangle$, representing the central irradiance normalized by its corresponding aberration-free value. (*a*) As a function of D/r_0 and (*b*) as a function of ϵ.

value of ϵ for small values of D/r_0, remains nearly constant for $D/r_0 = 3$, and increases monotonically for $D/r_0 = 10$. Some typical values of the Strehl ratio are listed in Table 1 for several values of ϵ and D/r_0.

Since $S_{ex}(\epsilon) = \pi(1-\epsilon^2)D^2/4$, the aberration-free central irradiance $\langle P_{ex}\rangle S_{ex}(\epsilon)/\lambda^2 R^2$ for a fixed total power $\langle P_{ex}\rangle$ increases with D as D^2. To see how the aberrated central irradiance varies with D, we consider a quantity[18]

$$\eta(\epsilon; D/r_0) = (1-\epsilon^2)(D/r_0)^2\langle S(\epsilon; D/r_0)\rangle \tag{47a}$$

$$= 8(D/r_0)^2 \int_0^1 \langle \tau(\nu; \epsilon; D/r_0)\rangle \exp\left[-3.44(\nu D/r_0)^{5/3}\right]\nu d\nu \tag{47b}$$

Figure 7 shows how η varies with D/r_0. Its aberration-free (or diffraction-limited) value varies as $(1-\epsilon^2)(D/r_0)^2$. For very small values of D/r_0, the atmospheric MTF reduction factor is approximately

TABLE 1 Long (LE) and Short-Exposure (SE) Time-Averaged Strehl Ratio for Various Values of ϵ and D/r_0

	$D/r_0 = 1$		$D/r_0 = 2$		$D/r_0 = 5$		$D/r_0 = 10$	
ϵ	LE	SE	LE	SE	LE	SE	LE	SE
0	0.446	0.889	0.175	0.691	0.035	0.204	0.009	0.023
0.25	0.429	0.890	0.169	0.694	0.036	0.207	0.010	0.024
0.50	0.391	0.892	0.160	0.699	0.040	0.216	0.012	0.027
0.75	0.345	0.889	0.152	0.691	0.050	0.211	0.017	0.033

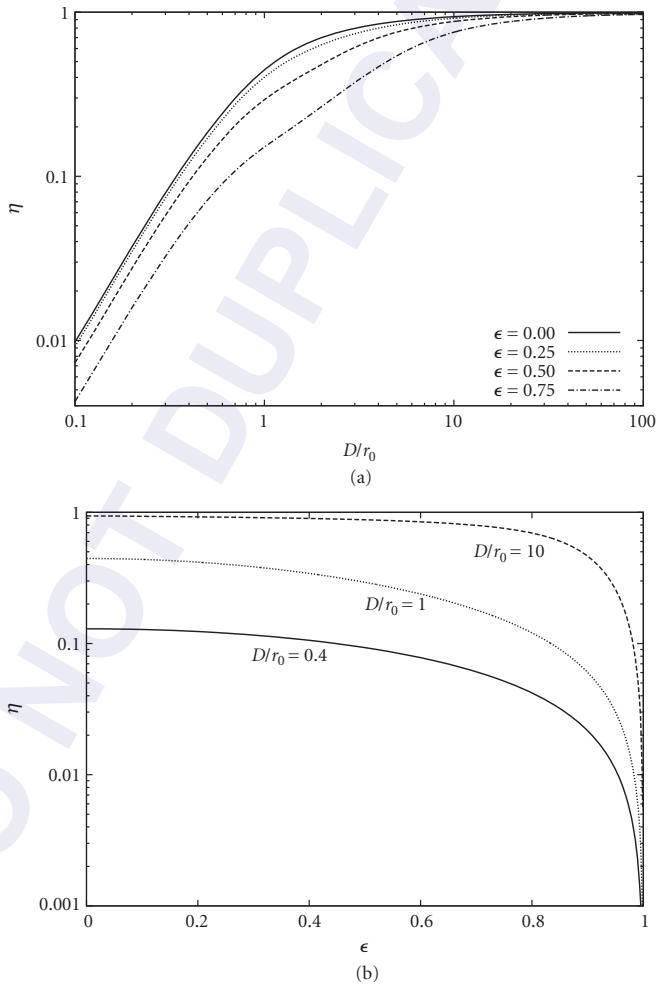

FIGURE 7 Variation of long-exposure $\eta(\epsilon; D/r_0)$, representing the time-averaged central irradiance normalized by its aberration-free value for a circular pupil of diameter r_0 but with the same total power as the annular pupil. (*a*) As a function of D/r_0 and (*b*) as a function of ϵ.

equal to unity. Accordingly, $\langle S(\epsilon; D/r_0)\rangle$ is also approximately equal to unity, and the aberrated value of η increases with D/r_0 as in the aberration-free case. However, it increases slowly as D/r_0 increases, with a negligible increase beyond a certain value of D/r_0, depending on the value of ϵ. The contribution to the integral in Eq. (47*b*) comes from values of v small enough that the factor in the exponent is not vanishingly small. Since, $\tau(v;\epsilon) \simeq 1$ near the origin irrespective of the value of ϵ, Eq. (47*b*) for large values of D/r_0 may be written

$$\begin{aligned}\eta(\epsilon; D/r_0) &= 8(D/r_0)^2 \int_0^1 \exp\left[-3.44(vD/r_0)^{5/3}\right] v\,dv \\ &= 8(3.44)^{-6/5}(3/5)\int_0^\infty x^{(6/5)-1}\exp(-x)\,dx \\ &= 1 \end{aligned} \tag{48}$$

where $x = 3.44(vD/r_0)^{5/3}$ and the integral over x is the gamma function $\Gamma(6/5)$. Thus,

$$\eta(\epsilon; D/r_0) \to 1 \text{ as } D/r_0 \to \infty \tag{49}$$

independent of the value of ϵ. As is evident from Fig. 7, the saturation effects of atmospheric turbulence occur at larger and larger values of D/r_0 as ϵ increases. The two asymptotes of $\eta(\epsilon; D/r_0)$ for a given value of ϵ intersect at the point given by $(1-\epsilon^2)(D/r_0)^2 = 1$ or $D/r_0 = (1-\epsilon^2)^{-1/2}$.[18]

The unnormalized aberrated central irradiance is given by

$$\langle I_i(0;\epsilon; D/r_0)\rangle = \frac{\langle P_{ex}\rangle S_{ex}(\epsilon)}{\lambda^2 R^2}\langle S(\epsilon; D/r_0)\rangle \tag{50a}$$

$$= \frac{\langle P_{ex}\rangle S_a}{\lambda^2 R^2}\eta(\epsilon; D/r_0) \tag{50b}$$

where $S_a = \pi r_0^2/4$ is the *coherent area* of the atmosphere. Hence, regardless of how large D is, the central irradiance is less than or equal to the aberration-free central irradiance for a system with a circular exit pupil of diameter r_0, equality approaching as $D/r_0 \to \infty$. The limiting value of the central irradiance is independent of the value of ϵ. Since $S_a \sim r_0^2 \sim \lambda^{12/5}$, the limiting value varies with wavelength as $\lambda^{2/5}$. It is evident from Eq. (50*b*) that η represents the aberrated central irradiance normalized by the aberration-free value $\langle P_{ex}\rangle S_a/\lambda^2 R^2$ for a circular pupil of diameter r_0.

In astronomical observations, the time-averaged image power given by $\langle P_{ex}\rangle = \pi(1-\epsilon^2)D^2\langle I_0\rangle$, where $\langle I_0\rangle$ is the time-averaged irradiance across the exit pupil, increases as D increases. However, if the observation is made against a uniform background, then the background irradiance in the image also increases as D^2. Hence, regardless of the value of ϵ, the detectability of a point object is limited by turbulence to a value corresponding to an exit pupil of diameter r_0, no matter how large the diameter D of the exit pupil is. In the case of a laser transmitter with a fixed value of laser power P_{ex}, the central irradiance on a target will again be limited to its aberration-free value for an exit pupil of diameter r_0, regardless of how large its beam diameter is. Similarly, the ratio of the signal and noise powers in an optical heterodyne detection of a turbulence-degraded signal is limited to the aberration-free value corresponding to an exit pupil of diameter r_0.

Figure 8 shows how the time-averaged irradiance distribution or the PSF and encircled power change as D/r_0 increases for several values of ϵ. The PSFs are normalized to unity at the center, the actual central value being the LE Strehl ratio given in Table 1. As ϵ increases, power flows from the central bright spot into the diffraction rings. As D/r_0 increases, the diffraction rings disappear and the PSFs become smooth, and a given fraction of total power is contained in a circle of larger and larger radius.

4.6 MODAL EXPANSION OF ABERRATION FUNCTION

So far we have considered the degradation of system performance by propagation through atmospheric turbulence without any knowledge of the magnitude or the type of the phase aberrations introduced by it. In this section, we expand the Kolmogorov turbulence-degraded aberration function into a complete set of orthonormal polynomials and determine its time-averaged variance as well as the variance and covariance of the expansion coefficients.

We expand the aberration function $\Phi(\rho, \theta; \epsilon)$ in terms of a complete set of Zernike annular polynomials $Z_j(\rho, \theta; \epsilon)$ that are orthonormal over the unit annulus in the form[5–8]

$$\Phi(\rho, \theta; \epsilon) = \sum_j a_j(\epsilon) Z_j(\rho, \theta; \epsilon) \tag{51}$$

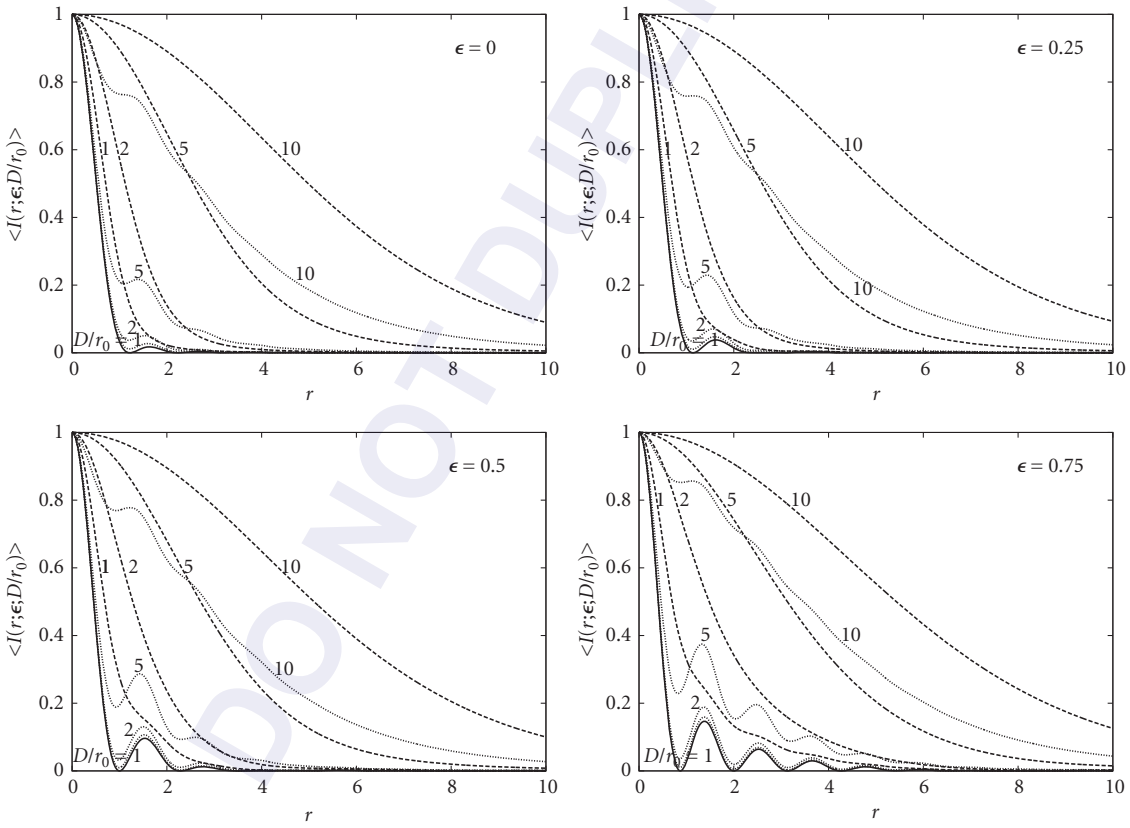

FIGURE 8 Time-averaged irradiance $\langle I(r; \epsilon; D/r_0)\rangle$ and encircled power $\langle P(r_c; \epsilon, D/r_0)\rangle$ distributions for circular and annular pupils. The solid curves represent the aberration-free distributions, and the dashed and dotted curves represent the corresponding long- and short-exposure distributions.

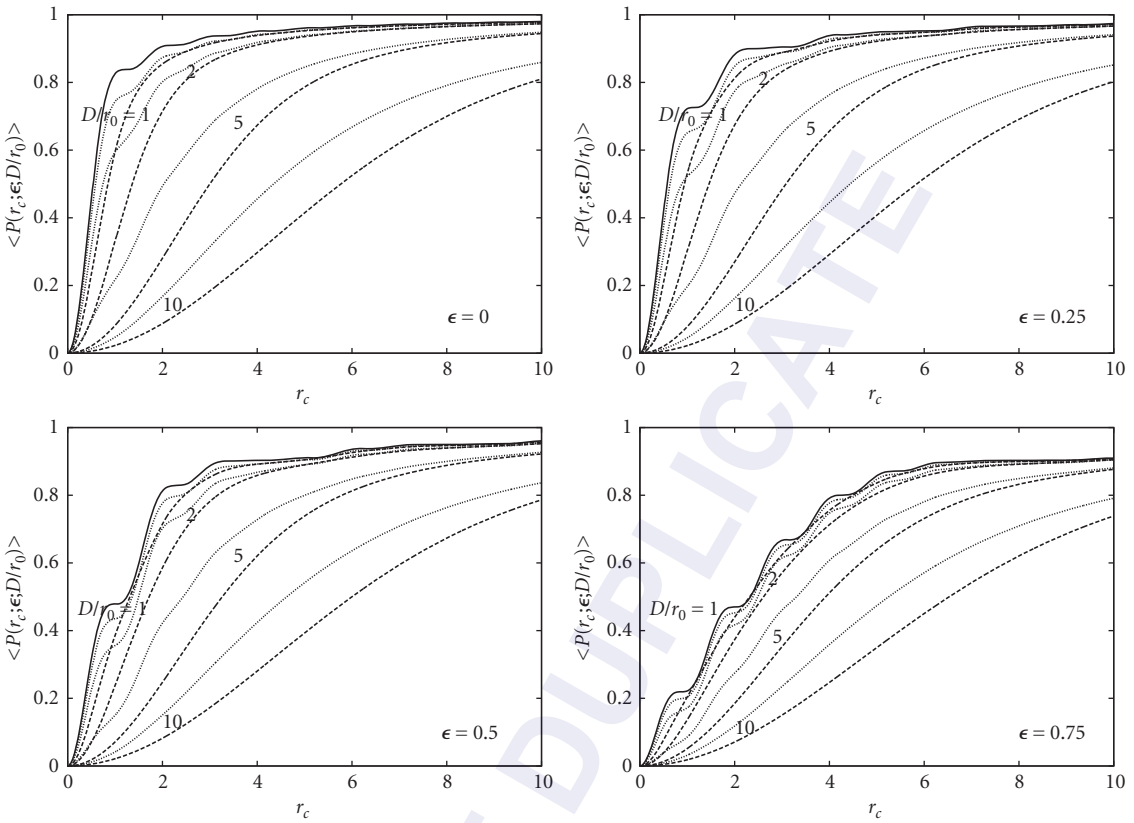

FIGURE 8 (*Continued*)

where $a_j(\epsilon)$ are the expansion coefficients of the polynomials, $\epsilon \le \rho \le 1$ and $0 \le \theta < 2\pi$. Since the phase aberration is a Gaussian random variable with a zero time-averaged value, so are the expansion coefficients. The annular polynomials are given by

$$Z_{\text{even}\,j}(\rho,\theta;\epsilon) = \sqrt{2(n+1)}R_n^m(\rho;\epsilon)\cos m\theta,\ m \neq 0 \tag{52a}$$

$$Z_{\text{odd}\,j}(\rho,\theta;\epsilon) = \sqrt{2(n+1)}R_n^m(\rho;\epsilon)\sin m\theta,\ m \neq 0 \tag{52b}$$

$$Z_j(\rho,\theta;\epsilon) = \sqrt{n+1}R_n^0(\rho;\epsilon),\ m = 0 \tag{52c}$$

where n and m are positive integers (including zero) and $n - m \ge 0$ and even.

The index n represents the radial degree or the order of a polynomial, since it represents the highest power of ρ in the polynomial, and m is called the azimuthal frequency. The index j is a polynomial-ordering number and is a function of both n and m. The polynomials are ordered such that an even j corresponds to a symmetric polynomial varying as $\cos m\theta$, while an odd j corresponds to an antisymmetric polynomial varying as $\sin m\theta$. A polynomial with a lower value of n is ordered first, while for a given value of n, a polynomial with a lower value of m is ordered first.

TABLE 2 Relationship Among the Polynomial Indices n, m, and j

n	m	j	n	m	j
0	0	1	6	0	22
1	1	2, 3	6	2	23, 24
2	0	4	6	4	25, 26
2	2	5, 6	6	6	27, 28
3	1	7, 8	7	1	29, 30
3	3	9, 10	7	3	31, 32
4	0	11	7	5	33, 34
4	2	12, 13	7	7	35, 36
4	4	14, 15	8	0	37
5	1	16, 17	8	2	38, 39
5	3	18, 19	8	4	40, 41
5	5	20, 21	8	6	42, 43
			8	8	44, 45

The relationships among the indices j, n, and m are given in Table 2. For example, when $n = 4$ and $m = 2$, then $j = 12$ for the cos 2θ polynomial and $j = 13$ for the sin 2θ polynomial. The number of polynomials for a given value of n is $n + 1$, and the number of polynomials up to and including a certain order n is given by

$$N_n = (n + 1)(n + 2)/2 \tag{53}$$

The radial annular polynomials $R_n^m(\rho;\epsilon)$ obey the orthogonality relation

$$\int_{\epsilon}^{1} R_n^m(\rho;\epsilon) R_{n'}^m(\rho;\epsilon)\rho\, d\rho = \frac{1-\epsilon^2}{2(n+1)}\delta_{nn'} \tag{54}$$

where $\delta_{nn'}$ is a Kronecker delta. Accordingly, the annular polynomials obey the orthonormality condition

$$\int_{\epsilon}^{1}\int_{0}^{2\pi} Z_j(\rho,\theta;\epsilon)\, Z_{j'}(\rho,\theta;\epsilon)\rho\, d\rho\, d\theta \Bigg/ \int_{\epsilon}^{1}\int_{0}^{2\pi} \rho\, d\rho\, d\theta = \delta_{jj'} \tag{55}$$

The Zernike expansion coefficients are given by

$$a_j(\epsilon) = \frac{1}{\pi(1-\epsilon^2)}\int_{\epsilon}^{1}\int_{0}^{2\pi} \Phi(\rho,\theta;\epsilon) Z_j(\rho,\theta;\epsilon)\rho\, d\rho\, d\theta \tag{56}$$

as may be seen by substituting Eq. (51) into Eq. (56) and using the orthonormality Eq. (55).

The first eleven annular polynomials are listed in Table 3, where

$$R_1^1(\rho;\epsilon) = \frac{\rho}{(1+\epsilon^2)^{1/2}} \tag{57a}$$

$$R_2^0(\rho;\epsilon) = \frac{(2\rho^2 - 1 - \epsilon^2)}{(1-\epsilon^2)} \tag{57b}$$

$$R_2^2(\rho;\epsilon) = \frac{\rho^2}{(1+\epsilon^2+\epsilon^4)^{1/2}} \tag{57c}$$

TABLE 3 Orthonormal Zernike Annular Polynomials $Z_j(\rho, \theta; \epsilon)$

j	n	m	$Z_j(\rho,\theta;\epsilon)$	Aberration Name*
1	0	0	$R_0^0(\rho;\epsilon)=1$	Piston
2	1	1	$2R_1^1(\rho;\epsilon)\cos\theta$	x tilt
3	1	1	$2R_1^1(\rho;\epsilon)\sin\theta$	y tilt
4	2	0	$\sqrt{3}R_2^0(\rho;\epsilon)$	Defocus
5	2	2	$\sqrt{6}R_2^2(\rho;\epsilon)\sin 2\theta$	Primary astigmatism at 45°
6	2	2	$\sqrt{6}R_2^2(\rho;\epsilon)\cos 2\theta$	Primary astigmatism at 0°
7	3	1	$\sqrt{8}R_3^1(\rho;\epsilon)\sin\theta$	Primary y coma
8	3	1	$\sqrt{8}R_3^1(\rho;\epsilon)\cos\theta$	Primary x coma
9	3	3	$\sqrt{8}R_3^3(\rho;\epsilon)\sin 3\theta$	
10	3	3	$\sqrt{8}R_3^3(\rho;\epsilon)\cos 3\theta$	
11	4	0	$\sqrt{5}R_4^0(\rho;\epsilon)$	Primary spherical

*The name must precede with "orthonormal annular," e.g., orthonormal annular primary x coma.

$$R_3^1(\rho;\epsilon)=\frac{3(1+\epsilon^2)\rho^3-2(1+\epsilon^2+\epsilon^4)\rho}{(1-\epsilon^2)\left[(1+\epsilon^2)(1+4\epsilon^2+\epsilon^4)\right]^{1/2}} \tag{57d}$$

$$R_3^3(\rho;\epsilon)=\frac{\rho^3}{(1+\epsilon^2+\epsilon^4+\epsilon^6)^{1/2}} \tag{57e}$$

and

$$R_4^0(\rho;\epsilon)=\frac{6\rho^4-6(1+\epsilon^2)\rho^2+1+4\epsilon^2+\epsilon^4}{(1-\epsilon^2)^2} \tag{57f}$$

Of course, they reduce to the corresponding circle polynomials as $\epsilon \to 0$.

4.7 COVARIANCE AND VARIANCE OF EXPANSION COEFFICIENTS

From Eq. (56), the covariance or cross-correlation of the expansion coefficients may be written

$$\langle a_j(\epsilon)a_{j'}(\epsilon)\rangle=\frac{1}{\pi^2(1-\epsilon^2)^2}\int\int Z_j(\rho,\epsilon)Z_{j'}(\rho';\epsilon)\langle\Phi(\rho;\epsilon)\Phi(\rho';\epsilon)\rangle d\rho\, d\rho' \tag{58}$$

where $\boldsymbol{\rho}$ is the normalized position vector of a pupil point. It can be obtained by using the Fourier transforms of the annular polynomials.[9] The autocorrelation, that is, the mean square value or the variance of an expansion coefficient, may be obtained from Eq. (58) by letting $j=j'$, that is, by letting $n=n'$ and $m=m'$.

A closed-form analytical solution is obtained when $m=n=n'$

$$\left\langle\left[a_n^n(\epsilon)\right]^2\right\rangle=\frac{0.0229(n+1)\Gamma(n-5/6)\pi^{8/3}}{2^{5/3}\Gamma(17/6)(1-\epsilon^2)\left[1-\epsilon^{2(n+1)}\right]}\left(\frac{D}{r_0}\right)^{5/3}$$
$$\times\left[\frac{(1+\epsilon^{2n+17/3})\Gamma(14/3)}{\Gamma(17/6)\Gamma(n+23/6)}-\frac{2\epsilon^{2(n+1)}}{(n+1)!}F_1\left(n-\frac{5}{6},-\frac{11}{6};n+2;\epsilon^2\right)\right] \tag{59}$$

where $F_1(a,b;c;z)$ is a hypergeometric function. Since $r_0 \propto \lambda^{6/5}$, the variance in terms of the optical path-length errors [obtained by multiplying $\left\langle \left[a_n^n(\epsilon)\right]^2 \right\rangle$ by $(\lambda/2\pi)^2$] is independent of λ, as expected in the absence of atmospheric dispersion.

For a circular pupil,[19] the following results can be obtained from the corresponding results for an annular pupil by letting $\epsilon \to 0$:

$$\langle a_j a_{j'} \rangle = 0.1534(-1)^{(n+n'-2m)/2}[(n+1)(n'+1)]^{1/2}(D/r_0)^{5/3}\delta_{mm'} \times \frac{\Gamma(14/3)\Gamma[(n+n'-5/3)/2]}{\Gamma[(n-n'+17/3)/2]\Gamma[(n'-n+17/3)/2]\Gamma[(n+n'+23/3)/2]}, \; n,n' \neq 0 \tag{60}$$

and

$$\left\langle a_j^2 \right\rangle = 0.7587\frac{\Gamma(n-5/6)}{\Gamma(n+23/6)}(n+1)\left(\frac{D}{r_0}\right)^{5/3}, \; n \neq 0 \tag{61}$$

Numerical values of variance and covariance are given in Tables 4 and 5 for various values of ϵ including zero. We note that when $\epsilon = 0$, the variance of an aberration coefficient depends on

the value of n, but is independent of the value of m. Thus, for example, $\langle a_4^2\rangle = \langle a_5^2\rangle = \langle a_6^2\rangle$, or $\langle a_7^2\rangle = \langle a_8^2\rangle = \langle a_9^2\rangle = \langle a_{10}^2\rangle$. However, when $\epsilon \neq 0$, the variance depends on the values of both n and m, but it is independent of whether it is a cosine or a sine mode. Thus, for example, $\langle a_4^2(\epsilon)\rangle \neq \langle a_5^2(\epsilon)\rangle = \langle a_6^2(\epsilon)\rangle$, or $\langle a_7^2(\epsilon)\rangle = \langle a_8^2(\epsilon)\rangle \neq \langle a_9^2(\epsilon)\rangle = \langle a_{10}^2(\epsilon)\rangle$. Similarly, the covariance for given values of n and n' are independent of their m values when $\epsilon = 0$. For example, $\langle a_4 a_{11}\rangle = \langle a_5 a_{13}\rangle = \langle a_6 a_{12}\rangle$, or $\langle a_7 a_{17}\rangle = \langle a_8 a_{16}\rangle = \langle a_9 a_{19}\rangle = \langle a_{10} a_{18}\rangle$. However, when $\epsilon \neq 0$, equality is obtained only when the m values are also equal. For example, $\langle a_4(\epsilon) a_{11}(\epsilon)\rangle \neq \langle a_5(\epsilon) a_{13}(\epsilon)\rangle = \langle a_6(\epsilon) a_{12}(\epsilon)\rangle$, or $\langle a_7(\epsilon) a_{17}(\epsilon)\rangle = \langle a_8(\epsilon) a_{16}(\epsilon)\rangle \neq \langle a_9(\epsilon) a_{19}(\epsilon)\rangle = \langle a_{10}(\epsilon) a_{18}(\epsilon)\rangle$. The first nonzero cross-correlations are the tilt-coma cross-correlations $\langle a_2(\epsilon) a_8(\epsilon)\rangle$ and $\langle a_3(\epsilon) a_7(\epsilon)\rangle$. Moreover, for a given value of n, the correlation values decrease rapidly as the order difference $n' - n$ increases.

Figures 9 and 10 show the variance and covariance of Zernike coefficients as a function of ϵ for some low-order terms. The variance of terms with $m = n$ increase monotonically with an increasing value of ϵ, e.g., tip and tilt variances $\langle a_2^2\rangle$ and $\langle a_3^2\rangle$, or astigmatism variances $\langle a_5^2\rangle$ and $\langle a_6^2\rangle$. For other terms, e.g., coma $\langle a_7^2\rangle$ and $\langle a_8^2\rangle$, or defocus $\langle a_4^2\rangle$ and spherical aberration $\langle a_{11}^2\rangle$, they generally decrease monotonically and approach zero as $\epsilon \to 1$. Similarly, the covariances of tilt with coma, for example, $\langle a_2(\epsilon) a_8(\epsilon)\rangle$, and defocus with primary or secondary spherical aberration, that is, $\langle a_4(\epsilon) a_{11}(\epsilon)\rangle$ or $\langle a_4(\epsilon) a_{22}(\epsilon)\rangle$, approach zero as $\epsilon \to 1$.

4.8 ANGLE OF ARRIVAL FLUCTUATIONS

Depending on the measurement process, the angle of arrival can be defined by the Zernike tilts of the wavefront or the centroid of the aberrated PSF. The first is referred to as the Z-tilt and represents the least square fit of the linear terms to the aberration function or equivalently the gradient of the wavefront at the center of the pupil. The PSF centroid, however, represents the mean value of the wavefront gradient across the pupil. The tilt associated with the centroid is referred to as the G- or the gradient-tilt.[1,20]

From Eq. (51), the wavefront tilt aberration introduced by turbulence is given by

$$\begin{aligned}\Phi_t(\rho,\theta;\epsilon) &= a_2(\epsilon)Z_2(\rho,\theta;\epsilon) + a_3(\epsilon)Z_3(\rho,\theta;\epsilon)\\ &= 2[a_2(\epsilon)R_1^1(\rho;\epsilon)\cos\theta + a_3(\epsilon)R_1^1(\rho;\epsilon)\sin\theta]\\ &= \frac{2}{(1+\epsilon^2)^{1/2}}[a_2(\epsilon)\rho\cos\theta + a_3(\epsilon)\rho\sin\theta]\end{aligned} \tag{62}$$

Or, in Cartesian coordinates,

$$\Phi_t(x, y; \epsilon) = \frac{2}{(1+\epsilon^2)^{1/2}}[a_2(\epsilon)x + a_3(\epsilon)y] \tag{63}$$

The wavefront tilt displaces the image to a point $[x_t(\epsilon),\ y_t(\epsilon)]$ given by[21]

$$[x_t(\epsilon), y_t(\epsilon)] = 2F\frac{\lambda}{2\pi}\left(\frac{\partial\Phi_t}{\partial x},\ \frac{\partial\Phi_t}{\partial y}\right)$$

$$= \frac{2\lambda F}{\pi(1+\epsilon^2)^{1/2}}[a_2(\epsilon),\ a_3(\epsilon)] \tag{64}$$

Accordingly, the angle of arrival of the wave is given by

$$[\alpha(\epsilon),\ \beta(\epsilon)] = \frac{1}{R}[x_t(\epsilon),\ y_t(\epsilon)]$$

$$= \frac{2\lambda}{\pi D(1+\epsilon^2)^{1/2}}[a_2(\epsilon),\ a_3(\epsilon)] \tag{65}$$

Or, the mean square fluctuation of the angle of arrival is given by

$$\left[\sigma_\alpha^2(\epsilon),\ \sigma_\beta^2(\epsilon)\right] = \left(\frac{2\lambda}{\pi D}\right)^2 \frac{1}{(1+\epsilon^2)}\left\langle a_2^2(\epsilon),\ a_3^2(\epsilon)\right\rangle \tag{66}$$

where from Eq. (59)

$$\left\langle a_2^2(\epsilon)\right\rangle = \left\langle a_3^2(\epsilon)\right\rangle$$

$$= \frac{0.9858}{(1+\epsilon^2)(1-\epsilon^2)^2}\left[0.4554(1+\epsilon^{23/3}) - \epsilon^4 F_1\left(\frac{1}{6}, -\frac{11}{6}; 3; \epsilon^2\right)\right]\left(\frac{D}{r_0}\right)^{5/3} \tag{67}$$

Accordingly, the standard deviation of the angular fluctuations based on the Zernike tilts is given by

$$[\sigma_\alpha(\epsilon)]_Z = [\sigma_\beta(\epsilon)]_Z = \frac{2}{\pi(1+\epsilon^2)^{1/2}}\frac{\lambda}{D}\left[\left\langle a_2^2(\epsilon)\right\rangle\right]^{1/2} \tag{68}$$

Since $\left\langle a_2^2(\epsilon)\right\rangle \sim (D/r_0)^{5/3}$, Eq. (68) shows that the mean square fluctuation of the image displacement decreases with the pupil diameter D as $D^{-1/3}$. Moreover, since $r_0 \sim \lambda^{6/5}$, we find that the fluctuation is independent of the wavelength, as expected in the absence of any atmospheric dispersion. For a circular pupil, substituting $\left\langle a_2^2\right\rangle = \left\langle a_3^2\right\rangle = 0.449(D/r_0)^{5/3}$, we obtain

$$(\sigma_\alpha)_Z = (\sigma_\beta)_Z = \frac{2}{\pi}\frac{\lambda}{D}\left[\left\langle a_2^2\right\rangle\right]^{1/2}$$

$$= 0.4265\frac{\lambda}{D}\left(\frac{D}{r_0}\right)^{5/6} \tag{69}$$

Since the wavefront tilt produced by turbulence is independent of the shape of the pupil, except for its correlation with the coma terms, $\left\langle a_2^2(\epsilon)\right\rangle$ increases with ϵ approximately as $1+\epsilon^2$. This is illustrated in Fig. 11, where $\left\langle a_2^2(\epsilon)\right\rangle$ and $(1+\epsilon^2)\left\langle a_2^2\right\rangle$ are compared with each other as a function of ϵ. Accordingly, the angular fluctuation depends very weakly on the obscuration ratio. For example, when $\epsilon = 0.5$, the constant 0.4265 on the right-hand side of Eq. (69) is replaced by 0.4246.

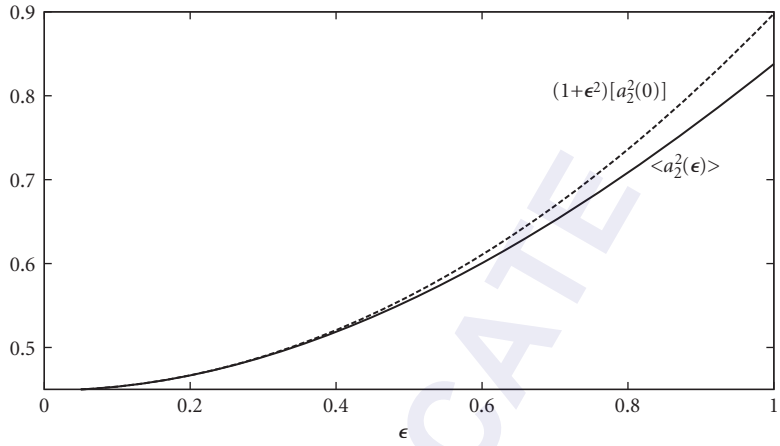

FIGURE 11 Comparison of tilt variance $\langle a_2^2(\epsilon)\rangle$ with $(1+\epsilon^2)\langle a_2^2\rangle$.

Tatarski gives an expression for the fluctuations of the angle of arrival based on the centroid of the aberrated PSF for a circular pupil.[22] His analysis can be extended to systems with annular pupils. However, we consider the centroid in terms of the Zernike annular-polynomial expansion coefficients of the aberration function. This approach gives insight into why the G-tilt is different from the Z-tilt, why the two tilts are approximately equal to each other, and why the G-tilt is smaller.

Neglecting the amplitude variations introduced by turbulence, the centroid (x_c, y_c) of an aberrated PSF is given by the mean value of the gradient of the aberration function[11,23]

$$(x_c, y_c) = \frac{R}{S_p}\iint\left[\frac{\partial W(x,y)}{\partial x}, \frac{\partial W(x,y)}{\partial y}\right]dx\,dy \tag{70}$$

where $W(x, y)$ is the wave aberration at a point (x, y) on a pupil of area S_p. If we write the aberration function in terms of the Zernike annular polynomials in the form

$$W(\rho,\theta;\epsilon) = \sum_{n=0}^{\infty}\sum_{m=0}^{n}[2(n+1)/(1+\delta_{m0})]^{1/2}R_n^m(\rho;\epsilon)[c_{nm}(\epsilon)\cos m\theta + s_{nm}(\epsilon)\sin m\theta] \tag{71}$$

where $c_{nm}(\epsilon)$ and $s_{nm}(\epsilon)$ are the *Zernike annular expansion coefficients*, it can be shown that the centroid of the corresponding PSF is given by[11,23]

$$[x_c(\epsilon),\ y_c(\epsilon)] = \frac{2F}{1-\epsilon^2}\sum_{n=1}^{\infty}{}'\sqrt{2(n+1)}\left[R_n^1(1;\epsilon) - \epsilon R_n^1(\epsilon;\epsilon)\right][c_{n1}(\epsilon),\ s_{n1}(\epsilon)] \tag{72}$$

where a prime on the summation sign indicates a summation over only the odd integral values of n. Thus, the only aberrations that contribute to the centroid are those with $m = 1$. Aberrations of the type $R_n^1(\rho;\epsilon)\cos\theta$ contribute to x_c and those of the type $R_n^1(\rho;\epsilon)\sin\theta$ contribute to y_c, which also follows from the symmetry considerations of the aberrations. Keeping the tilt and only the primary coma terms (and thus neglecting higher orders of coma owing to their small magnitudes) in Eq. (72), we obtain

$$[\sigma_\alpha(\epsilon)]_G = [\sigma_\beta(\epsilon)]_G$$

$$= \frac{1}{\pi(1-\epsilon^2)}\frac{\lambda}{D}\left[4A^2(\epsilon)\langle a_2^2(\epsilon)\rangle + 8B^2(\epsilon)\langle a_8^2(\epsilon)\rangle + 8\sqrt{2}\frac{1-\epsilon^2}{(1+\epsilon^2)^{1/2}}B(\epsilon)\langle a_2(\epsilon)a_8(\epsilon)\rangle\right]^{1/2} \tag{73}$$

where, from Eqs. (57*a*) and (57*d*),

$$A(\epsilon) = R_1^1(1;\epsilon) - \epsilon R_1^1(\epsilon;\epsilon) = \frac{1-\epsilon^2}{(1+\epsilon^2)^{1/2}} \tag{74a}$$

and

$$B(\epsilon) = R_3^1(1;\epsilon) - \epsilon R_3^1(\epsilon;\epsilon) = \frac{1+3\epsilon^2-3\epsilon^4-\epsilon^6}{(1-\epsilon^2)[(1+\epsilon^2)(1+4\epsilon^2+\epsilon^4)]^{1/2}} \tag{74b}$$

If we retain only the Zernike tilt terms, we obtain the Z-tilt given by Eq. (68).

For a circular pupil, $A(\epsilon)$ and $B(\epsilon)$ both reduce to unity, and Eq. (73) reduces to

$$(\sigma_\alpha)_G = (\sigma_\beta)_G = \frac{\lambda}{\pi D}\left[4\langle a_2^2\rangle + 8\langle a_8^2\rangle + 8\sqrt{2}\langle a_2 a_8\rangle\right]^{1/2} \tag{75}$$

Substituting for $\langle a_2^2\rangle$, $\langle a_8^2\rangle$, and $\langle a_2 a_8\rangle$ from Tables 4 and 5, we obtain

$$(\sigma_\alpha)_G = 0.4132\frac{\lambda}{D}\left(\frac{D}{r_0}\right)^{5/6} \tag{76}$$

The dependence of G- and Z-tilts on ϵ is illustrated in Fig. 12. The G-tilt is smaller than the Z-tilt by approximately 3 percent. It is not surprising that the Z- and G-tilts are approximately equal to each other. Since the Zernike tilt aberrations account for 87 percent or more of the aberration variance (see Sec. 4.11 and Fig. 16), the variance of the coma aberration(s) is relatively small. The G-tilt is smaller than the Z-tilt because of the negative correlations of the tilt coefficients with the coma coefficients.

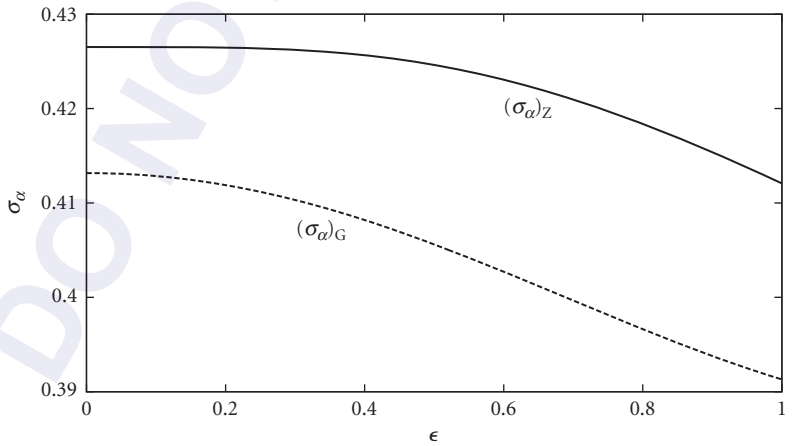

FIGURE 12 Dependence of the angle of arrival fluctuations on the obscuration ratio ϵ, illustrating the small difference between the Zernike wavefront tilt $[\sigma_\alpha(\epsilon)]_Z$ and the centroid-based G-tilt $[\sigma_\alpha(\epsilon)]_G$.

4.9 ABERRATION VARIANCE AND APPROXIMATE STREHL RATIO

The piston autocorrelation $\langle a_1^2(\epsilon)\rangle$ for Kolmogorov turbulence, obtained by letting $j = j' = 1$ in Eq. (58), so that both n and n' are equal to zero, is infinity.[9] The mean square value $\langle \Phi^2(\epsilon)\rangle$ of the aberration is also infinite, but the difference of the two is finite. Since the mean value $\langle \Phi(\epsilon)\rangle$ of the aberration is zero, $\langle \Phi^2(\epsilon)\rangle$ is also the variance of the aberration. However, the piston aberration $Z_1(\rho, \theta; \epsilon)$, being a constant, does not affect the aberration variance or the image quality. Accordingly, we refer to the piston-removed variance as simply the aberration variance. It is given by

$$\begin{aligned}\sigma_\Phi^2(\epsilon) &\equiv \langle \Phi^2(\epsilon)\rangle - \langle a_1^2(\epsilon)\rangle \\ &= \frac{0.046\pi^{11/3}}{2^{5/3}\Gamma(17/6)\Gamma(11/6)(1-\epsilon^2)^2}\left[\frac{\Gamma(14/3)(1+\epsilon)^{17/3}}{\Gamma(17/6)\Gamma(23/6)} - 2\epsilon^2 F_1\left(-\frac{5}{6}, -\frac{11}{6}, 2; \epsilon^2\right)\right]\left(\frac{D}{r_0}\right)^{5/3}\end{aligned} \tag{77}$$

Letting $\epsilon = 0$ for a circular pupil, Eq. (77) reduces to

$$\begin{aligned}\sigma_\Phi^2 &\equiv \langle \Phi^2\rangle - \langle a_1^2\rangle \\ &= 1.0324(D/r_0)^{5/3}\end{aligned} \tag{78}$$

Figure 13 shows how $\Delta_1(\epsilon) \equiv \sigma_\Phi^2(\epsilon)$ in units of $(D/r_0)^{5/3}$ varies with ϵ. Its value increases monotonically from 1.0324 for a circular pupil ($\epsilon = 0$) to 1.843 for an infinitesimally thin ring pupil ($\epsilon \to 1$).

The approximate expression $S \simeq \exp(-\sigma_\Phi^2)$ for the Strehl ratio[11,24,25] is not suitable for calculating the time-averaged Strehl ratio for a random aberration, especially when its value is small. For example, the Strehl ratio given by

$$\langle S_1(D/r_0)\rangle \simeq \exp[-1.03(D/r_0)^{5/3}] \tag{79}$$

is illustrated in Fig. 14 by the dashed curve, which is quite steep owing to the $(D/r_0)^{5/3}$ dependence of σ_Φ^2. Even for a small value of $D/r_0 = 1$, it gives a Strehl ratio of 0.357, compared to a true value of

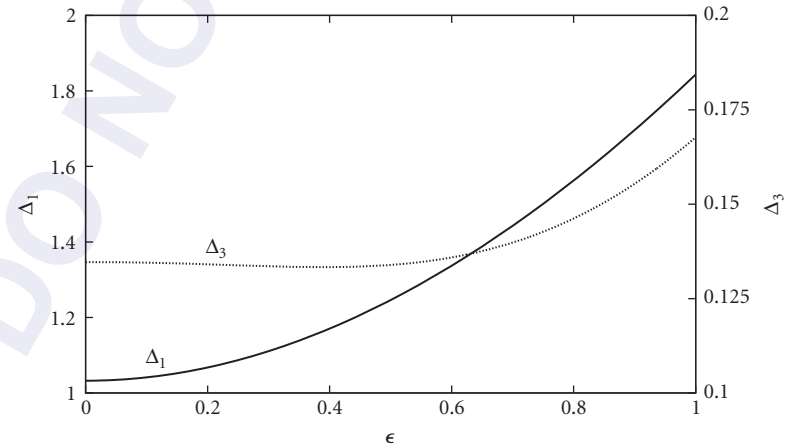

FIGURE 13 Piston-removed aberration variance $\Delta_1(\epsilon) \equiv \sigma_\Phi^2(\epsilon)$ and tilt-corrected variance $\Delta_3(\epsilon)$ in units of $(D/r_0)^{5/3}$ a function of ϵ.

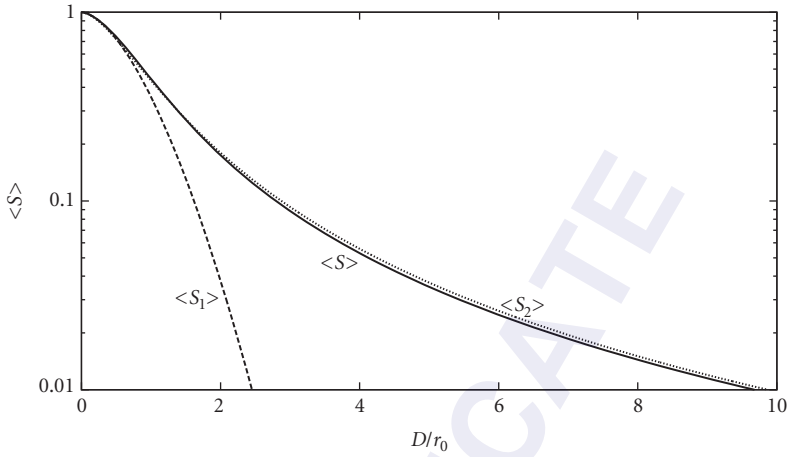

FIGURE 14 Comparison of exact and approximate long-exposure Strehl ratios for a circular pupil.

0.446. For larger values of D/r_0, it underestimates the Strehl ratio by larger factors. It is not surprising that Eq. (79) yields an underestimate of the true value of the Strehl ratio. If we write Eq. (14) in the form

$$\mathcal{D}_\Phi(r) = \langle[\Phi(0) - \Phi(r)]^2\rangle = 2[\sigma_\Phi^2 - R_\Phi(r)] \tag{80}$$

where

$$R_\Phi(r) = \langle\Phi(0)\Phi(r)\rangle \tag{81}$$

is the autocorrelation of the phase aberration and substitute in Eq. (24), we find that the Strehl ratio is given by Eq. (79) only when the phase correlation is zero. Otherwise, it will yield a larger value. Unfortunately, the phase correlation function for Kolmogorov turbulence is not defined; only the phase structure function is. A much better approximation is given by

$$\langle S_2(D/r_0)\rangle \simeq [1 + (D/r_0)^{5/3}]^{-6/5} \tag{82}$$

as may be seen from Fig. 14, where it is illustrated by the dotted curve. It overestimates the true value only slightly.

4.10 MODAL CORRECTION OF ATMOSPHERIC TURBULENCE

If the first J modes of the phase aberration are corrected, the corrected phase error may be written

$$\Phi_c(\rho, \theta; \epsilon) = \sum_{j=1}^{J} a_j(\epsilon) Z_j(\rho, \theta; \epsilon) \tag{83}$$

Accordingly, the residual phase aberration is given by

$$\Phi_J(\rho, \theta; \epsilon) = \Phi(\rho, \theta; \epsilon) - \Phi_c(\rho, \theta; \epsilon) = \sum_{j=J+1}^{\infty} a_j(\epsilon) Z_j(\rho, \theta; \epsilon) \tag{84}$$

Hence, the mean square value of the residual aberration is given by

$$\begin{aligned} \Delta_J(\epsilon) &= \langle [\Phi_J(\rho, \theta; \epsilon)]^2 \rangle \\ &= \pi^{-1} \int_0^1 \int_0^{2\pi} \left\langle \left[\Phi(\rho, \theta; \epsilon) - \sum_{j=1}^{J} a_j(\epsilon) Z_j(\rho, \theta; \epsilon) \right]^2 \right\rangle \rho \, d\rho \, d\theta \\ &= \Delta_1(\epsilon) - \sum_{j=2}^{J} \left\langle a_j^2(\epsilon) \right\rangle \end{aligned} \tag{85}$$

where $\Delta_1(\epsilon) \equiv \sigma_\Phi^2(\epsilon)$. Numerical values of $\Delta_J(\epsilon)$ are given in Table 6 for several values of ϵ. Figure 13 shows how $\Delta_3(\epsilon)$ (the piston-removed and tilt-corrected variance) varies with ϵ. We note that it is nearly constant until ϵ is larger than approximately 0.5. However, as shown in Fig. 15, $\Delta_6(\epsilon)$ piston removed and aberrations corrected up to and including astigmatism) and $\Delta_{11}(\epsilon)$ (the piston removed and aberrations corrected up to and including primary spherical aberration) first increase slightly with ϵ and then decrease considerably, and finally increase rapidly as $\epsilon \to 1$.

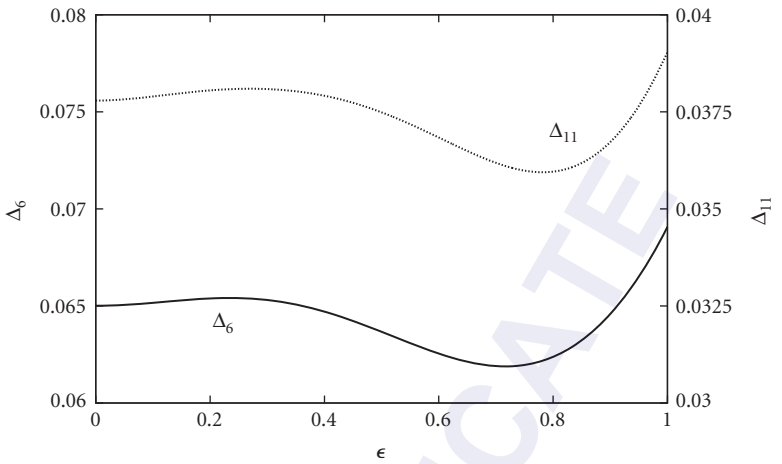

FIGURE 15 $\Delta_J(\epsilon)$ of the residual aberration in units of $(D/r_0)^{5/3}$ after correction of $J = 6$ and $J = 11$ modes.

The residual phase structure function after correction of the first J modes is given by

$$\begin{aligned}\mathcal{D}_J(\vec{\rho},\vec{\rho}';\epsilon) &= \langle[\Phi_J(\vec{\rho};\epsilon) - \Phi_J(\vec{\rho}';\epsilon)]^2\rangle \\ &= \langle\{[\Phi(\vec{\rho};\epsilon) - \Phi(\vec{\rho}';\epsilon)] - [\Phi_c(\vec{\rho};\epsilon) - \Phi_c(\vec{\rho}';\epsilon)]\}^2\rangle \\ &= \mathcal{D}_\Phi(\vec{\rho},\vec{\rho}';\epsilon) - \langle[\Phi_c(\vec{\rho};\epsilon) - \Phi_c(\vec{\rho}';\epsilon)]^2\rangle \end{aligned} \tag{86}$$

$$-2\langle[\Phi_c(\vec{\rho};\epsilon) - \Phi_c(\vec{\rho}';\epsilon)][\Phi_J(\vec{\rho};\epsilon) - \Phi_J(\vec{\rho}';\epsilon)]\rangle \tag{87}$$

where, as in Eq. (14),

$$\mathcal{D}_\Phi(\vec{\rho},\vec{\rho}';\epsilon) = \langle[\Phi(\vec{\rho},\epsilon) - \Phi(\vec{\rho}';\epsilon)]^2\rangle \tag{88}$$

is the long-exposure phase structure function. From Eq. (14), $\mathcal{D}_\Phi(\vec{\rho},\vec{\rho}';\epsilon)$ depends on $|\vec{\rho}-\vec{\rho}'|$, or from Eqs. (18) and (21*c*) on $\nu = |\vec{\rho}-\vec{\rho}'|/2$. For Kolmogorov turbulence in the near field, since $\mathcal{D}_\Phi = \mathcal{D}_w$, we may write from Eq. (29)

$$\mathcal{D}_\Phi(\nu;\epsilon) = 6.88(\nu D/r_0)^{5/3} \tag{89}$$

It is independent of ϵ, as expected, since it is a characteristic of turbulence.

The MCF for the residual phase aberration after correction of the first J modes is given by

$$M_J(\nu;\epsilon) = \exp\left\{i\left\langle[\Phi_J(\vec{\rho};\epsilon) - \Phi_J(\vec{\rho}';\epsilon)]^2\right\rangle\right\} = \exp[-(1/2)\mathcal{D}_J(\nu;\epsilon)] \tag{90}$$

The corresponding time-averaged MTF is accordingly given by

$$\langle\tau(\nu;\epsilon;D/r_0)\rangle_J = \tau(\nu;\epsilon)\exp[-(1/2)\mathcal{D}_J(\nu;\epsilon)] \tag{91}$$

The MTF at a certain frequency or the Strehl ratio for a given value of D/r_0 improves as more and more modes are corrected. Of course, $J = \infty$ represents complete correction, that is the aberration-free case.

4.11 SHORT-EXPOSURE IMAGE

It is evident from Tables 4 and 5 that a large portion of the phase aberration introduced by turbulence is a random wavefront tilt caused by large eddies and represented by the coefficients $a_2(\epsilon)$ and $a_3(\epsilon)$. Figure 16 shows the relative tilt-corrected variance $[(\Delta_1(\epsilon) - \Delta_3(\epsilon))/\Delta_1(\epsilon)]$ as a function of ϵ. It increases from a value of approximately 87 percent for a circular pupil to nearly 91 percent as $\epsilon \to 1$. Thus, if the tilt is corrected in (near) real time with a steering mirror, the variance of the phase aberration for a circular pupil is reduced by a factor of $1.03/0.134 \simeq 7.7$. Hence, unless D/r_0 is very large, a significant improvement in the quality of an image is obtained by correcting the wavefront tilt. A short-exposure image is equivalent to a tilt-free image, and a tilt-corrected image yields a time-averaged short-exposure image. For a circular pupil, the phase aberration with a standard deviation of 1 radian is obtained without any correction (except for the piston mode) when $D = r_0$. However, if the x and y tilts are corrected, we find from the expression for Δ_3, D can be as large a 3.34 r_0 for one radian of phase aberration.

Now the tilt coefficients $[a_2(\epsilon), a_3(\epsilon)]$ correlate with the primary coma coefficients $[a_8(\epsilon), a_7(\epsilon)]$, secondary coma coefficients $[a_{16}(\epsilon), a_{17}(\epsilon)]$, tertiary coma coefficients $[a_{30}(\epsilon), a_{29}(\epsilon)]$, and so on. Neglecting their correlation with coefficients other than the primary coma coefficients, the tilt-corrected phase structure function may be written[9]

$$\mathcal{D}_3(v;\epsilon) = \mathcal{D}_\Phi(v;\epsilon) - \frac{16v^2}{1+\epsilon^2}\left\langle a_2^2(\epsilon)\right\rangle - \frac{32\sqrt{2}v^2[(1+\epsilon^2)(6v^2-6v+1)-2\epsilon^4]}{(1-\epsilon^2)(1+6\epsilon^2+10\epsilon^4+6\epsilon^6+\epsilon^8)^{1/2}}\langle a_2(\epsilon)a_8(\epsilon)\rangle \quad (92)$$

It is evident that unlike the uncorrected phase structure function, the tilt-corrected structure function does depend on the diameter D. For a circular pupil, Eq. (92) reduces to

$$\begin{aligned}\mathcal{D}_3(v) &= \mathcal{D}_\Phi(v) - 16v^2\left\langle a_2^2\right\rangle - 32\sqrt{2}v^2(6v^2-6v+1)\langle a_2 a_8\rangle \\ &= 6.8839v^{5/3}(1 - 0.9503v^{1/3} - 0.5585v^{4/3} + 0.5585v^{7/3}(D/r_0)^{5/3}\end{aligned} \quad (93)$$

$\mathcal{D}_3(v)$ has a maximum value of $0.344(D/r_0)^{5/3}$ at $v = 1$, which is 1/20 of the value 6.88 $(D/r_0)^{5/3}$ without any correction (i.e., for $J = 1$), illustrating a significant benefit of the tilt correction. When $\epsilon \neq 0$, $\mathcal{D}_3(v;\epsilon)$ is larger for larger values of ϵ, indicating more severe fluctuations of the wavefront.

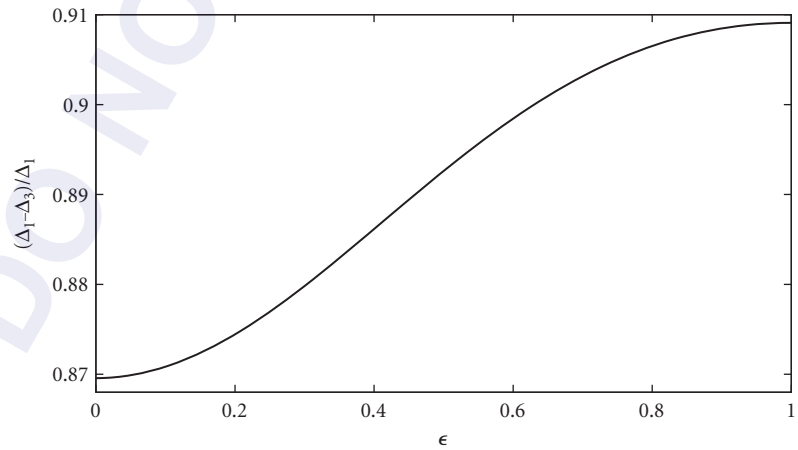

FIGURE 16 Relative tilt-corrected phase variance $[(\Delta_1(\epsilon) - \Delta_3(\epsilon))/\Delta_1(\epsilon)]$ as a function of the obscuration ratio ϵ.

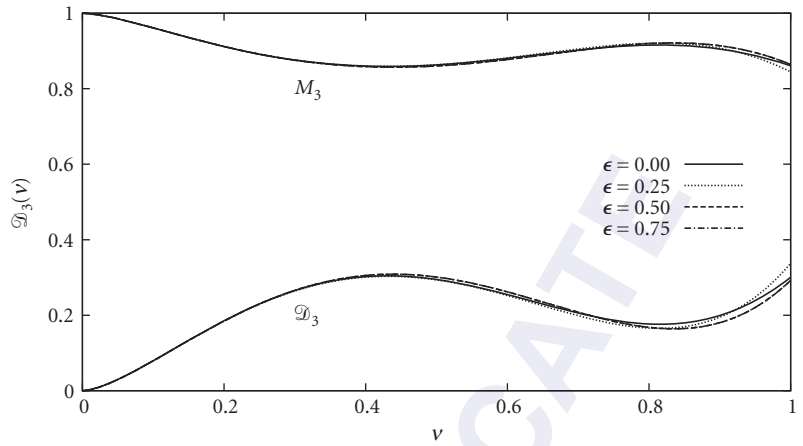

FIGURE 17 Tilt-corrected structure function $\mathcal{D}_3(v;\epsilon)$ and the corresponding mutual coherence function $M_3(v;\epsilon)$.

Using Eq. (92), the short-exposure MTF can be calculated as

$$\langle \tau(v;\epsilon;D/r_0)\rangle_3 = \tau(v;\epsilon)M_3(v;\epsilon;D/r_0) \tag{94}$$

where

$$M_3(v;\epsilon;D/r_0) = \exp[-(1/2)\mathcal{D}_3(v;\epsilon;D/r_0)] \tag{95}$$

is the tilt-corrected or short-exposure MCF or the MTF reduction factor associated with atmospheric turbulence. This factor does depend on the pupil diameter D, in contrast to the long-exposure MTF reduction factor given by Eq. (36), which is independent of D. As expected, it is smaller than the long-exposure reduction factor. Figure 17 shows how the tilt-corrected structure function and the corresponding MCF vary with v. The corresponding long-exposure functions are included for comparison.

The time-averaged Strehl ratio of the tilt-corrected image is given by

$$\langle S(\epsilon;D/r_0)\rangle_3 = \frac{8}{(1-\epsilon^2)}\int_0^1 \langle \tau(v;\epsilon;D/r_0)\rangle_3 \, v\,dv \tag{96}$$

Replacing the long-exposure atmospheric MTF reduction factor in Eq. (47*a*) by the short-exposure MTF reduction factor, the short-exposure central irradiance η_{SE} may be written

$$\eta_3(\epsilon;D/r_0) = (1-\epsilon^2)\left(\frac{D}{r_0}\right)^2 \langle S(\epsilon;D/r_0)\rangle_3 \tag{97}$$

The Strehl ratio $\langle S\rangle_3$ and the central irradiance η_3 are shown in Figs. 18 and 19, respectively. Some typical values of the tilt-corrected Strehl ratios are given in Table 1 for various values of D/r_0 and ϵ. For small values of D/r_0, η_3 increases approximately as for a diffraction-limited system, since the aberration is small; reaches a maximum (e.g., 3.74 for $D/r_0 = 3.5$ for a circular pupil), and then decreases slowly but monotonically to unity. Since the image displacement due to wavefront tilt decreases as $D^{-1/3}$, the effect of tilt correction becomes negligible for large values of D/r_0 due to the large residual phase errors. As in the case of a circular pupil, if the covariance of the tilt coefficients with others is ignored, for example $\langle a_2(\epsilon)a_8(\epsilon)\rangle$ in Eq. (92) is neglected, an unrealistic overcorrection will result.[11,26,27]

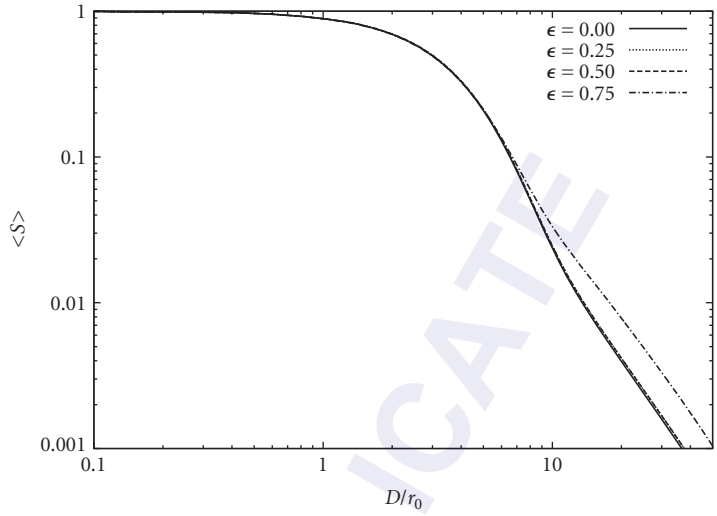

FIGURE 18 Variation of time-averaged short-exposure Strehl ratio $\langle S(\epsilon; D/r_0)\rangle_3$ with D/r_0.

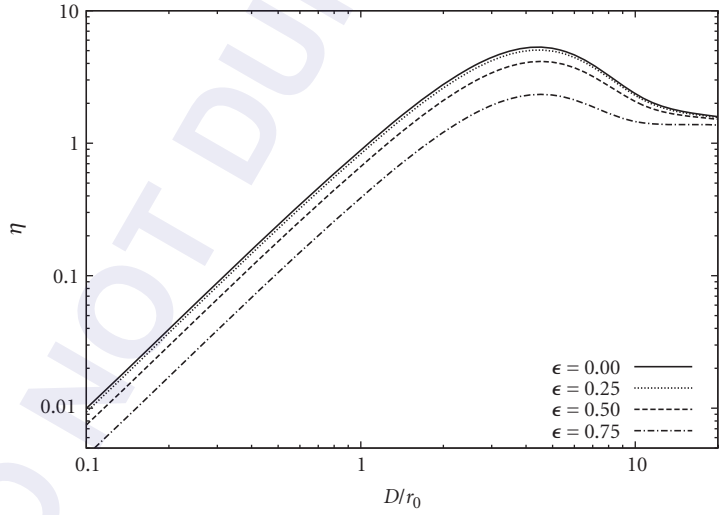

FIGURE 19 Variation of time-averaged short-exposure central irradiance $\langle \eta(\epsilon; D/r_0)\rangle_3$ with D/r_0.

For a circular pupil, Fig. 20 shows how the tilt-corrected time-averaged Strehl ratio varies with D/r_0. The uncorrected Strehl ratio is also shown to illustrate the improvement made by the tilt correction. An approximate value of the Strehl ratio given by $\exp(-\Delta_3)$, where

$$\Delta_3 = 0.134(D/r_0)^{5/3} \tag{98}$$

is the tilt-corrected time-averaged phase aberration variance, and shown by the dashed curve underestimates the true value $\langle S\rangle_3$.

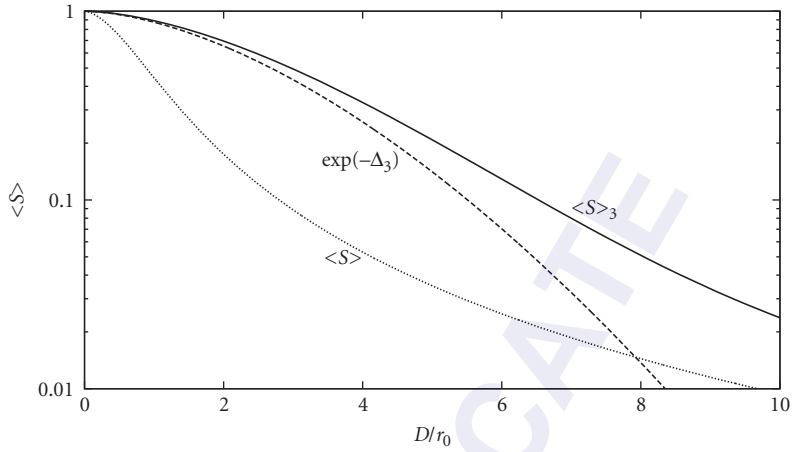

FIGURE 20 Short-exposure Strehl ratio $\langle S \rangle_3$ compared with its approximate value $\exp(-\Delta_3)$. The long-exposure Strehl ratio $\langle S \rangle$ is also shown to illustrate the improvement made by the tilt correction.

An example of an instantaneous short-exposure PSF illustrating the structure of the image of a star as seen by a ground-based telescope with a circular pupil and $D/r_0 = 10$ is shown in Fig. 21, where it is compared with the corresponding aberration-free image. On the average, the standard deviation $\sqrt{\Delta_3}$ of the instantaneous aberration is 2.5 radians or 0.4λ. We note that the image is broken up into small spots called *speckles*, which is a characteristic of large spatially random aberrations. The size of a speckle is determined by D, its angular radius being approximately equal to λ/D. The image size lies between its diffraction-limited value λ/D and its long-exposure value λ/r_0 (varying as $\lambda^{-0.2}$). The image becomes progressively worse as r_0 decreases, showing the effects of what astronomers call *seeing*. However, the size of a speckle decreases as D increases without affecting the long-exposure image size λ/r_0. Thus, an increase in D does not significantly improve the resolution of the system (as determined by the overall size of the image). The angular spot radius in units of λ/D representing the point at which the irradiance drops to half of its central value is given in Table 7 for both the short- and long-exposure images for various values of D/r_0 and ϵ, and compared with the corresponding

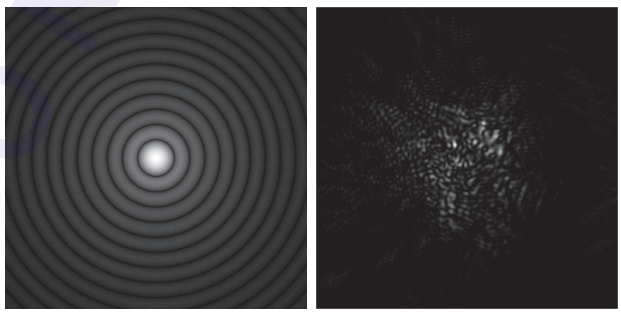

FIGURE 21 Instantaneous short-exposure PSF compared with the corresponding aberration-free PSF.

TABLE 7 Angular Spot Radius of Short-Exposure (SE), Long-Exposure (LE), and Diffraction-Limited (DL) Images in Units of λ/D for Various Values of ϵ and D/r_0

		$D/r_0=1$		$D/r_0=2$		$D/r_0=5$		$D/r_0=10$	
ϵ	DL	LE	SE	LE	SE	LE	SE	LE	SE
0	0.515	0.708	0.516	1.122	0.518	2.552	0.560	4.983	2.650
0.25	0.497	0.698	0.498	1.151	0.501	2.595	0.539	5.021	2.686
0.5	0.456	0.688	0.457	1.280	0.459	2.711	0.498	5.106	2.840
0.75	0.406	0.700	0.407	1.480	0.411	3.130	0.465	5.432	3.469

diffraction-limited value. We note that, whereas the LE radius is roughly D/r_0 times the DL radius, the SE radius for small values of D/r_0, for example $D/r_0=5$, is roughly equal to the DL radius, but for large values of D/r_0, for example $D/r_0=10$, it is about half the LE radius. Of course, as ϵ increases and more and more light goes into the diffraction rings, these factors change somewhat. For small values of D/r_0, the diffraction ring structure of the DL image, smoothed out in the LE image, returns in the SE image. This is more and more evident for larger and larger values of ϵ.

If the image wander is corrected in real time and the image is averaged over time, the speckles disappear and the image becomes smooth. Such PSFs and the corresponding encircled power can be obtained from Eqs. (43) and (44), respectively, by substituting the short-exposure OTF given by Eq. (94). The MTF, PSF, and encircled power thus obtained are shown by the dotted curves in Figs. 5 and 8 for several values of ϵ. The short-exposure image when randomly displaced over time yields a smooth long-exposure image, as illustrated by the dashed curves in Fig. 8. Modal correction of a Gaussian beam (including one with a central obscuration) propagating through turbulence has also been discussed by Wang using the Zernike circle polynomials[28] though such polynomials are not orthogonal over the Gaussian weighted (or an annular) pupil.[5,29]

4.12 ADAPTIVE OPTICS

The correction of wavefront errors in (near) real time is accomplished by using adaptive optics.[1–3] In practice, a steering mirror with only three actuators is used to correct the large x and y wavefront tilts (also called tip and tilt). The residual aberration is corrected by a deformable mirror, which is deformed by an array of actuators attached to it. The signals for the actuators are determined either by sensing the wavefront errors with a wavefront sensor in a closed loop to minimize the variance of the residual errors, or the actuators are actuated to produce Zernike modes (e.g., focus, two modes of astigmatism, two modes of coma) iteratively until sharpness of the image is maximized.[30–32] The signals are independent of the optical wavelength, provided atmospheric dispersion is negligible. The two approaches are referred to as *zonal* and *modal approaches*, respectively. The zonal approach has the advantage that the rate of correction is limited only by the rate at which the wavefront errors can be sensed and the actuators can be actuated. However, the amount of light that is used by the wavefront sensor is lost from the image. In practice, the image beam is split into two parts. The centroid of the image of one part is measured with a quad cell, and the tilt indicated by it is corrected with a steering mirror. The resulting tilt-corrected image of the other part with the residual aberration is corrected with a deformable mirror in a closed-loop manner.[33] In the modal approach, there is no loss of light, but the rate or the bandwidth of correction[34–36] can be slow due to its iterative nature, especially when turbulence is severe and a large number of modes must be corrected. Moreover, for imaging an extended object, wavefront sensing requires a point source in its vicinity, but the modal approach is applicable to the extended object itself.

Of course, adaptive optics can improve the image quality only if the object lies within an isoplanatic angle of turbulence. In the case of a ground-to-space laser illuminating a satellite, the angular travel

(point-ahead angle) of the satellite during the round-trip time of the beam to the satellite must be less than the isoplanatic angle of turbulence. An estimate of the isoplanatic angle can be obtained from[37]

$$\vartheta_0 = 0.058\lambda^{6/5}(\cos\vartheta)^{8/5}\left\{\int_0^L C_n^2(z)z^{5/3}dz\right\}^{-3/5} \tag{99}$$

Substituting Eq. (31) into Eq. (99), we obtain $\vartheta_0 = 7\,\mu\text{rad}$ for $\lambda = 0.5\,\mu\text{m}$. Thus, the $H-V_{5/7}$ model for C_n^2 yields $r_0 = 5$ cm and $\vartheta_0 = 7\,\mu\text{rad}$ for visible light; hence the 5/7 subscript.

4.13 SUMMARY

We have considered imaging through atmospheric turbulence by a system with an annular pupil, such as the Keck telescope. The results for a system with a circular pupil are obtained as a special case of those for the annular pupil. An atmospheric coherence length r_0 is defined such that the coherence of two points separated by this distance is 0.03. It is calculated using the well-known $H-V_{5/7}$ model for the refractive index structure parameter C_n^2, assuming Kolmogorov turbulence, for looking up and down at a point source through the atmosphere as well as for plane wave propagation (see Fig. 2). It is shown that turbulence limits the resolution of a system to one with pupil diameter r_0 regardless of the actual pupil diameter. The two-point angular resolution on ground when observed from any point in space varies approximately as λ/r_0, compared to the diffraction-limited resolution of λ/D. There is reciprocity in wave propagation through the turbulent atmosphere; otherwise adaptive optics couldn't have worked in ground-based astronomy. Accordingly, the PSF observed on an aircraft looking at a ground point object is the same as the irradiance distribution of a beam focused on ground from an aircraft. Similarly, the irradiance distribution of a beam focused in space from ground is the same as the PSF observed on ground looking at a space object. The effect of turbulence is shown in terms of the MTF, Strehl ratio, PSF, and encircled power for both long- and short-exposure images. How the image improves as more and more Zernike aberration modes are corrected is also discussed. The aberration function may also be expanded in terms of the Karhunen-Loève functions whose coefficients are statistically independent of each other.[27,38] It is found though that the effect of correlation of Zernike coefficients is negligible for $D/r_0 \le 4$.[26]

The dependence of the various image-related quantities on the obscuration ratio ϵ may be summarized as follows:

1. Atmospheric turbulence dominates the degradation of MTF; the MTF gain at high frequencies due to the pupil obscuration is lost even for weak turbulence (compare Figs. 4 and 5). The Strehl ratio is similarly dominated by turbulence (see Fig. 6).
2. The piston-removed aberration variance in units of $(D/r_0)^{5/3}$ increases monotonically from a value of 1.0324 for a circular pupil ($\epsilon = 0$) to a value of 1.843 for an infinitesimally thin ring pupil ($\epsilon \to 1$) (see Fig. 13).
3. The fluctuations in the angle of arrival depend weakly on the pupil obscuration (see Figs. 12 and 13).
4. The time-averaged variance of some aberration coefficients increases with ϵ and decreases for others (Fig. 9). For example the variance of tilt and astigmatism increases, but that of defocus and spherical aberration decreases and approaches zero as $\epsilon \to 1$. The covariance follows a similar trend (Fig. 10).
5. When a certain number of Zernike aberration modes is corrected, for example with a deformable mirror, the image quality improves. The residual aberration variance when the first J modes are corrected is given in Table 6. If only tip and tilt modes are corrected, say with a steering mirror, the aberration variance is reduced by 87 percent for a circular pupil and slightly larger (up to 90 percent) for an annular pupil. Figure 19 illustrates the improvement in the Strehl ratio. The aberration-free Airy pattern representing the image of a star breaks up into speckles, as illustrated in Fig. 21. The time-averaged short-exposure OTFs are compared in Fig. 5 with the corresponding long-exposure results. The PSFs and encircled-power curves are similarly compared in Fig. 8.

5.1 GLOSSARY

C_n^2	refractive index structure parameter
d_0	section size for laser beacon adaptive optics
$\mathcal{D}_n$	refractive index structure function
$\mathcal{D}_\phi$	phase structure function
E_f^2	mean square phase error due to fitting error
E_{FA}^2	mean square phase error due to focus anisoplanatism
E_n^2	mean square phase error due to sensor read noise
E_s^2	mean square phase error due to servo lag
f_G	Greenwood frequency
$f_{\mathrm{T_G}}$	Tyler *G*-tilt tracking frequency
$F_\phi(f)$	phase power spectrum
$F_{\phi\mathrm{G}}(f)$	*G*-tilt power spectrum
$H(f, f_c)$	servo response function
N_{pde}	number of photo-detected electrons per wavefront subaperture
r_0	Fried's coherence length
$\mathrm{SR_{HO}}$	Strehl ratio resulting from higher-order phase errors
$\mathrm{SR_{tilt}}$	Strelil ratio due to full-aperture tilt
$Z_j(\rho, \theta)$	Zernike polynomials
σ_θ	rms full-aperture tracking error
$\sigma_{\theta G}$	rms full-aperture *G*-tilt induced by the atmosphere
θ_0	isoplanatic angle

5.2 INTRODUCTION

An Enabling Technology

Adaptive optics (AO) is *the* enabling technology for many applications requiring the real-time control of light propagating through an aberrating medium. Today, significant advances in AO system performance for scientific, commercial, and military applications are being made because of improvements in component technology, control algorithms, and signal processing. For example, the highest-resolution images of living human retinas ever made have been obtained using AO.[1–3] Increased resolution of retinal features could provide ophthalmologists with a powerful tool for the early detection and treatment of eye diseases. Adaptive optics has brought new capabilities to the laser materials processing industry, including precision machining of microscopic holes and parts.[4,5] Beaming power to space to raise satellites from low earth orbit to geosynchronous orbit, to maneuver satellites that are already in orbit, and to provide electricity by illuminating solar panels remains a topic of commercial interest.[6,7] Recent work has shown that high-energy pulsed lasers, corrected for atmospheric distortions with AO, could be used to alter the orbits of space debris objects,[8] causing them to reenter the atmosphere much sooner than natural atmospheric drag—creating an opportunity for the environmental restoration of space. High-speed optical communication between the ground, aircraft, and spacecraft (including very deep space probes) is a topic of continuing interest that would benefit from the use of AO.[9] Adaptive optics offers significant benefit to a large variety of military applications, including the U.S. Air Force Airborne Laser program, in which a high-powered chemical oxygen-iodine laser will be mounted in an aircraft to engage boosting missiles at long ranges.[10] Adaptive optics will be used to predistort the laser beam as it leaves the aircraft to compensate for the atmospheric distortions that the beam encounters as it propagates to the missile target.

Perhaps the most widely known and discussed application for AO is imaging through the atmosphere. Military sites are now using AO on medium-sized ground-based telescopes [of the order of 4 meters (m)] to inspect low-earth-orbiting satellites. However, the most dramatic use of AO is in astronomy. Astronomers have been plagued by the atmosphere for centuries—since the invention of the telescope. Indeed, distortion caused by turbulence is the principal motivation for launching large telescopes into space. However, if ground-based telescopes were able to achieve diffraction-limited resolution and high Strehl ratios, a significant obstacle to new discoveries and more productive research would be overcome. Adaptive optics, originally proposed by the astronomer Horace Babcock in 1953,[11] may enable that to happen, creating a revolution in ground-based optical astronomy. Adaptive optics is especially important in light of the large new telescope mirrors. Incredible advances in mirror technology have made 8-m-diameter monolithic mirrors almost commonplace (four have seen first light and five more are under construction). These are in addition to the two 10-m Keck telescopes and the 11-m Hobby-Eberly telescope, all of which use segmented primaries. The atmosphere limits the resolution of ground-based telescopes to an equivalent diameter that is equal to Fried's coherence length, r_0 (a few tens of centimeters at visible wavelengths at the best sites).[12] Adaptive optics offers the potential for telescopes to achieve diffraction-limited imaging and high throughput to spectroscopic instruments. Furthermore, interferometric arrays of large telescopes will enable unprecedented imaging resolution of faint objects, given that the unit telescopes can each produce nearly distortion-free wave fronts. Because imaging through the atmosphere is a topic of great interest, and because it embodies all aspects of AO technology, this discussion is oriented toward that application.

The chapter is organized as follows: Sec. 5.3 describes the basic concept of AO as applied to ground-based telescopes. Section 5.4 is a short summary of the classical description of atmospheric turbulence and parameters that are important for designing and evaluation of AO systems. Section 5.5 is a description of the hardware and the software that are needed for practical implementation of AO. This includes tracking, wavefront sensing, processors, and wavefront correctors. Section 5.6 is a discussion of design issues for top-level system performance trades using scaling laws and formulas.

5.3 THE ADAPTIVE OPTICS CONCEPT

This section provides a brief, qualitative overview of how AO imaging systems work. Figure 1 is a highly simplified diagram that illustrates the principles. In this figure, a conventional telescope is shown on the left and one that is equipped with AO is shown on the right. The science object

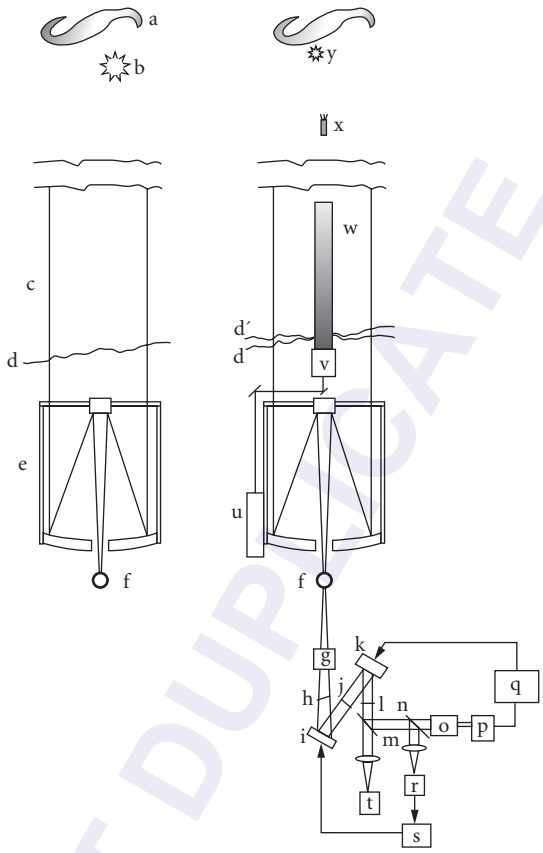

FIGURE 1 Conventional telescope with no AO (left) and additional components needed for AO (right). (*a*) Object of interest, (*b*) natural guide star, (*c*) atmospheric turbulence, (*d*) aberrated wavefront (including tilt and higher-order distortions) after passing through the turbulent atmosphere, (*d′*) aberrated wavefront from the laser beacon with full-aperture tilt removed, (*e*) telescope, (*f*) aberrated image, (*g*) relay optics, (*h*) demagnified aberrated wavefront including full-aperture tilt, (*i*) fast-steering mirror, (*j*) tilt-removed wavefront with only higher-order aberrations remaining, (*k*) deformable mirror, (*l*) corrected wavefront, (*m*) aperture-sharing element, (*n*) tilt sensor pickoff beam splitter, (*o*) relay optics, (*p*) higher-order wavefront sensor, (*q*) electronic processor to compute deformable mirror commands, (*r*) full-aperture tilt sensor, (*s*) tilt mirror processor and controller, (*t*) science camera, (*u*) laser for generating laser beacons, (*v*) launch telescope for the beacon laser, (*w*) Rayleigh laser beacon, (*x*) mesospheric sodium laser beacon, and (*y*) faint natural guide star for full-aperture tilt sensing.

(*a*) and a natural guide star (*b*) are at the top of the figure. The turbulent atmosphere (*c*) creates higher-order phase distortion and an overall tilt on wavefronts reaching the telescope (*d*). The telescope (*e*) forms an aberrated image (*f*) at the location of the camera or spectrograph. The natural guide star is used, either manually or automatically, to correct pointing errors in the telescope mount and the overall wavefront tilt that are induced by atmospheric turbulence.

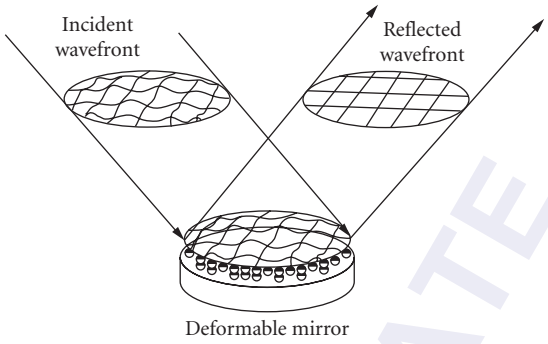

FIGURE 2 Deformable mirror concept in which phase aberrations on an incident wavefront are removed by setting the deformable mirror to the conjugate of the aberration.

The objectives of the AO system are to continuously remove the higher-order distortion and to stabilize the position of the image by removing the overall tilt. The components are shown on the right side of Fig. 1. One can think of the AO system as a dynamic optical system that simultaneously relays the original image to a new focal plane [the camera (*t*)] while removing both the higher-order aberrations (those distortions having spatial frequencies higher than tilt) with the deformable mirror (*k*) and the tilt aberrations with the fast-steering mirror (*i*), leaving only a minor amount of residual error in the wave front (*l*). The appropriate optical relay telescopes (*g* and *o*) are used as required by the particular implementation.

Figure 2 illustrates how a deformable mirror removes phase aberrations that are induced by atmospheric turbulence. The conjugate of the measured wavefront distortion is imposed on the surface of the deformable mirror so that on reflection, the distortions are removed. The AO system is never able to perfectly match the distortions in the wavefront because of a number of error sources that will be discussed in later sections.

To set the figure on the deformable mirror, the AO system must get information about the turbulent atmosphere by measuring its effect on the wavefronts from a beacon—a source of light such as a bright star (see Fig. 1, item *b*) located at or near the science object. The object itself may serve as the beacon if it is bright enough (either by self-emission, as in the case of a star or astronomical object, or by reflection of natural or man-made light, as in the case of artificial satellites). When a natural star does not exist or when the object itself is not bright enough, it may be possible to use an artificial beacon generated by a low-power laser (see Fig. 1, item *u*). A laser beacon can be created either by Rayleigh scattering up to a range of about 20 km, or by resonant scattering of atomic species such as sodium in the mesosphere, at an altitude of 90 km above Earth's surface. In the implementation that is shown in Fig. 1, a laser beam that is capable of exciting the D_2 line in atomic sodium in the mesosphere is projected from behind the secondary mirror of the telescope.

Control signals for the wavefront corrector mirrors are generated by a full-aperture tracking sensor (see Fig. 1, item *r*) and a wavefront sensor (*p*) by observing the residual error in the beacon wavefront (*l*). An aperture-sharing element (*m*) directs light from the beacon into the wavefront sensor, which is located at an image of the entrance pupil of the telescope. The wavefront sensor samples the slope of the wavefront over subaperture regions of the order of r_0 in size—for which the wavefront is essentially an undistorted, but tilted, plane wave—measuring the tilt and reporting that tilt as a wavefront phase gradient. The computer (*q*) combines the subaperture gradient measurements and "reconstructs" a best estimate of the residual phase error at specific points in the aperture, generally the locations of the actuators of the deformable mirror. Error signals derived from the reconstructed wavefront are sent to the deformable mirror to further reduce the residual error.

The tracking sensor measures the overall tilt of the beacon wavefront by computing the centroid of a focused image of the beacon that is formed by the full aperture of the telescope (or by other, more sophisticated means). The tracker processor (*s*) generates an error signal that controls the fast-steering mirror to keep the image of the beacon centered on the tracking sensor. It is also possible to derive full-aperture tilt information from the higher-order wavefront sensor, but optimum tracking performance usually requires a specialized sensor and processor. When a laser beacon is used to obtain higher-order wavefront information, it is still necessary to use a natural guide star to derive full-aperture tilt information: The laser beacon's position in the sky is not known with respect to an inertial reference (like a star), because its path on the upward propagation is random. To first order the beacon does not appear to move at all in the tracker due to near perfect reciprocity on the upward and downward paths, generating a return wavefront having no full aperture tilt as shown at (d') in Fig. 1. The requirement to use a natural guide star for tracking is not as serious as it first sounds, however, because it is much more likely that a natural guide star can be found near the science object that satisfies tracking requirements but is still too faint for higher-order wavefront measurements. This is possible because the full aperture of the telescope and a small number of specialized detectors can be used for tracking so that stars fainter by a factor of $\sim(D/r_0)^2$ that are available to the wavefront sensor become available to the tracking sensor.

Figure 1 is highly simplified. The details of the optics have been left out to emphasize the main principles. For instance, it is customary to form an image of the entrance pupil of the telescope onto the fast-steering mirror, the deformable mirror, and again on the wavefront sensor. At least two powered optical elements are required to generate each of these images. Even more sophisticated approaches have been proposed in which multiple deformable mirrors are reimaged to layers in the turbulence. The nature of the aperture-sharing element will vary significantly depending on the adopted philosophy for the system. For example, if obtaining enough light for the wavefront sensor is a problem (as is usually the case in astronomy), it is prudent to send the entire spectrum over which the detectors are responsive to the wavefront sensor and divert only the absolute minimum needed part of the spectrum to the imaging sensor. This approach also means that the optics must be designed to work over a wide spectral range (e.g., from 450 to 1000 nm for a visible wavefront sensor) and also requires careful design of atmospheric dispersion correction. Furthermore, there are innovative approaches for implementing the wavefront corrector mirrors. The Steward Observatory group is developing a tilting, deformable secondary mirror for the new 6.5-m primary replacement at the Multiple Mirror Telescope (MMT) and 8.4-m Large Binocular Telescope (LBT) observatories.[13] This arrangement requires only two reflecting surfaces between the sky and the camera.

5.4 THE NATURE OF TURBULENCE AND ADAPTIVE OPTICS REQUIREMENTS

Turbulence Generation and the Kolmogorov Model

This section summarizes the classical description of atmospheric turbulence and its effect on the propagation of light. The literature on this topic is enormous. Our purpose here is to introduce the principles and define a few important parameters that are relevant to the operation of adaptive optical systems. The references cited throughout provide more detail.

Atmospheric turbulence is generated by solar heating of the Earth's surface. Air at the surface of the Earth is warmed in the day and cooled at night. Temperature gradients develop, creating a convective flow of large masses of air. Turbulence develops as large-scale masses of air break up into smaller spatial scales and dissipate their energy to the surrounding air. The effects of turbulence on electromagnetic wave propagation is governed by the nature of the spatial and temporal fluctuations of the index of refraction of air. The refractive index of air at optical wavelengths obeys the formula[14]

$$n = 1 + 77.6\left[1 + \frac{7.52 \cdot 10^{-3}}{\lambda^2}\right]\frac{P}{T} \cdot 10^{-6} \tag{1}$$

where λ is the wavelength of light in micrometers, P is the atmospheric pressure in millibars, and T is the atmospheric temperature in kelvins (K). The effect of atmospheric pressure changes on n are small and can, for problems of interest in this chapter, be neglected. The dominant influence on variations of n is the air temperature. At visible wavelengths, $dn/dT \sim 10^{-6}$ at standard pressure and temperature. This means that two 1-m-long columns of air having a temperature difference of 1 K create roughly one wave of optical path difference for visible light, a very significant effect. We can model the index of refraction as the sum of two parts,

$$n(\mathbf{r}, t, \lambda) = n_0(\mathbf{r}, \lambda) + n_1(\mathbf{r}, t) \tag{2}$$

where n_0 represents the deterministic, slowly changing contribution (such as variation with height above the ground), and n_1 represents the random fluctuations arising from turbulence. The wavelength dependence of n_1 is ignored. Furthermore, typical values of n_1 are several orders of magnitude smaller than unity.

During the 1940s, Andrey Nikolayevich Kolmogorov (1903–1987) developed theories[15] describing how energy is dissipated in the atmosphere and modeled the spatial power spectrum of turbulent velocity fluctuations. V. I. Tatarskii postulated the applicability of the Kolmogorov spatial power spectrum to refractive index fluctuations and then solved the wave equation for the power spectrum of Kolmogorov's model and determined the effect on propagation through weak turbulence.[16] David L. Fried subsequently extended Tatarskii's results to describe phase distortions of turbulence in terms of Zernike polynomials[17] and derived his famous atmospheric coherence diameter parameter r_0, as a measure of optical resolution.[12] Nearly all subsequent work in statistical atmospheric optics is based on the contributions of Kolmogorov, Tatarskii, and Fried. The effects of turbulence on wave propagation are critical because the spatial and temporal frequency distribution and optical depth of the phase aberrations drive the design requirements for beacon brightness, wavefront sensing, tracking, electronic processing, and wavefront corrector mirror subsystems in a real-time phase compensation system.

For refractive index fluctuations, the Kolmogorov spatial power spectral density, $\Phi_n(\kappa)$, is given by

$$\Phi_n(\kappa) = 0.033 C_n^2 \kappa^{-11/3} \tag{3}$$

where κ is the spatial wavenumber and C_n^2 is the refractive index structure constant, a measure of the optical strength of turbulence. The wavenumber κ is inversely related to the size of the turbulent eddies in the atmosphere. Equation (3) is valid between two limits of κ called the inertial subrange. The scale size of eddies for the smallest values of κ in the inertial subrange is called the outer scale, denoted $L_0 = 2\pi/\kappa_0$, and is of the order of meters to kilometers. The inner scale, $l_0 = 2\pi/\kappa_m$, or smallest eddies in the inertial subrange, is of the order of millimeters. For values of κ outside the inertial subrange, the von Kármán spectrum is often used in place of Eq. (3) to avoid mathematical complications as κ approaches zero. The von Kármán spectrum has the form

$$\Phi_n(\kappa) \cong \frac{0.033 C_n^2}{(\kappa^2 + \kappa_0^2)^{11/6}} \exp\left(-\frac{\kappa^2}{\kappa_m^2}\right) \tag{4}$$

where κ_0 and κ_m are the spatial wavenumbers for the outer and inner scales.

The Variation of n and the C_n^2 Parameter

Tatarskii introduced structure functions to describe the effect of turbulence on wave propagation. Structure functions describe how a physical parameter is *different* between two points in space or time. The structure function of the index of refraction, $\mathcal{D}_n(\mathbf{r})$ is defined as

$$\mathcal{D}_n(\mathbf{r}) = \{[n_1(\mathbf{r}') - n_1(\mathbf{r}' - \mathbf{r})]^2\} \tag{5}$$

where $n_1(\mathbf{r})$ represents the fluctuating part of the index of refraction and $\{\ldots\}$ represents an ensemble average over the turbulent conditions. The autocorrelation function and power spectral density form a three-dimensional Fourier transform pair (a useful relation used many times in statistical optics), and using that relationship, it can be shown that[18]

$$\mathcal{D}_n(r) = C_n^2 r^{2/3} \tag{6}$$

where we have also assumed that the fluctuations are isotropic and dropped the vector dependence on r. Equation (6) is the defining equation for the refractive index structure constant, C_n^2, in that the numerical coefficient on the right side of Eq. (6) is unity. Defined in this way, C_n^2 is a measure of the optical strength of turbulence.

A few meters above the ground, C_n^2 has an average value of the order of 10^{-14} m$^{-2/3}$, rapidly decreasing by three or four orders of magnitude at heights above 10 km. Several means have been developed to measure the C_n^2 profile, including in situ instruments on balloons as well as remote sensing optical and radar techniques.[19, 20] Several mathematical models of C_n^2 profiles have been developed based on experimental data. One of the most widely used was suggested by Hufnagel[21] and modified to include boundary layer effects by Valley.[22] The expression for the Hufnagel-Valley model for C_n^2 is

$$C_n^2(h) = 5.94 \cdot 10^{-23} h^{10} e^{-h} \left(\frac{W}{27}\right)^2 + 2.7 \cdot 10^{-16} e^{-2h/3} + A e^{-10h} \tag{7}$$

where h is the height above the site in kilometers, W is an adjustable wind correlating parameter, and A is a scaling constant, almost always taken to be $A = 1.7 \cdot 10^{-14}$. Winker[23] suggested $W = 21$ producing the $\mathrm{HV}_{5/7}$ model named from the fact that the resulting profile yields a value of Fried's coherence diameter of $r_0 = 5$ cm and an isoplanatic angle of $\theta_0 = 7\,\mu$rad for zenith propagation at 0.5 μm. (The parameters r_0 and θ_0 are defined and their relationships to C_n^2 are given in Sec. 5.4.) The $\mathrm{HV}_{5/7}$ model has been widely used in the evaluation of AO system performance. Figure 3 shows how C_n^2, computed with this model, varies with altitude.

The Hufnagel-Valley model is useful for continental sites or sites with well-developed boundary layers. The C_n^2 profile, which is associated with mountaintop sites that are surrounded by water

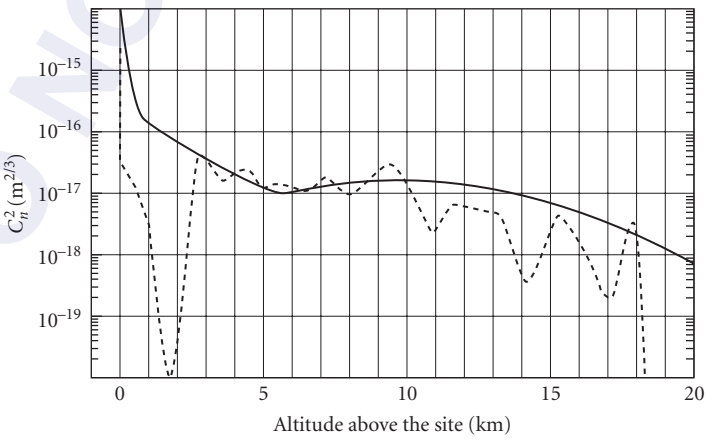

FIGURE 3 C_n^2 profiles for the $\mathrm{HV}_{5/7}$ model (solid curve) and for average seeing conditions at Mauna Kea (dotted curve).

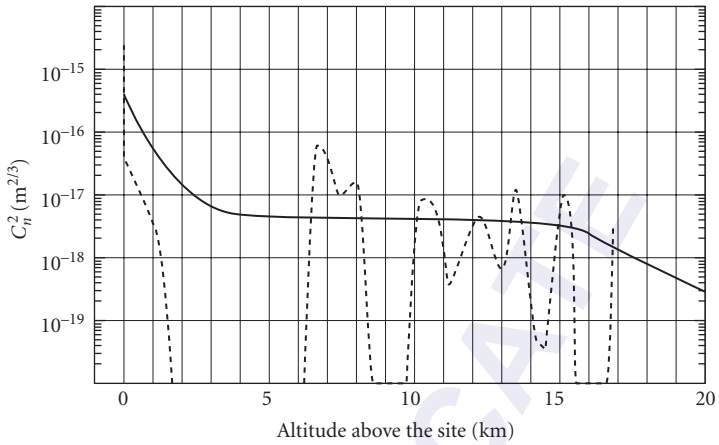

FIGURE 4 Average seeing C_n^2 profile analytical model for Paranal, Chile [site of European Southern Observatory's (ESO's) Very Large Telescope (VLT) (solid curve)], and a C_n^2 profile that is representative of best seeing conditions (occurring less than 10 percent of the time) at Mauna Kea (dotted curve) and represents 0.25 arcsec seeing. Note how the turbulence appears as layers and the lack of a boundary layer in the Mauna Kea profile. Similar conditions have also been observed at Paranal and La Palma.

(e.g., Mauna Kea or La Palma) or mountaintop sites that are close to a coastline [so as to be above the marine boundary layer (e.g., Paranal, Chile)], often exhibits distinct layers of turbulence, but little or no boundary layer in the first few kilometers above the ground. A C_n^2 profile that is representative of average seeing for Mauna Kea is also shown in Fig. 3 and yields an r_0 of 18 cm and θ_0 of 15 μrad. Figure 4 shows a C_n^2 profile for Mauna Kea representative of the 90th-percentile best seeing (note the distinct layering), giving an r_0 of 45 cm, and an analytical model that is used for average seeing at Paranal,[24] giving an r_0 of 18 cm.

Wave Propagation in Turbulence

An electromagnetic wave propagating in the atmosphere must satisfy Maxwell's equations—in particular, the electric and magnetic fields must satisfy the time-independent Helmholtz equation:

$$\nabla^2 U(\mathbf{r}) + n^2 k^2 U(\mathbf{r}) = 0 \tag{8}$$

where $k = 2\pi/\lambda$ and n is the refractive index of air. $U(\mathbf{r})$ is the complex phasor representation of a spatial wave:

$$U(\mathbf{r}) = A(\mathbf{r}) e^{i\phi(\mathbf{r})} \tag{9}$$

where the amplitude $A(\mathbf{r})$ and phase $\phi(\mathbf{r})$ are random variables governed by the statistics of the fluctuations of the refractive index, n. There is no closed-form solution for $A(\mathbf{r})$ and $\phi(\mathbf{r})$.

The surfaces in space that are defined by $\phi_0(\mathbf{r}) =$ constant are wavefronts. For starlight arriving at the top of the atmosphere, the wavefronts are planes of infinite extent. When a plane wave passes

through the atmosphere, whose refractive index varies randomly along each propagation path, the plane wave becomes distorted. The total phase change from that in a vacuum along a path z is

$$\Delta\phi = \phi_0 - k\int_0^z n_1(z)dz \tag{10}$$

where $k = 2\pi/\lambda$, and $n_1(z)$ is the fluctuating part of the index of refraction. If this equation could be evaluated along every direction, one could construct the three-dimensional shape of the wavefront at any position along its propagation path due to phase changes induced by atmospheric turbulence. This is, of course, an intractable problem in terms of a closed-form solution since the fluctuations of the index of refraction are a random process.

A phase deformation that propagates far enough becomes an amplitude fluctuation as different parts of the propagating wavefront combine to create regions of constructive and destructive interference. This effect is called scintillation—the twinkling of starlight is a famous example. Amplitude fluctuations are generally not severe for astronomical observing, and 70 to 80 percent or more of the distortions can be removed by phase-only compensation (by using a steering mirror and deformable mirror). However, both the amplitude and phase of the wave are random variables, and the most general representation of the wave is as given in Eq. (9).

The historically accepted approach to dealing with wave propagation in turbulence was introduced by Tatarskii by use of the Rytov transformation. The Rytov transformation defines a complex quantity ψ as the natural logarithm of U: $\psi = \ln U$. This substitution allows a solution to the wave equation in the form of a multiplicative perturbed version of the free space field:

$$U(\mathbf{r}) = A_0(\mathbf{r})e^{i\phi_0(\mathbf{r})}e^{\ln[A(\mathbf{r})/A_0(\mathbf{r})]-i[\phi_0(\mathbf{r})-\phi(\mathbf{r})]} \tag{11}$$

Since the field at any point is the superposition of many independent contributions of propagating waves in the turbulent medium, we expect the fluctuating parts of the field to obey Gaussian statistics (invoking the central limit theorem). This means if $\ln(A/A_0)$ obeys Gaussian statistics, we expect the amplitude fluctuations to be log-normally distributed. Most experimental evidence supports this for weak fluctuations. Tatarskii's results make it possible to compute important characteristic functions and to use the properties of Gaussian random processes to develop practical descriptions of the effects of turbulence.

Fried's Coherence Diameter, r_0, and the Spatial Scale of Turbulence

Hufnagel and Stanley[25] extended Tatarskii's work and developed an expression for the modulation transfer function in terms of the mutual coherence function. Fried[26] developed an expression for *phase* structure function, $\mathcal{D}_\phi$ of a propagating electromagnetic plane wave showing that it is proportional to the 5/3 power of spatial separation, r, and is given by*

$$\mathcal{D}_\phi(\boldsymbol{r}) = \{[\phi(\boldsymbol{r}') - \phi(\boldsymbol{r}'-\boldsymbol{r})]^2\} = \left[2.91\left(\frac{2\pi}{\lambda}\right)^2\int C_n^2(z)dz\right]r^{5/3} \tag{12}$$

where λ is the wavelength of propagation, $C_n^2(z)$ is the position-dependent refractive index structure constant and integration is over the optical path to the source.

*In the more general case where amplitude effects are significant, the *wave* structure function, $\mathcal{D}(r) = \mathcal{D}_x(r) + \mathcal{D}_\phi(r)$, should be used, but since it has exactly the same value as given by Eq. (12), and since conventional AO does not correct intensity fluctuations, the amplitude term will be dropped for the material that is presented here.

Fried[26] developed a very useful relationship between the phase structure function and a particular measure of optical resolution—the volume under the two-dimensional optical transfer function. Defined in this way, the seeing-limited resolving power asymptomatically approaches a limiting value as the aperture size increases. The limiting value is set by the strength of the turbulence. Fried defined a quantity called the coherence diameter, r_0, such that the limiting resolution that is obtained in the presence of atmospheric turbulence is the same as that that is obtained by a diffraction-limited lens of diameter r_0 in a vacuum. Its value can be computed from the definition[17]

$$r_0 = 0.185\lambda^{6/5}(\cos\psi)^{3/5}\left[\int_0^\infty C_n^2(h)dh\right]^{-3/5} \tag{13}$$

where λ is the wavelength, $C_n^2(h)$ is the vertical profile of the index of refraction structure constant, h is the height above the ground, ψ is the angle between the propagation direction and the zenith, and the integral is evaluated from the ground to an altitude at which $C_n^2(h)$ no longer contributes significantly (typically 20 km). This equation explicitly shows r_0 scales with wavelength as $\lambda^{6/5}$ and with zenith angle as $(\cos\psi)^{3/5}$. By convention, the numerical values of r_0 are usually expressed at 0.5 μm for zenith viewing. At the best astronomical sites, the median value of r_0 is from 15 to 25 cm, corresponding to seeing conditions of $\lambda/r_0 = 0.7$ to 0.4 arcsec. The best intracontinental mountaintop sites exhibit median values of r_0 between 10 and 20 cm, and average intracontinental sites have r_0 values between 5 and 10 cm.[20]

Given the definition of r_0 in Eq. (13), the phase structure function becomes

$$\mathcal{D}_\phi(r) = 6.88\left(\frac{r}{r_0}\right)^{5/3} \tag{14}$$

Fried defined r_0 so that the knee in the curve showing resolving power as a function of diameter occurs at $D/r_0 = 1$, where D is the aperture diameter of the imaging telescope. Most scaling laws of interest to AO are expressed in terms of the ratio D/r_0.

Turbulence Noll[27] developed a description of the average spatial content of turbulence-induced wavefront distortion in terms of Zernike polynomials. The Zernike polynomials are often used to describe the classical aberrations of an optical system—tilt, defocus, astigmatism, coma, and spherical aberration. Noll expresses the phase of the distorted wavefront over a circular aperture of radius, R, as

$$\phi(\rho,\theta) = \sum_j a_j Z_j(\rho,\theta) \tag{15}$$

where Z_j is a modified set of the orthogonal Zernike polynomials defined over points in the aperture at reduced radius $\rho = r/R$ and azimuthal angle θ. The Z_j is given by

$$\left.\begin{aligned} Z_{\text{even}j} &= \sqrt{n+1}R_n^m(\rho)\sqrt{2}\cos m\theta \\ Z_{\text{odd}j} &= \sqrt{n+1}R_n^m(\rho)\sqrt{2}\sin m\theta \end{aligned}\right\} m \neq 0 \tag{16}$$

$$Z_j = \sqrt{n+1}R_n^0(\rho) \qquad m = 0 \tag{17}$$

where

$$R_n^m(\rho) = \sum_{s=0}^{(n-m)/2} \frac{(-1)^s(n-s)!}{s![(n+m)/2-s]![(n-m)/2-s]!}\rho^{n-2s} \tag{18}$$

The indices n and m are always postive integers and satisfy $m \le n$ and $n - m =$ even. The index, j, is a mode-ordering number and depends on n and m.

The a_j are coefficients having mean square values that accurately weight the particular Zernike mode to represent the Kolmogorov distribution of turbulence. Using this approach, Noll computed the values of a_j and showed that the piston-removed wavefront distortion for Kolmogorov turbulence averaged over an aperture of diameter, D, expressed as a mean square value in units of square radians (rad^2) of optical phase is

$$\langle \phi^2 \rangle = 1.0299 \left(\frac{D}{r_0} \right)^{5/3} \tag{19}$$

Table 1 lists the strengths of the first 21 Zernike modes, and the residual mean square distortion as each component is removed. Data in this table show that the two components of tilt (X and Y axes) make up 87 percent of the total wavefront distortion.

Noll's results are useful for estimating the performance of an AO system if one can estimate how many Zernike modes the system will correct (a rule of thumb is approximately one mode is corrected per deformable mirror actuator for systems having large numbers of actuators). Figure 5 shows the mean square residual phase error for a range of values of D/r_0. Generally, the mean square residual error should be much less than 1 rad^2. Even if all 21 modes listed in Table 1 are corrected, the mean square residual error for conditions in which D/r_0 is 20, for example, $0.0208(20)^{5/3} = 3.06$ rad^2, is a very significant, generally unacceptable error.

When more than 21 modes are corrected, the residual mean square wavefront error is given by[27]

$$\sigma_M^2 = 0.2944\, M^{-(\sqrt{3}/2)} (D/r_0)^{5/3} \tag{20}$$

where M is the number of modes corrected. Figure 6 shows the required number of Zernike modes to be removed as a function of D/r_0 for three image quality conditions. As an example, if r_0 is 12 cm at

TABLE 1 Mean Square Wavefront Distortion Contributions (in rad^2) from the First 21 Zernike Modes of Atmospheric Aberrations and Residual Error As Each Term Is Corrected

Aberration	Contribution	Distortion

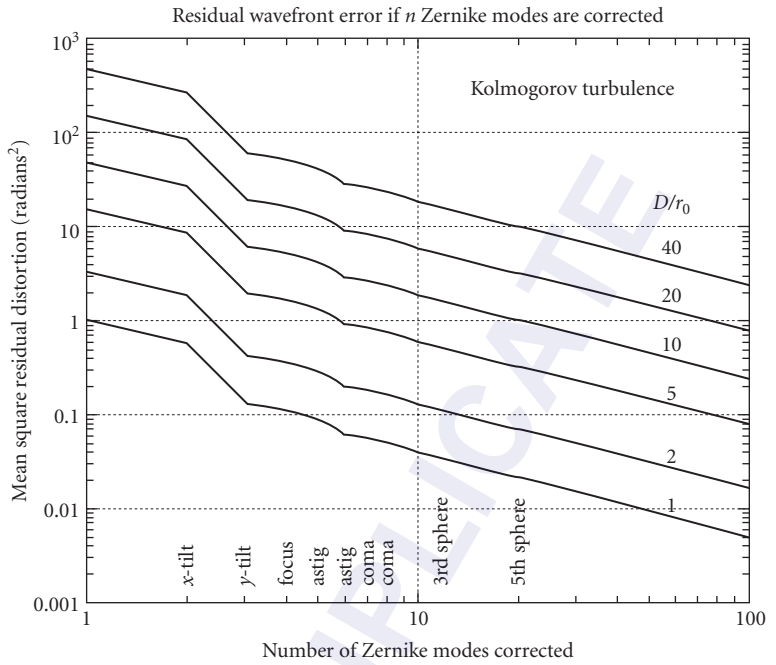

FIGURE 5 Residual mean square phase distortion when n Zernike modes of atmospheric turbulence are corrected for various values of D/r_0.

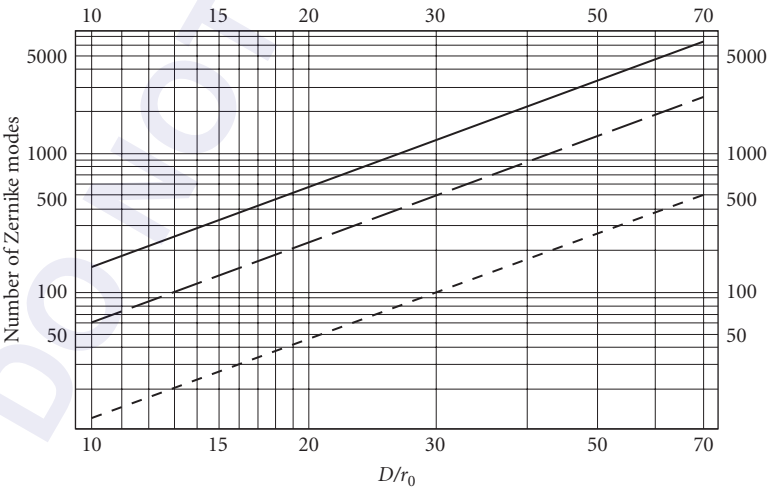

FIGURE 6 Required number of modes to be corrected (roughly the number of actuators or degrees of freedom in the deformable mirror) as a function of D/r_0. Solid curve: $\lambda/15$ image quality; dashed curve: $\lambda/10$ image quality; dotted curve: $\lambda/5$ image quality. In these curves, r_0 is evaluated at the imaging wavelength.

0.8 μm and the telescope aperture is 3.5 m, $D/r_0 = 29$, and more than 1000 modes must be removed to achieve $\lambda/15$ image quality, but only 100 modes need be removed if $\lambda/5$ image quality is sufficient. If r_0 is 60 cm at 1.6 μm and $D = 10$ m, we must remove nearly 400 modes to achieve $\lambda/15$ image quality. For imaging applications, several techniques for postprocessing are well established[28] and allow significant enhancements of images that are obtained in real time with AO. Postprocessing may be justification to allow the relaxation of wavefront quality requirements in an AO system. However, for spectroscopy (or other applications requiring high Strehl ratios in real time), there may be little choice but to design the AO system with the required number of degrees of freedom needed to achieve desired Strehl ratios.

The results in Table 1 can be used to estimate the maximum stroke requirement for the actuators in the deformable mirror. Assuming that tilt will be corrected with a dedicated two-axis beam-steering mirror, the root-mean-square (rms) higher-order distortion is (from Table 1) $0.366(D/r_0)^{5/6}$ rad of phase. A practical rule of thumb is that the deformable mirror surface should be able to correct five times the rms wavefront distortion to get 99 percent of the peak values. Since a reflected wavefront has twice the distortion of the mirror's surface (reducing the stroke requirement by a factor of 2), the maximum actuator stroke requirement for operation becomes

$$\sigma_m(\mu\text{m}) = 0.073\left(\frac{D}{r_0}\right)^{5/6} \tag{21}$$

where σ_m is the maximum actuator stroke in μm, and r_0 is the value of Fried's coherence diameter at a wavelength of 0.5 μm along the line of sight corresponding to the maximum zenith angle of interest. Figure 7 shows the maximum stroke that is required for several aperture diameters as a function of seeing conditions. This figure assumes the outerscale is much larger than the aperture diameter and Kolmogorov turbulence. If the outerscale is of the order of the aperture size or even smaller, the stroke requirements will be reduced.

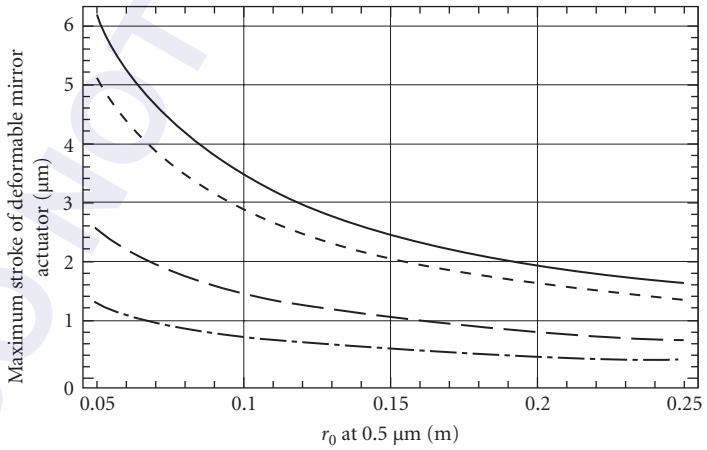

FIGURE 7 Maximum stroke requirement of actuators in the deformable mirror. The curves are for aperture diameters (from top to bottom) of 10, 8, 3.5, and 1.5 m. The value of r_0 is for an observing wavelength of 0.5 μm along the line of sight corresponding to the maximum zenith angle of interest, and the stroke is in micrometers. These curves are independent of wavelength since they do not include any dispersion effects.

Atmospheric Tilt and Its Effect on the Strehl Ratio

Tilt comprises 87 percent of the power in atmospheric turbulence-induced wavefront distortion (see the preceding section). The Strehl ratio of an image that is due to jitter alone is approximated to better than 10 percent by the equation[29, 30]

$$\mathrm{SR}_{\mathrm{tilt}} = \frac{1}{1 + \frac{\pi^2}{2}\left(\frac{\sigma_\theta}{\lambda/D}\right)^2} \tag{22}$$

where σ_θ is the one-axis rms angular jitter. Figure 8 shows how the one-axis rms jitter affects system Strehl ratio. Greenwood and Fried[31] derived bandwidth requirements for AO systems and developed expressions for the variance of full-aperture tilt that is induced by turbulence. The one-axis angular jitter variance (units of angular rad^2) is given by

$$\sigma_{\theta G}^2 = 0.170\left(\frac{\lambda}{D}\right)^2\left(\frac{D}{r_0}\right)^{5/3} \tag{23}$$

where $\sigma_{\theta G}$ is the rms *G*-tilt. *G*-tilt is the average gradient over the wavefront and is well approximated by most centroid trackers. For *Z*-tilt (the direction of the normal of the best-fit plane to the wavefront distortion), the coefficient in Eq. (23) is 0.184. Consequently, a tracking sensor that measures the centroid of the focused image improperly estimates the *Z*-tilt; this has been called centroid anisoplanatism.[30]

Figure 9 shows the dependence of $\sigma_{\theta G}$ on aperture diameter for two seeing conditions, one representative of a continental site and one of a mountaintop island like Mauna Kea, Hawaii.

The effect of atmospheric tilt on the Strehl ratio can be seen by substituting Eq. (23) into Eq. (22). Figure 10 shows that the loss in the Strehl ratio due to jitter alone is significant. For $D/r_0 = 1$, the atmospherically induced jitter limits the Strehl ratio to 0.54. It is most important to effectively control image motion that is created by full-aperture atmospheric tilt.

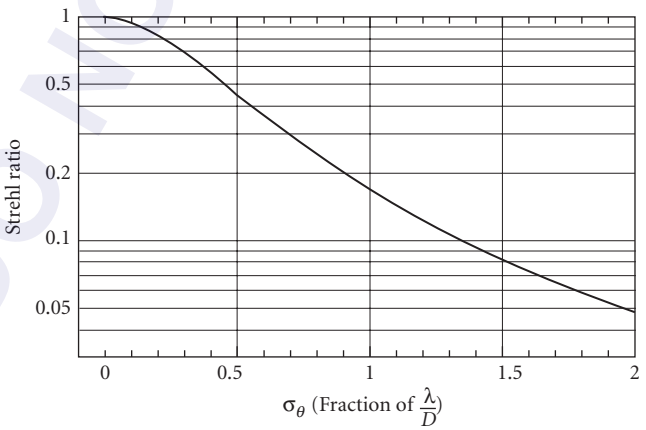

FIGURE 8 Strehl ratio versus one-axis rms jitter expressed as a fraction of λ/D.

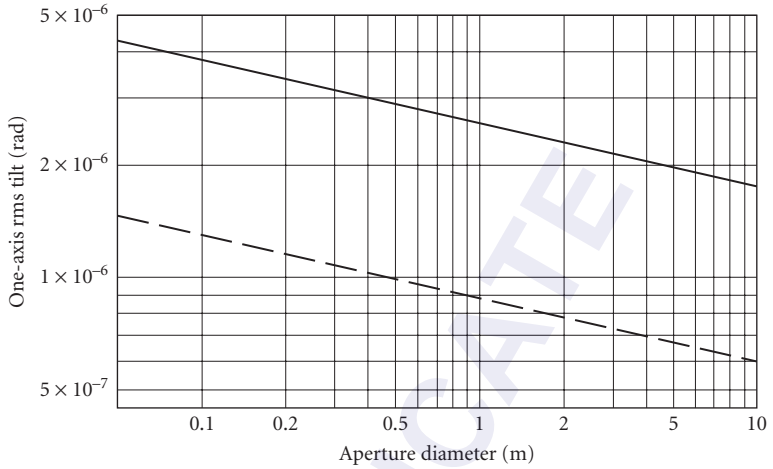

FIGURE 9 One-axis rms tilt for atmospheric turbulence. The upper line corresponds to an r_0 of 5 cm and the lower curve corresponds to an r_0 of 18 cm, both referenced to 0.5 μm and zenith. The value of full-aperture tilt is independent of wavelength for a given seeing condition.

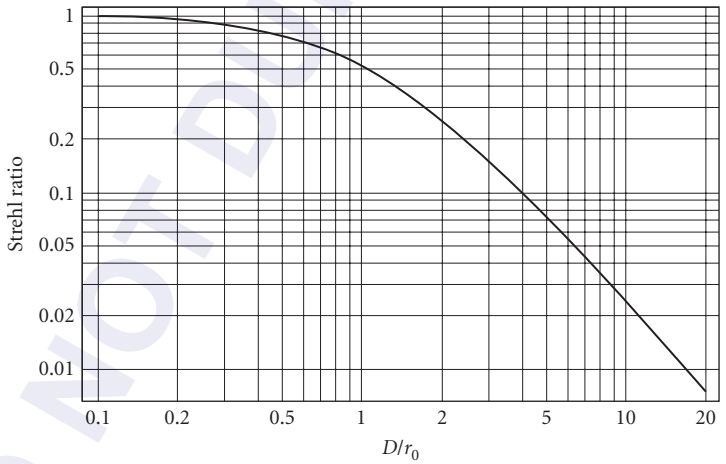

FIGURE 10 The effect of turbulence-induced jitter on system Strehl ratio.

Tracking: Bandwidth and Steering Mirror Stroke Requirements

Tyler[32] has considered the problem of required tracking bandwidth by computing the tilt power spectrum and determining the error rejection achieved by a steering mirror under control of an RC-type servo. He considers both *G*-tilt and *Z*-tilt. Temporal fluctuations are derived by translating "frozen-turbulence" realizations past the telescope's aperture. The hypothesis is that the internal structure of the turbulence changes more slowly than its mass transport by the wind (but this assumption may not suffice for today's giant-aperture telescopes). The results for power spectra are

in integral form, requiring numerical evaluation. Sasiela[33] uses Mellin transforms to derive a solution in terms of a power series of ratios of gamma functions. The asymptotic limits for high and low frequencies are, however, tractable in a form that is easily evaluated. We consider here the results for only *G*-tilt since that is the most likely implementation in a real system (approximated by a centroid tracker). The low-frequency limit for *G*-tilt is

$$\lim_{f\to 0} F_{\phi G}(f) = 0.804 D^{-1/3} \sec\psi\, f^{-2/3} \int_0^\infty C_n^2(h)[v(h)/D]^{-1/3} dh \tag{24}$$

and the high-frequency limit is

$$\lim_{f\to \infty} F_{\phi G}(f) = 0.0110 D^{-1/3} \sec\psi\, f^{-11/3} \int_0^\infty C_n^2(h)[v(h)/D]^{8/3} dh \tag{25}$$

where $F_{\phi G}(f)$ is the one-axis *G*-tilt power spectrum in rad^2/Hz, D is the aperture diameter, ψ is the zenith angle, and $v(h)$ is the transverse wind component along a vertical profile. Note that the tilt spectrum goes as $f^{-2/3}$ at low frequencies and as $f^{-11/3}$ at high frequencies.

The disturbances described in Eqs. (24) and (25) can be partially corrected with a fast-steering mirror having an RC filter response, $H(f, f_c)$, of the form

$$H(f, f_c) = \frac{1}{1 + i\dfrac{f}{f_c}} \tag{26}$$

where f_c represents a characteristic frequency [usually the 3 decibel (dB) response]. The uncorrected power in the residual errors can be computed from control theory using the relation

$$\sigma_{\theta G}^2 = \int_0^\infty |1 - H(f, f_c)|^2 F_{\phi G}(f) df \tag{27}$$

where $F_{\phi G}(f)$ is the power spectrum (rad^2/Hz) of *G*-tilt induced by optical turbulence.

For a steering mirror response function given by Eq. (26), the *G*-tilt variance is given by

$$\sigma_{\theta G}^2 = \int_0^\infty \frac{(f/f_{3\text{dB}})^2}{1 + (f/f_{3\text{dB}})^2} F_{\phi G}(f) df \tag{28}$$

In the limit of a small (zero) servo bandwidth, this equation represents the tilt that is induced by atmospheric turbulence. Expressing the variance of the jitter in terms of the diffraction angle (λ/D) results in the same expression as Eq. (23).

What does the servo bandwidth need to be? Tyler defines a *G*-tilt tracking frequency characteristic of the atmospheric turbulence profile and wind velocity as

$$f_{T_G} = 0.331 D^{-1/6} \lambda^{-1} \sec^{1/2}\psi \left[\int_0^\infty C_n^2(h) v^2(h) dh\right]^{1/2} \tag{29}$$

such that the variance of the tilt can be expressed as

$$\sigma_\theta^2 = \left(\frac{f_{T_G}}{f_{3\text{dB}}}\right)^2 \left(\frac{\lambda}{D}\right)^2 \tag{30}$$

Three wind velocity profiles are shown in Fig. 11. The analytical model of Bufton[34] is given by

$$v_B(h) = 5 + 37 e^{-(h-12)^2/25} \tag{31}$$

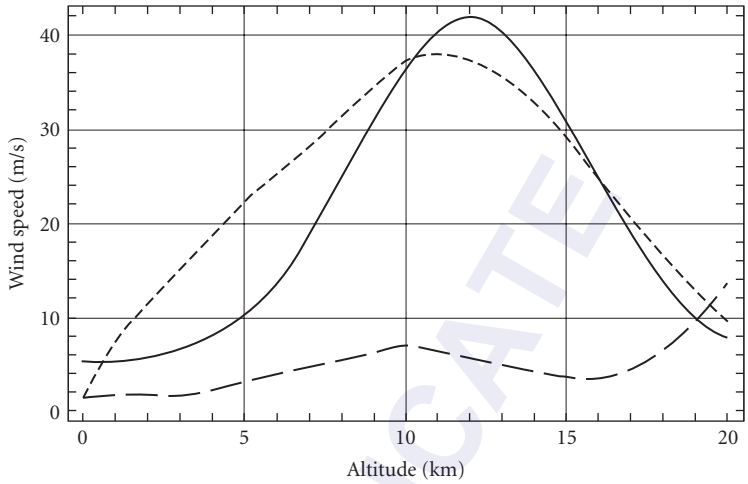

FIGURE 11 Wind profiles. The solid curve is an analytical model by Bufton. The doted and dashed curves are based on two decades of rawinsonde measurements at Albuquerque, New Mexico, and are known as SOR winter and SOR summer models, respectively. These two models show clearly the absence of a jet stream in the summer months.

where h is the height above ground in km and v_B the wind speed in m/s. The other two curves in Fig. 11 are based on measurements made with National Weather Service sounding balloons launched in Albuquerque, New Mexico. They show a marked contrast between winter and summer months and the effect of the jet stream.

When the 3-dB closed-loop tracking servo frequency equals the G-tilt tracking frequency (the Tyler frequency), the one-axis rms jitter is equal to λ/D. The track bandwidth needs to be four times the Tyler frequency in order for $\sigma_{\theta G}$ to be $1/4(\lambda/D)$, a condition that provides a Strehl ratio due to tilt of greater than 80 percent. Figure 12 shows the required 3-dB tracking bandwidths to

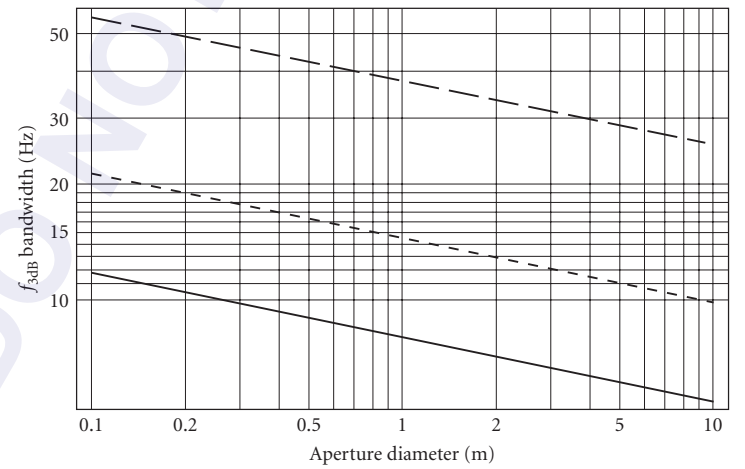

FIGURE 12 Required 3-dB tracking bandwidth to achieve Strehl ratio of 0.82. The dashed curve is for the SOR winter wind and $HV_{5/7}$ profiles; the dotted curve is for the Mauna Kea average C_n^2 profile and Bufton wind profile; the solid curve is for the SOR summer wind and $HV_{5/7}$ C_n^2 profiles. All three curves are for 0.5 μm wavelength.

meet this criterion for three combinations of wind and C_n^2 profiles as a function of aperture diameter. Other combinations can be computed easily by using Eq. (29) and the wind profiles that are shown in Fig. 11.

The one-axis rms tilt that is induced by the atmosphere is given by Eq. (23). When specifying the maximum excursion of a tilt mirror, the mirror should be able to move five times $\sigma_{\theta G}$ in order to accommodate over 99 percent of the tilt spectrum. We also need to account for the optical magnification between the tilt mirror and the primary mirror of the telescope. If, for instance, the tilt mirror has a diameter of 10 cm, the telescope aperture is 10 m, and r_0 is 18 cm (dashed curve in Fig. 9), the required maximum stroke of the tilt mirror is 0.6 μrad (from Fig. 9) times 50 ($5\sigma_{\theta G} \times$ optical magnification of 10) or 30 μrad.

Higher-Order Phase Fluctuations and Bandwidth Requirements

Time delays that are caused by detector readout and data processing create errors in the phase correction that is applied to the deformable mirror—the correction being applied is relevant to an error that is measured at an earlier time. The control system concepts discussed in the preceding two sections are also relevant to higher-order errors. The residual errors can be computed knowing the closed-loop servo response, $H(f, f_c)$, where f_c represents a characteristic frequency (usually the 3-dB response) and the disturbance. The uncorrected power is similar to Eq. (27) and is given by

$$\sigma_r^2 = \int_0^\infty |1 - H(f, f_c)|^2 F_\phi(f) df \tag{32}$$

where $F_\phi(f)$ is the power spectrum (rad^2/Hz) of the phase distortions that are induced by optical turbulence. At high frequencies, Greenwood[35] showed that $F_\phi(f)$ is proportional to $f^{-8/3}$ and is given by

$$\lim_{f\to\infty} F_\phi(f) = 0.0326k^2 f^{-8/3} \int_0^\infty C_n^2(z) v^{5/3}(z) dz \tag{33}$$

where $k = 2\pi/\lambda$, f is the frequency in Hertz, and $v(z)$ is the transverse component of the wind profile. The closed-loop response of the AO servo can be modeled as a conventional resistorcapacitor (RC) filter making

$$H(f, f_c) = \frac{1}{1 + i\dfrac{f}{f_c}} \tag{34}$$

the characteristic frequency becomes

$$f_c = \left[0.102 \left(\frac{k}{\sigma_r} \right)^2 \int_0^\infty C_n^2(z) v^{5/3}(z) dz \right]^{3/5} \tag{35}$$

Figure 11 shows three wind profiles, one analytical and two based on measured data. For the $HV_{5/7}C_n^2$ profile and the SOR summer and winter wind models and $\sigma_r = 0.2\pi$, then f_c = 23 and 95 Hz, respectively.

The value of f_c for which $\sigma_r = 1$ is known as the Greenwood frequency and is given explicitly as

$$f_G = \frac{2.31}{\lambda^{6/5}} \left[\int_0^L C_n^2(z) v(z)^{5/3} dz \right]^{3/5} \tag{36}$$

Tyler[36] shows that the mean square residual phase in an AO control system having a –3-dB closed-loop bandwidth of $f_{3\text{dB}}$Hz is

$$\sigma^2_{\phi_{\text{servo}}} = (f_G / f_{3\text{dB}})^{5/3} \tag{37}$$

In a real system, this means that the closed-loop servo bandwidth should be several times the Greenwood frequency in order to "stay up with the turbulence" and keep the residual wavefront error to acceptable levels. Note that the Greenwood frequency scales as $\lambda^{-6/5}$ (the inverse of r_0 and θ_0 scaling) and that zenith angle scaling depends on the specific azimuthal wind direction.

Anisoplanatism

Consider two point sources in the sky (a binary star) and an instrument to measure the wavefront distortion from each. As the angular separation between the sources increases, the wavefront distortions from each source become decorrelated. The *isoplanatic angle* is that angle for which the difference in mean square wavefront distortion is 1 rad^2. Fried[37] defined the isoplanatic angle, θ_0, as

$$\theta_0 = 0.058 \lambda^{6/5} (\sec \psi)^{-8/5} \left[\int_0^\infty C_n^2(h) h^{5/3} dh \right]^{-3/5} \tag{38}$$

where the integral is along a vertical path through the atmospheric turbulence. Note that θ_0 scales as $\lambda^{6/5}$ (the same as r_0), but as $(\cos\psi)^{8/5}$ with zenith angle. Fried has shown that if a very large diameter ($D/r_0 >> 1$) imaging system viewing along one path is corrected by an AO system, the optical transfer function of the system viewing along a different path separated by an angle θ is reduced by a factor $\exp[-(\theta/\theta_0)^{5/3}]$. (For smaller diameters, there is not so much reduction.) The numerical value of the isoplanatic angle for zenith viewing at a wavelength of 0.5 μm is of the order of a few arc seconds for most sites. The isoplanatic angle is strongly influenced by high-altitude turbulence (note the $h^{5/3}$ weighting in the preceding definition). The small value of the isoplanatic angle can have very significant consequences for AO by limiting the number of natural stars suitable for use as reference beacons and by limiting the corrected field of view to only a few arc seconds.

Turbulence on Imaging and Spectroscopy

The optical transfer function (OTF) is one of the most useful performance measures for the design and analysis of AO imaging systems. The OTF is the Fourier transform of the optical system's point spread function. For an aberration-free circular aperture, the OTF for a spatial frequency **f** is well known[38] to be

$$\mathbf{H}_0(\mathbf{f}) = \frac{2}{\pi} \left[\arccos\left(\frac{\mathbf{f}\bar{\lambda}F}{D} \right) - \frac{\mathbf{f}\bar{\lambda}F}{D} \sqrt{1 - \left(\frac{\mathbf{f}\bar{\lambda}F}{D} \right)^2} \right] \tag{39}$$

where D is the aperture diameter, F is the focal length of the system, and $\bar{\lambda}$ is the average imaging wavelength. Notice that the cutoff frequency (where the OTF of an aberration-free system reaches 0) is equal to $D/\bar{\lambda}F$.

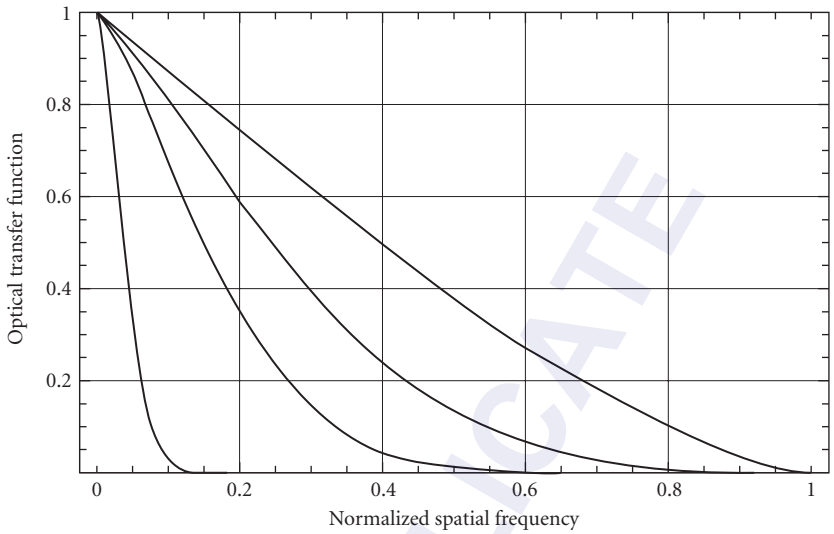

FIGURE 13 The OTF due to the atmosphere. Curves are shown for (top to bottom) $D/r_0 = 0.1,\ 1,\ 2,$ and 10. The cutoff frequency is defined when the normalized spatial frequency is 1.0 and has the value $D/\lambda F$, where F is the focal length of the telescope and D is its diameter.

Fried[26] showed that for a long-exposure image, the OTF is equal to $\mathbf{H}_0(\mathbf{f})$ times the long-exposure OTF due to turbulence, given by

$$\mathbf{H}_{\mathrm{LE}}(\mathbf{f}) = \exp\left\{-\frac{1}{2}D\left(\bar{\lambda}F\mathbf{f}\right)\right\} = \exp\left\{-\frac{1}{2}\,6.88\left(\frac{\bar{\lambda}F\mathbf{f}}{r_0}\right)^{5/3}\right\} \tag{40}$$

where D is the wave structure function and where we have substituted the phase structure function that is given by Eq. (14). Figure 13 shows the OTF along a radial direction for a circular aperture degraded by atmospheric turbulence for values of D/r_0 ranging from 0.1 to 10. Notice the precipitous drop in the OTF for values of $D/r_0 > 2$. The objective of an AO system is, of course, to restore the high spatial frequencies that are lost due to turbulence.

Spectroscopy is a very important aspect of observational astronomy and is a major contributor to scientific results. The goals of AO for spectroscopy are somewhat different than for imaging. For imaging, it is important to stabilize the corrected point spread function in time and space so that postprocessing can be performed. For spectroscopy, high Strehl ratios are desired in real time. The goal is flux concentration and getting the largest percentage of the power collected by the telescope through the slit of the spectrometer. A 4-m telescope is typically limited to a resolving power of $R \sim$ 50,000. Various schemes have been tried to improve resolution, but the instruments become large and complex.

However, by using AO, the corrected image size decreases linearly with aperture size, and very high resolution spectrographs are, in principle, possible without unreasonable-sized gratings. A resolution of 700,000 was demonstrated on a 1.5-m telescope corrected with AO.[39] Tyler and Ellerbroek[40] have estimated the sky coverage at the galactic pole for the Gemini North 8-m telescope at Mauna Kea as a function of the slit power coupling percentage for a 0.1-arcsec slit width at J, H, and K bands in the near IR. Their results are shown in Fig. 14 for laser guide star (top curves) and natural guide star (lower curves) operation.

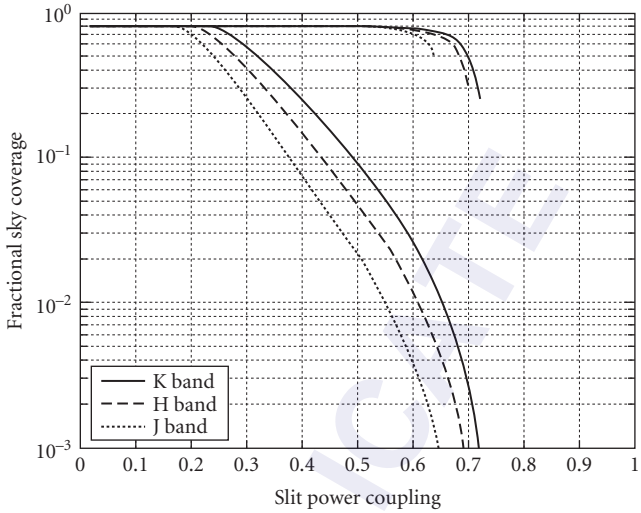

FIGURE 14 Spectrometer slit power sky coverage at Gemini North using NGS (lower curves) and LGS adaptive optics. See text for details.

The higher-order AO system that was analyzed[40] for the results in Fig. 14 employs a 12-by-12 subaperture Shack-Hartmann sensor for both natural guide star (NGS) and laser guide star (LGS) sensing. The spectral region for NGS is from 0.4 to 0.8 μm and the 0.589-μm LGS is produced by a 15-watt laser to excite mesospheric sodium at an altitude of 90 km. The wavefront sensor charge-coupled device (CCD) array has 3 electrons of read noise per pixel per sample and the deformable mirror is optically conjugate to a 6.5-km range from the telescope. The tracking is done with a 2-by-2-pixel sensor operating at J + H bands with 8 electrons of read noise. Ge et al.[41] have reported similar results with between 40 and 60 percent coupling for LGSs and nearly 70 percent coupling for NGSs brighter than 13th magnitude.

5.5 AO HARDWARE AND SOFTWARE IMPLEMENTATION

Tracking

The wavefront tilt averaged over the full aperture of the telescope accounts for 87 percent of the power in turbulence-induced wavefront aberrations. Full-aperture tilt has the effect of blurring images and reducing the Strehl ratio of point sources. The Strehl ratio due to tilt alone is given by[29, 30]

$$\mathrm{SR}_{\mathrm{tilt}} = \frac{1}{1 + \dfrac{\pi^2}{2}\left(\dfrac{\sigma_\theta}{\bar{\lambda}/D}\right)^2} \tag{41}$$

where σ_θ is the one-axis rms full-aperture tilt error, $\bar{\lambda}$ is the imaging wavelength, and D is the aperture diameter. Figure 8 is a plot showing how the Strehl ratio drops as jitter increases. This figure

shows that in order to maintain a Strehl ratio of 0.8 due to tilt alone, the image must be stabilized to better than $0.25\lambda/D$. For an 8-m telescope imaging at 1.2 μm, $0.25\lambda/D$ is 7.75 milliarcsec.

Fortunately, there are several factors that make tilt sensing more feasible than higher-order sensing for faint guide stars that are available in any field. First, we can use the entire aperture, a light gain over higher-order sensing of roughly $(D/r_0)^2$. Second, the image of the guide star will be compensated well enough that its central core will have a width of approximately λ/D rather than λ/r_0 (assuming that tracking and imaging are near the same wavelength). Third, we can track with only four discrete detectors, making it possible to use photon-counting avalanche photodiodes (or other photon-counting sensors), which have essentially no noise at the short integration times required (~10 ms). Fourth, Tyler[42] has shown that the fundamental frequency that determines the tracking bandwidth is considerably less (by as much as a factor of 9) than the Greenwood frequency, which is appropriate for setting the servo bandwidth of the deformable mirror control system. One must, however, include the vibrational disturbances that are induced into the line of sight by high-frequency jitter in the telescope mount, and it is dangerous to construct a simple rule of thumb comparing tracking bandwidth with higher-order bandwidth requirements.

The rms track error is given approximately by the expression

$$\sigma_\theta = 0.58 \frac{\text{angular image size}}{\text{SNR}_V} \tag{42}$$

where SNR_V is the voltage signal-to-noise ratio in the sensor. An error of $\sigma_\theta = \lambda/4D$ will provide a Strehl ratio of approximately 0.76. If the angular image size is λ/D, the SNR_V needs to be only 2. Since we can count on essentially shot-noise-limited performance, in theory we need only four detected photoelectrons per measurement under ideal conditions (in the real world, we should plan on needing twice this number). Further averaging will occur in the control system servo.

With these assumptions, it is straightforward to compute the required guide star brightness for tracking. Results are shown in Fig. 15 for 1.5-, 3.5-, 8-, and 10-m telescope apertures, assuming a 500-Hz sample rate and twice-diffraction-limited AO compensation of higher-order errors of the guide star at the track wavelength. These results are not inconsistent with high-performance tracking

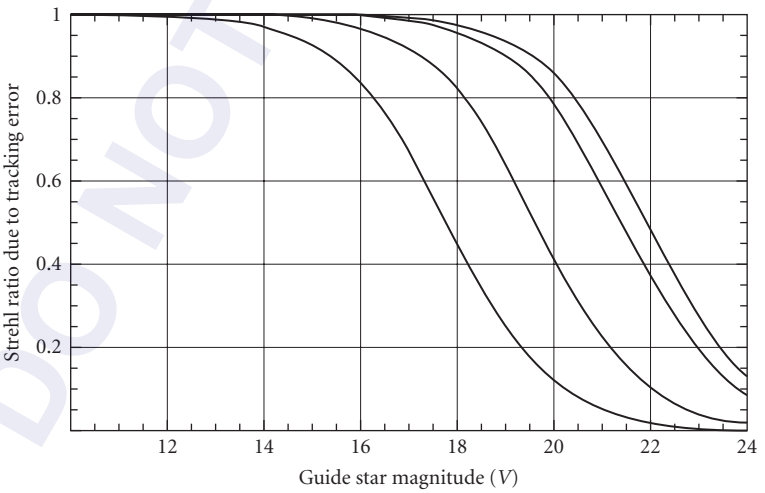

FIGURE 15 Strehl ratio due to tracking jilter. The curves are (top to bottom) for 10-, 8-, 3.5-, and 1.5-m telescopes. The assumptions are photon shot-noise-limited sensors, 25 percent throughput to the track sensor, 200-nm optical bandwidth, and 500-Hz sample rate. The track wavelength is 0.9 μm.

systems already in the field, such as the HRCam system that has been so successful on the Canada-France-Hawaii Telescope at Mauna Kea.[43]

As mentioned previously, the track sensor can consist of just a few detectors implemented in a quadrant-cell algorithm or with a two-dimensional CCD or IR focal plane array. A popular approach for the quad-cell sensor is to use an optical pyramid that splits light in four directions to be detected by individual detectors. Avalanche photodiode modules equipped with photon counter electronics have been used very successfully for this application. These devices operate with such low dark current that they are essentially noise-free and performance is limited by shot noise in the signal and quantum efficiency.

For track sensors using focal plane arrays, different algorithms can be used depending on the tracked object. For unresolved objects, centroid algorithms are generally used. For resolved objects (e.g., planets, moons, asteroids, etc.), correlation algorithms may be more effective. In one instance at the Starfire Optical Range, the highest-quality images of Saturn were made by using an LGS to correct higher-order aberrations and a correlation tracker operating on the rings of the planet provided tilt correction to a small fraction of λ/D.[44]

Higher-Order Wavefront Sensing and Reconstruction: Shack-Hartmann Technique

Higher-order wavefront sensors determine the *gradient,* or slope, of the wavefront measured over subapertures of the entrance pupil, and a dedicated controller maps the slope measurements into deformable mirror actuator voltages. The traditional approach to AO has been to perform these functions in physically different pieces of hardware—the wavefront sensor, the wavefront reconstructor and deformable mirror controller, and the deformable mirror. Over the years, several optical techniques (Shack-Hartmann, various forms of interferometry, curvature sensing, phase diversity, and many others) have been invented for wavefront sensing. A large number of wavefront reconstruction techniques, geometries, and predetermined or even adaptive algorithms have also been developed. A description of all these techniques is beyond the scope of this document, but the interested reader should review work by Wallner,[45] Fried,[46] Wild,[47] and Ellerbroek and Rhoadarmer.[48]

A wavefront sensor configuration in wide use is the Shack-Hartmann sensor.[49] We will use it here to discuss wavefront sensing and reconstruction principles. Figure 16 illustrates the concept. An array of lenslets is positioned at a relayed image of the exit pupil of the telescope. Each lenslet represents a subaperture—in the ideal case, sized to be less than or equal to r_0 at the sensing wavelength.

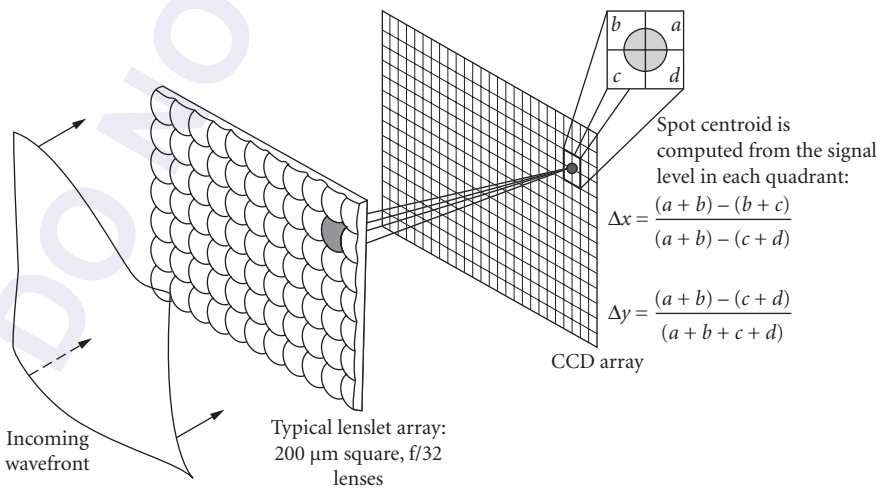

FIGURE 16 Geometry of a Shack-Hartmann sensor.

For subapertures that are roughly r_0 in size, the wavefront that is sampled by the subaperture is essentially flat but tilted, and the objective of the sensor is to measure the value of the subaperture tilt. Light collected by each lenslet is focused to a spot on a two-dimensional detector array. By tracking the position of the focused spot, we can determine the *X*- and *Y*-tilt of the wavefront averaged over the subaperture defined by the lenslet. By arranging the centers of the lenslets on a two-dimensional grid, we generate gradient values at points in the centers of the lenslets. Many other geometries are possible resulting in a large variety of patterns of gradient measurements.

Figure 17 is a small-scale example from which we can illustrate the basic equations. In this example, we want to estimate the phase at 16 points on the corners of the subapertures (the Fried geometry of the Shack-Hartmann sensor), and to designate these phases as $\phi_1, \phi_2, \phi_3, \ldots, \phi_{16}$, using wavefront gradient measurements that are averaged in the centers of the subapertures, $S_{1x}, S_{1y}, S_{2x}, S_{2y}, \ldots, S_{9x}, S_{9y}$. It can be seen by inspection that

$$S_{1x} = \frac{(\phi_2 + \phi_6) - (\phi_1 + \phi_5)}{2d}$$

$$S_{1y} = \frac{(\phi_5 + \phi_6) - (\phi_1 + \phi_2)}{2d}$$

$$\cdots$$

$$S_{9x} = \frac{(\phi_{16} + \phi_{12}) - (\phi_{11} + \phi_{15})}{2d}$$

$$S_{9y} = \frac{(\phi_{15} + \phi_{16}) - (\phi_{11} + \phi_{12})}{2d}$$

This system of equations can be written in the form of a matrix as

$$\begin{bmatrix} S_{1x} \\ S_{2x} \\ S_{3x} \\ S_{5x} \\ S_{6x} \\ S_{7x} \\ S_{8x} \\ S_{9x} \\ S_{1y} \\ S_{2y} \\ S_{3y} \\ S_{4y} \\ S_{5y} \\ S_{6y} \\ S_{7y} \\ S_{8y} \\ S_{9y} \end{bmatrix} = \frac{1}{2d} \begin{bmatrix} -1 & 1 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 1 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & -1 & 1 \\ -1 & -1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & -1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & -1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & -1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & -1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & -1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & -1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & -1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & -1 & 0 & 0 & 1 & 1 \end{bmatrix} \begin{bmatrix} \phi_1 \\ \phi_2 \\ \phi_3 \\ \phi_4 \\ \phi_5 \\ \phi_6 \\ \phi_7 \\ \phi_8 \\ \phi_9 \\ \phi_{10} \\ \phi_{11} \\ \phi_{12} \\ \phi_{13} \\ \phi_{14} \\ \phi_{15} \\ \phi_{16} \end{bmatrix} \tag{43}$$

These equations express gradients in terms of phases,

$$\mathbf{S} = H\Phi \tag{44}$$

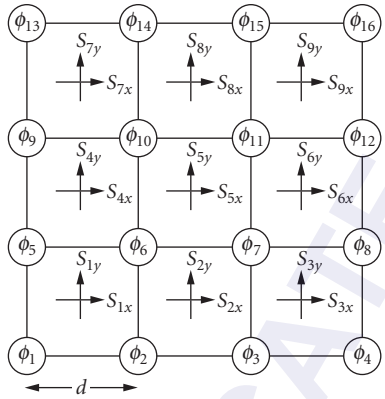

FIGURE 17 A simple Shack-Hartmann sensor in the Fried geometry.

where $\mathbf{\Phi}$ is a vector of the desired phases, H is the measurement matrix, and $\mathbf{S}$ is a vector of the measured slopes.

However, in order to control the actuators in the deformable mirror, we need a control matrix, M, that maps subaperture slope measurements into deformable mirror actuator control commands. In essence, we need to invert Eq. (44) to make it of the form

$$\mathbf{\Phi} = M\mathbf{S} \tag{45}$$

where M is the desired control matrix. The most straightforward method to derive the control matrix, M, is to minimize the difference in the measured wavefront slopes and the actual slopes on the deformable mirror. We can do this by a maximum a posteriori method accounting for actuator influence functions in the deformable mirror, errors in the wavefront slope measurements due to noise, and statistics of the atmospheric phase distortions. If we do not account for any effects except the geometry of the actuators and the wavefront subapertures, the solution is a least-squares estimate (the most widely implemented to date). It has the form

$$\mathbf{\Phi} = [H^T H]^{-1} H^T \mathbf{S} \tag{46}$$

and is the *pseudoinverse* of H. (For our simple geometry shown in Fig. 17, the pseudoinverse solution is shown in Fig. 18.) Even this simple form is often problematical since the matrix $[H^T H]$ is often singular or acts as a singular matrix from computational roundoff error and cannot be inverted.

However, in these instances, singular-value-decomposition (SVD) algorithms can be used to directly compute a solution for the inverse of H. Singular value decomposition decomposes an $m \times n$ matrix into the product of an $m \times n$ matrix (U), an $n \times n$ diagonal matrix (D), and an $n \times n$ square matrix (V). So that

$$H = UDV^T \tag{47}$$

and H^{-1} is then

$$H^{-1} = VD^{-1}U^T \tag{48}$$

FIGURE 18 Least-squares reconstructor matrix for the geometry shown in Fig. 17.

If H is singular, some of the diagonal elements of D will be zero and D^{-1} cannot be defined. However, this method allows us to obtain the closest possible solution in a least-squares sense by zeroing the elements in the diagonal of D^{-1} that come from zero elements in the matrix D. We can arrive at a solution that discards only those equations that generated the problem in the first place. In addition to straightforward SVD, more general techniques have been proposed involving iterative solutions for the phases.[46, 50, 51]

In addition, several other "tricks" have been developed to alleviate the singularity problem. For instance, piston error is normally ignored, and this contributes to the singularity since there are then an infinite number of solutions that could give the same slope measurements. Adding a row of 1s to the measurement matrix H and setting a corresponding value of 0 in the slope vector for piston allows inversion.[52]

In the implementation of Shack-Hartmann sensors, a reference wavefront must be provided to calibrate imperfections in the lenslet array and distortions that are introduced by any relay optics to match the pitch of the lenslet array to the pitch of the pixels in the detector array. It is general practice to inject a "perfect" plane wave into the optical train just in front of the lenslet array and to record the positions of all of the Shack-Hartmann spots. During normal operation, the wavefront sensor gradient processor then computes the difference between the spot position of the residual error wavefront and the reference wavefront.

Laser Beacons (Laser Guide Stars)

Adaptive optical systems require a beacon or a source of light to sense turbulence-induced wave distortions. From an anisoplanatic point of view, the ideal beacon is the object being imaged. However, most objects of interest to astronomers are not bright enough to serve as beacons.

It is possible to create artificial beacons (also referred to as synthetic beacons) that are suitable for wavefront sensing with lasers as first demonstrated by Fugate et al.[53] and Primmerman et al.[54] Laser beacons can be created by Rayleigh scattering of focused beams at ranges between 15 and 20 km or by resonant scattering from a layer of sodium atoms in the mesosphere at an altitude of between 90 and 100 km. Examples of Rayleigh beacon AO systems are described by Fugate et al.[55] for the SOR 1.5-m telescope and by Thompson et al.[56] for the Mt. Wilson 100-in telescope; examples of sodium beacon AO systems are described by Olivier et al.[57] for the Lick 3-m Shane telescope and by Butler et al.[58] for the 3.5-m Calar Alto telescope. Researchers at the W. M. Keck Observatory at Mauna Kea are in the process of installing a sodium dye laser to augment their NGS AO system on Keck II.

The laser beacon concept was first conceived and demonstrated within the U.S. Department of Defense during the early 1980s (see Fugate[59] for a short summary of the history). The information developed under this program was not declassified until May 1991, but much of the early work was published subsequently.[60] The laser beacon concept was first published openly by Foy and Labeyrie[61] in 1985 and has been of interest in the astronomy community since.

Even though laser beacons solve a significant problem, they also introduce new problems and have two significant limitations compared with bright NGSs. The new problems include potential light contamination in science cameras and tracking sensors, cost of ownership and operation, and observing complexities that are associated with propagating lasers through the navigable airspace and near-earth orbital space, the home of thousands of space payloads. The technical limitations are that laser beacons provide no information on full-aperture tilt, and that a "cone effect" results from the finite altitude of the beacon, which contributes an additional error called focus (or focal) anisoplanatism. Focus anisoplanatism can be partially alleviated by using a higher-altitude beacon, such as a sodium guide star, as discussed in the following.

Focus Anisoplanatism The mean square wavefront error due to the finite altitude of the laser beacon is given by

$$\sigma_{\mathrm{FA}}^2 = (D/d_0)^{5/3} \tag{49}$$

where d_0 is an effective aperture size corrected by the laser beacon that depends on the height of the laser beacon, the C_n^2 profile, the zenith angle, and the imaging wavelength. This parameter was defined by Fried and Belsher.[62] Tyler[63] developed a method to rapidly evaluate d_0 for arbitrary C_n^2 profiles given by the expression

$$d_0 = \lambda^{6/5} \cos^{3/5}(\psi) \left[\int C_n^2(z) F(z/H) dz \right]^{-3/5} \tag{50}$$

where H is the vertical height of the laser beacon and the function $F(z/H)$ is given by

$$\begin{aligned} F(z/H) &= 16.71371210(1.032421640 - 0.8977579487\boldsymbol{u}) \\ &\times[1+(1-z/H)^{5/3}] - 2.168285442 \\ &\times\left\{\frac{6}{11}\,{}_2F_1\left[-\frac{11}{6},-\frac{5}{6};2;\left(1-\frac{z}{H}\right)^2\right]\right. \\ &-\frac{6}{11}(z/H)^{5/3} - u\frac{10}{11}\left(1-\frac{z}{H}\right) \\ &\left.\times\,{}_2F_1\left[-\frac{11}{6},\frac{1}{6};3;\left(1-\frac{z}{H}\right)^2\right]\right\} \end{aligned} \tag{51}$$

for $z < H$ and

$$F(z/H) = 16.71371210(1.032421640 - 0.8977579487\boldsymbol{u}) \tag{52}$$

for $z > H$. In these equations, z is the vertical height above the ground, H is the height of the laser beacon, u is a parameter that is equal to zero when only piston is removed and that is equal to unity when piston and tilt are removed, and ${}_2F_1[a, b; c; z]$ is the hypergeometric function.

Equations (50) and (51) are easily evaluated on a programmable calculator or a personal computer. They are very useful for quickly establishing the expected performance of laser beacons for a particular C_n^2 profile, imaging wavelength, and zenith angle view. Figures 19 and 20 are plots of d_0 representing the best and average seeing at Mauna Kea and a site described by the HV_{57} turbulence profile. Since d_0 scales as $\lambda^{6/5}$, values at 2.2 μm are 5.9 times larger, as shown in the plots.

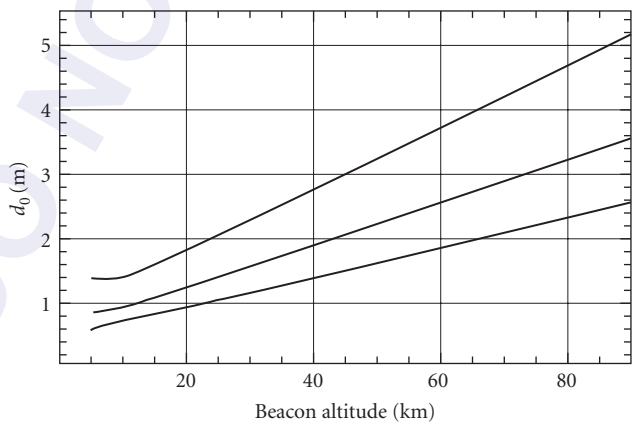

FIGURE 19 Values of d_0 versus laser beacon altitude for zenith imaging at 0.5 μm and (top to bottom) best Mauna Kea seeing, average Mauna Kea seeing, and the $HV_{5/7}$ turbulence profile.

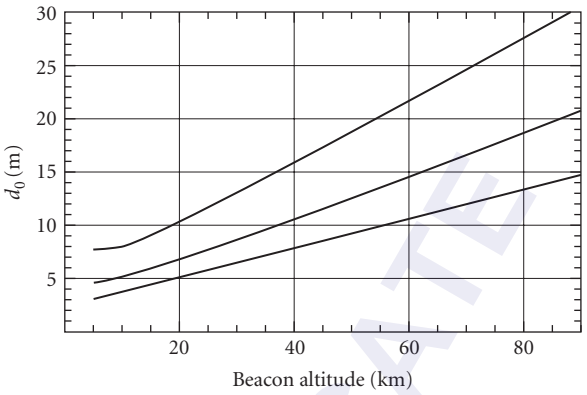

FIGURE 20 Values of d_0 versus laser beacon altitude for zenith imaging at 2.2 μm and (top to bottom) best Mauna Kea seeing, average Mauna Kea seeing, and the $HV_{5/7}$ turbulence profile.

It is straightforward to compute the Strehl ratio due only to focus anisoplanatism using the approximation $SR = e^{-\sigma_{FA}}$, where $\sigma_{FA}^2 = (D/d_0)^{5/3}$. There are many possible combinations of aperture sizes, imaging wavelength, and zenith angle, but to illustrate the effect for 3.5- and 10-m apertures, Figs. 21 and 22 show the focus anisoplanatism Strehl ratio as a function of wavelength for 15- and 90-km beacon altitudes and for three seeing conditions. As these plots show, the effectiveness of laser beacons is very sensitive to the aperture diameter, seeing conditions, and beacon altitude. A single Rayleigh beacon at an altitude of 15 km is essentially useless on a 10-m aperture in $HV_{5/7}$ seeing, but it is probably useful at a Mauna Kea—like site. One needs to keep in mind that the curves in Figs. 21 and 22 are the upper limits of performance since other effects will further reduce the Strehl ratio.

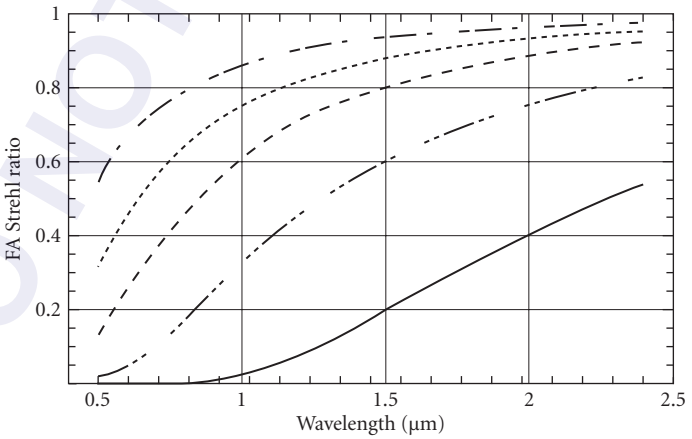

FIGURE 21 The telescope Strehl ratio due to focus anisoplanatism only. Conditions are for a 3.5-m telescope viewing at 30° zenith angle. Curves are (top to bottom): best seeing at Mauna Kea, 90-km beacon; average seeing at Mauna Kea, 90-km beacon; $HV_{5/7}$, 90-km beacon; best seeing at Mauna Kea, 15-km beacon; and $HV_{5/7}$, 15-km beacon.

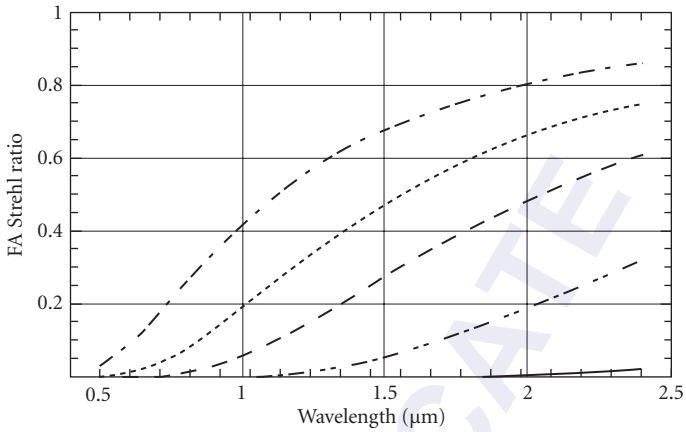

FIGURE 22 The telescope Strehl ratio due to focus anisoplanatism only. Conditions are for a 10.0-m telescope viewing at 30° zenith angle. Curves are (top to bottom): best seeing at Mauna Kea, 90-km beacon; average seeing at Mauna Kea, 90-km beacon; $HV_{5/7}$, 90-km beacon; best seeing at Mauna Kea, 15-km beacon; and $HV_{5/7}$, 15-km beacon.

Generation of Rayleigh Laser Beacons For Rayleigh scattering, the number of photo-detected electrons (pdes) per subaperture in the wavefront sensor, N_{pde}, can be computed by using a lidar equation of the form

$$N_{\text{pde}} = \eta_{\text{QE}} T_t T_r T_{\text{atm}}^2 \frac{A_{\text{sub}} \beta_{\text{BS}} \Delta l}{R^2} \frac{E_p \lambda}{hc} \tag{53}$$

where η_{QE} = quantum efficiency of the wavefront sensor
T_t = laser transmitter optical transmission
T_r = optical transmission of the wavefront sensor
T_{atm} = one-way transmission of the atmosphere
A_{sub} = area of a wavefront sensor subaperture
β_{BS} = fraction of incident laser photons backscattered per meter of scattering volume [steradian $(\text{sr})^{-1}\text{m}^{-1}$]
R = range to the midpoint of the scattering volume
Δl = length of the scattering volume—the range gate
E_p = energy per pulse
λ = laser wavelength
h = Planck's constant
c = speed of light

The laser beam is focused at range R, and the wavefront sensor is gated on and off to exclude backscattered photons from the beam outside a range gate of length Δl centered on range R. The volume-scattering coefficient is proportional to the atmospheric pressure and is inversely proportional to the temperature and the fourth power of the wavelength. Penndorf[64] developed the details of this relationship, which can be reduced to

$$\beta_{\text{BS}} = 4.26 \times 10^{-7} \frac{P(h)}{T(h)} \text{sr}^{-}\text{m}^{-1} \tag{54}$$

where values of number density, pressure, and temperature at sea level (needed in Penndorf's equations) have been obtained from the U.S. Standard Atmosphere.[65] At an altitude of 10 km, $\beta_{BS} = 5.1 \times 10^{-7}$ sr^{-1}m^{-1} and a 1-km-long volume of the laser beam scatters only 0.05 percent of the incident photons per steradian. Increasing the length of the range gate would increase the total signal that is received by the wavefront sensor; however, we should limit the range gate so that subapertures at the edge of the telescope are not able to resolve the projected length of the scattered light. Range gates that are longer than this criterion increase the size of the beacon's image in a subaperture and increase the rms value of the measurement error in each subaperture. A simple geometric analysis leads to an expression for the maximum range gate length:

$$\Delta L = 2\frac{\lambda R_b^2}{Dr_0} \tag{55}$$

where R_b is the range to the center of the beacon and D is the aperture diameter of the telescope. Figure 23 shows the computed signal in detected electrons per subaperture as a function of altitude for a 100-watt (W) average power laser operating at 1000 pulses per second at either 351 nm (upper curve) or 532 nm (lower curve). Other parameters used to compute these curves are listed in the figure caption. When all first-order effects are accounted for, notice that (for high-altitude beacons) there is little benefit to using an ultraviolet wavelength laser over a green laser—even though the scattering goes as λ^{-4}. With modern low-noise detector arrays, signal levels as low as 50 pdes are very usable; above 200 pdes, the sensor generally no longer dominates the performance.

Equations (53) and (55) accurately predict what has been realized in practice. A pulsed copper-vapor laser, having an effective pulse energy of 180 millijoules (mJ) per wavefront sample, produced 190 pdes per subaperture on the Starfire Optical Range 1.5-m telescope at a backscatter range of 10 km, range gate of 2.4 km, and subapertures of 9.2 cm. The total round-trip optical and quantum efficiency was only 0.4 percent.[55]

There are many practical matters on how to design the optical system to project the laser beam. If the beam shares any part of the optical train of the telescope, then it is important to inject the beam

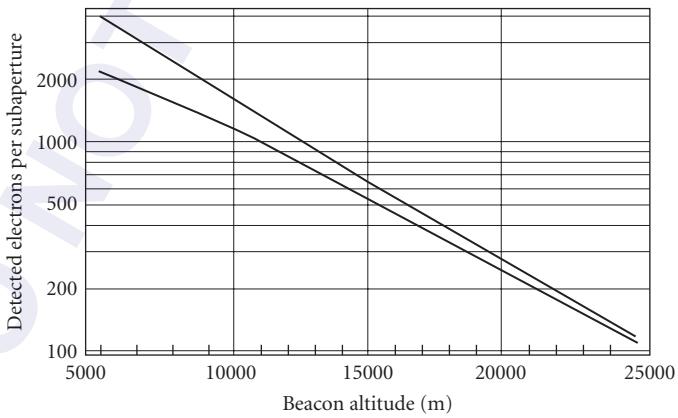

FIGURE 23 Rayleigh laser beacon signal versus altitude of the range gate for two laser wavelengths: 351 nm (top curve) and 532 nm (bottom curve). Assumptions for each curve: range gate length $= 2\lambda R_b^2/(Dr_0)$, $D = 1.5$ m, $r_0 = 5$ cm at 532 nm and 3.3 cm at 351 nm, $T_t = 0.30$, $T_r = 0.25$, $\eta_{QE} = 90$ percent at 532 nm and 70 percent at 351 nm, $E_p = 0.10$ J, subaperture size = 10 cm^2, one-way atmospheric transmission computed as a function of altitude and wavelength.

as close to the output of the telescope as feasible. The best arrangement is to temporally share the aperture with a component that is designed to be out of the beam train when sensors are using the telescope (e.g., a rotating reflecting wheel as described by Thompson et al.[56]). If the laser is injected optically close to wavefront sensors or trackers, there is the additional potential of phosphorescence in mirror substrates and coatings that can emit photons over a continuum of wavelengths longer than the laser fundamental. The decay time of these processes can be longer than the interpulse interval of the laser, presenting a pseudo-continuous background signal that can interfere with faint objects of interest. This problem was fundamental in limiting the magnitude of natural guide star tracking with photon counting avalanche photo diodes at the SOR 1.5-m telescope during operations with the copper-vapor laser.[66]

Generation of Mesospheric Sodium Laser Beacons As the curves in Figs. 21 and 22 show, performance is enhanced considerably when the beacon is at high altitude (90 versus 15 km). The signal from Rayleigh scattering is 50,000 times weaker for a beacon at 90 km compared with one at 15 km. Happer et al.[67] suggested laser excitation of mesospheric sodium in 1982; however, the generation of a beacon that is suitable for use with AO has turned out to be a very challenging problem. The physics of laser excitation is complex and the development of an optimum laser stresses modern materials science and engineering. This section only addresses how the temporal and spectral format of the laser affects the signal return. The engineering issues of building a laser are beyond the present scope.

The sodium layer in the mesosphere is believed to arise from meteor ablation. The average height of the layer is approximately 95 km above sea level and it is 10 km thick. The column density is only $2–5 \cdot 10^9$ atoms/cm^2, or roughly 10^3 atoms/cm^3. The temperature of the layer is approximately 200 K, resulting in a Doppler broadened absorption profile having a full width half maximum (FWHM) of about 3 gigahertz (GHz), which is split into two broad resonance peaks that are separated by 1772 MHz, caused by splitting of the $3S_{1/2}$ ground state. The natural lifetime of an excited state is only 16 ns. At high laser intensities (roughly 6 mW/cm^2 for lasers with a natural line width of 10 MHz or 5 W/cm^2 for lasers having spectral content that covers the entire Doppler broadened spectrum), saturation occurs and the return signal does not increase linearly with increasing laser power.

The three types of lasers that have been used to date for generating beacons are the continuous-wave (CW) dye laser, the pulsed-dye laser, and a solid-state sum-frequency laser. Continuous-wave dye lasers are available commercially and generally provide from 2 to 4 W of power. A specialized pulsed-dye lasers installed at Lick Observatory's 3-m Shane Telescope, built at Lawrence Livermore National Laboratory by Friedman et al.,[68] produces an average power of 20 W consisting of 100- to 150-ns-long pulses at an 11-kHz pulse rate. The sum-frequency laser concept relies on the sum-frequency mixing of the 1.064- and 1.319-μm lines of the Nd:YAG laser in a nonlinear crystal to produce the required 0.589-μm wavelength for the spectroscopic D_2 line. The first experimental devices were built by Jeys at MIT Lincoln Laboratory.[69, 70] The pulse format is one of an envelope of macropulses, lasting of the order of 100 μs, containing mode-locked pulses at roughly a 100-MHz repetition rate, and a duration of from 400 to 700 ps. The sum-frequency lasers built to date have had average powers of from 8 to 20 W and have been used in field experiments at SOR and Apache Point Observatory.[71, 72]

A comprehensive study of the physics governing the signal that is generated by laser excitation of mesospheric sodium has been presented by Milonni et al.[73, 74] for short, intermediate, and long pulses, and CW, corresponding to the lasers described previously. Results are obtained by numerical computations and involve a full-density matrix treatment of the sodium D_2 line. In some specific cases, it has been possible to approximate the results with analytical models that can be used to make rough estimates of signal strengths.

Figure 24 shows results of computations by Milonni et al. for short- and long-pulse formats and an analytical extension of numerical results for a high-power CW laser. Results are presented as the number of photons per square centimeter per millisecond received at the primary mirror of the telescope versus average power of the laser. The curves correspond to (top to bottom) the sum-frequency laser; a CW laser whose total power is spread over six narrow lines that are distributed across the Doppler profile; a CW laser having only one narrow line, and the pulsed-dye laser. The specifics are given in the caption for Fig. 24. Figure 25 extends these results to 200-W average power and shows

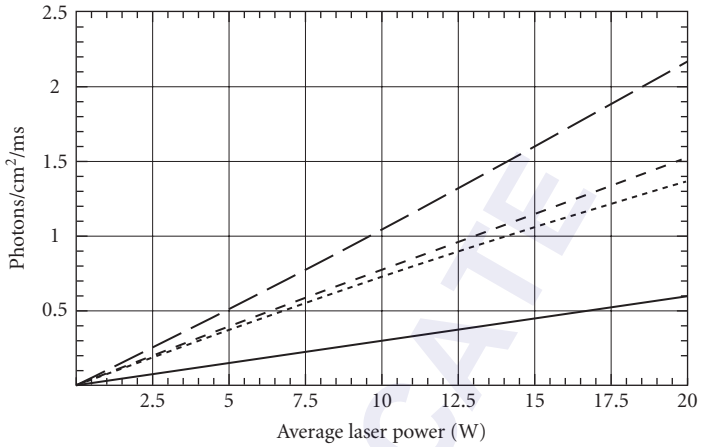

FIGURE 24 Sodium laser beacon signal versus average power of the pump laser. The lasers are (top to bottom) sum-frequency laser with a micropulse-macropulse format (150-μs macropulses filled with 700-ps micropulses at 100 MHz), a CW laser having six 10-MHz-linewidth lines, a CW laser having a single 10-MHz linewidth, and a pulsed-dye laser having 150-ns pulses at a 30-kHz repetition rate. The sodium layer is assumed to be 90 km from the telescope, the atmospheric transmission is 0.7, and the spot size in the mesosphere is 1.2 arcsec.

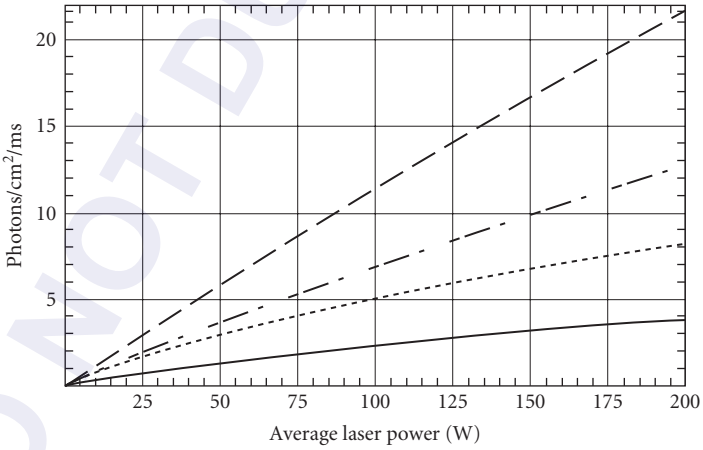

FIGURE 25 Sodium laser beacon signal versus average power of the pump laser. The lasers are (top to bottom) sum-frequency laser with a micropulse-macropulse format (150-μs macropulses filled with 700-ps micropulses at 100 MHz), a CW laser having six 10-MHz-linewidth lines, a CW laser having a single 10-MHz linewidth, and a pulsed-dye laser having 150-ns pulses at a 30-kHz repetition rate. The sodium layer is assumed to be 90 km from the telescope, the atmospheric transmission is 0.7, and the spot size in the mesosphere is 1.2 arcsec. Saturation of the return signal is very evident for the temporal format of the pulsed-dye laser and for the single-line CW laser. Note, however, that the saturation is mostly eliminated (the line is nearly straight) in the single-line laser by spreading the power over six lines. There appears to be very little saturation in the micropulse-macropulse format.

significant saturation for the pulsed-dye laser format and the single-frequency CW laser as well as some nonlinear behavior for the sum-frequency laser. If the solid-state laser technology community can support high-power, narrow-line CW lasers, this chart says that saturation effects at high power can be ameliorated by spreading the power over different velocity classes of the Doppler profile. These curves can be used to do first-order estimates of signals that are available from laser beacons that are generated in mesospheric sodium with lasers having these temporal formats.

Real-Time Processors

The mathematical process described by Eq. (45) is usually implemented in a dedicated processor that is optimized to perform the matrix multiplication operation. Other wavefront reconstruction approaches that are not implemented by matrix multiplication routines are also possible, but they are not discussed here.

Matrix multiplication lends itself to parallel operations and the ultimate design to maximize speed is to dedicate a processor to each actuator in the deformable mirror. That is, each central processing unit (CPU) is responsible for multiplying and accumulating the sum of each element of a row in the M matrix with each element of the slope vector **S**. The values of the slope vector should be broadcast to all processors simultaneously to reap the greatest benefit. Data flow and throughput is generally a more difficult problem than raw computing power. It is possible to buy very powerful commercial off-the-shelf processing engines, but getting the data into and out of the engines usually reduces their ultimate performance. A custom design is required to take full advantage of component technology that is available today.

An example of a custom-designed system is the SOR 3.5-m telescope AO system[75] containing 1024 digital signal processors running at 20 MHz, making a 20-billion-operations-per-second system. This system can perform a $(2048 \times 1024) \times (2048)$ matrix multiply to 16-bit precision (40-bit accumulation), low-pass-filter the data, and provide diagnostic data collection in less than 24 μs. The system throughput exceeds 400 megabytes per second (MB/s). Most astronomy applications have less demanding latency and throughput requirements that can be met with commercial off-the-shelf hardware and software. The importance of latency is illustrated in Fig. 26. This figure shows results

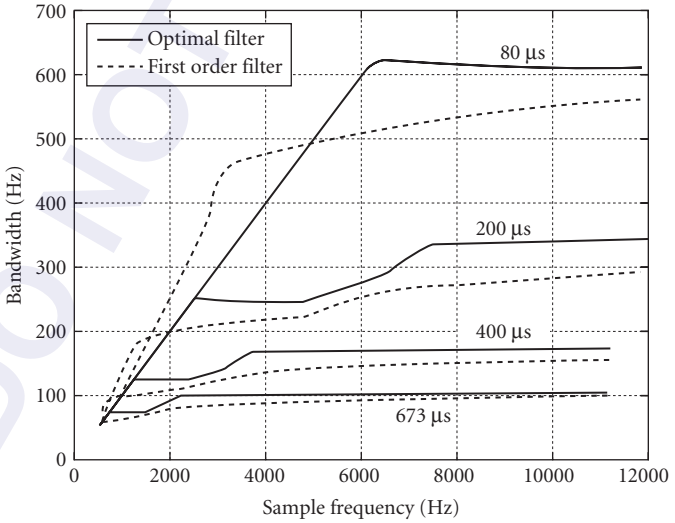

FIGURE 26 Effect of data latency (varying from 80 to 673 μs in this plot) on the control loop bandwidth of the AQ system. In this plot, the latency includes only the sensor readout and waverfront processing time.

of analytical predictions showing the relationship between control loop bandwidth of the AO system and the wavefront sensor frame rate for different data latencies.[76] These curves show that having a high-frame-rate wavefront sensor camera is not a sufficient condition to achieve high control loop bandwidth. The age of the data is of utmost importance. As Fig. 26 shows, the optimum benefit in control bandwidth occurs when the latency is significantly less than a frame time (~ 1/2).

Ensemble-averaged atmospheric turbulence conditions are very dynamic and change on the scale of minutes. Optimum performance of an AO system cannot be achieved if the system is operating on phase estimation algorithms that are based on inaccurate atmospheric information. Optimum performance requires changing the modes of operation in near-real time. One of the first implementations of adaptive control was the system ADONIS, which was implemented on the ESO 3.6-m telescope at La Silla, Chile.[77] ADONIS employs an artificial intelligence control system that controls which spatial modes are applied to the deformable mirror, depending on the brightness of the AO beacon and the seeing conditions.

A more complex technique has been proposed[48] that would allow continuous updating of the wavefront estimation algorithm. The concept is to use a recursive least-squares adaptive algorithm to track the temporal and spatial correlations of the distorted wavefronts. The algorithm uses current and recent past information that is available to the servo system to predict the wavefront for a short time in the future and to make the appropriate adjustments to the deformable mirror. A sample scenario has been examined in a detailed simulation, and the system Strehl ratio achieved with the recursive least-squares adaptive algorithm is essentially the same as an optimal reconstructor with *a priori* knowledge of the wind and turbulence profiles. Sample results of this simulation are shown in Fig. 27. The requirements for implementation of this algorithm in a real-time hardware processor have not been worked out in detail. However, it is clear that they are considerable, perhaps greater by an order of magnitude than the requirements for an ordinary AO system.

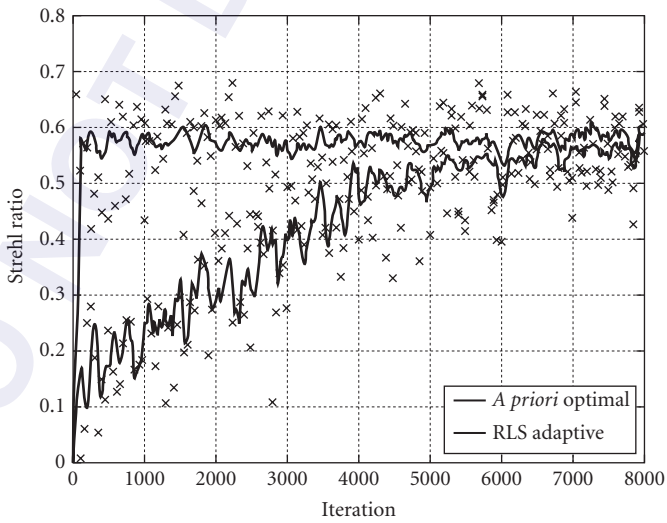

FIGURE 27 Results of a simulation of the Strehl ratio versus time for a recursive least-squares adaptive estimator (lower curve) compared with an optimal estimator having *a priori* knowledge of turbulence condtions (upper curve). The ×'s represent the instantaneous Strehl ratio computed by the simulation, and the lines represent the average values.

Other Higher-Order Wavefront Sensing Techniques

Various forms of shearing interferometers have been successfully used to implement wavefront sensors for atmospheric turbulence compensation.[78, 79] The basic principle is to split the wavefront into two copies, translate one laterally with respect to the other, and then interfere with them. The bright and dark regions of the resulting fringe pattern are proportional to the slope of the wavefront. Furthermore, a lateral shearing interferometer is self-referencing—it does not need a plane wave reference like the Shack-Hartmann sensor. Shearing interferometers are not in widespread use today, but they have been implemented in real systems in the past.[78]

Roddier[80, 81] introduced a new concept for wavefront sensing based on measuring local wavefront curvature (the second derivative of the phase). The concept can be implemented by differencing the irradiance distributions from two locations on either side of the focal plane of a telescope. If the two locations are displaced a distance, l, from the focus of the telescope and the spatial irradiance distribution is given by $I_1(\mathbf{r})$ and $I_2(\mathbf{r})$ at the two locations, then the relationship between the irradiance and the phase is given by

$$\frac{I_1(\mathbf{r})-I_2(-\mathbf{r})}{I_1(\mathbf{r})+I_2(-\mathbf{r})}=\frac{\lambda F^2(F-l)}{2\pi l^2}\left[\frac{\partial\phi}{\partial n}(\mathbf{r})\delta_c-\nabla^2\phi(\mathbf{r})\right] \tag{56}$$

where F is the focal length of the telescope, and the Dirac delta δ_c represents the outward-pointing normal derivative on the edge of the phase pattern. Equation (56) is valid in the geometrical optics approximation. The distance, l, must be chosen such that the validity of the geometrical optics approximation is ensured, requiring that the blur at the position of the defocused pupil image is small compared with the size of the wavefront aberrations desired to be measured. These considerations lead to a condition on l that

$$l \geq \theta_b \frac{F^2}{d} \tag{57}$$

where θ_b is the blur angle of the object that is produced at the positions of the defocused pupil, and d is the size of the subaperture determined by the size of the detector. For point sources and when $d > r_0, \theta_b = \lambda/r_0$ and $l \geq \lambda F^2/r_0 d$. For extended sources of angular size $\theta > \lambda/r_0, l$ must be chosen such that $l \geq \theta F^2/d$. Since increasing l decreases the sensitivity of the curvature sensor, in normal operations l is set to satisfy the condition $l \geq \lambda F^2/r_0 d$, but once the loop is closed and low-order aberrations are reduced, the sensitivity of the sensor can be increased by making l smaller. To perform wavefront reconstruction, an iterative procedure can be used to solve Poisson's equation. The appeal of this approach is that certain deformable mirrors such as piezoelectric bimorphs deform locally as nearly spherical shapes, and can be driven directly with no intermediate mathematical wavefront reconstruction step. This has not been completely realized in practice, but excellent results have been obtained with two systems deployed at Mauna Kea.[82] All implementations of these wavefront sensors to date have employed single-element avalanche photodiodes operating in the photon-counting mode for each subaperture. Since these devices remain quite expensive, it may be cost prohibitive to scale the curvature-sensing technique to very high density actuator systems. An additional consideration is that the noise gain goes up linearly with the number of actuators, not logarithmically as with the Shack-Hartmann or shearing interferometer.

The problem of deriving phase from intensity measurements has been studied extensively.[83–86] A particular implementation of multiple-intensity measurements to derive phase data has become known as phase diversity.[87] In this approach, one camera is placed at the focus of the telescope and another in a defocused plane with a known amount of defocus. Intensity gathered simultaneously from both cameras can be processed to recover the phase in the pupil of the telescope. The algorithms needed to perform this operation are complex and require iteration.[88] Such a technique does not presently lend itself to real-time estimation of phase errors in an adaptive optical system, but it could in the future.

Artificial neural networks have been used to estimate phase from intensity as well. The concept is similar to other methods using multiple-intensity measurements. Two focal planes are set up, one at the focus of the telescope and one near focus. The pixels from each focal plane are fed into the nodes of an artificial neural network. The output of the network can be set up to provide almost any desired

information from Zernike decomposition elements to direct-drive signals to actuators of a zonal, deformable mirror. The network must be trained using known distortions. This can be accomplished by using a deterministic wavefront sensor to measure the aberrations and using that information to adjust the weights and coefficients in the neural network processor. This concept has been demonstrated on real telescopes in atmospheric turbulence.[89] The concept works for low-order distortions, but it appears to have limited usefulness for large, high-density actuator adaptive optical systems.

Wavefront Correctors

There are three major classes of wavefront correctors in use today: segmented mirrors, bimorph mirrors, and stacked-actuator continuous-facesheet mirrors. Figure 28 shows the concept for each of these mirrors.

The segmented mirror can have piston-only or piston-and-tilt actuators. Since the individual segments are completely independent, it is possible for significant phase errors to develop between the segments. It is therefore important that these errors be controlled by real-time interferometry or by strain gauges or other position-measuring devices on the individual actuators. Some large segmented mirrors have been built[90] for DOD applications and several are in use today for astronomy.[91, 92]

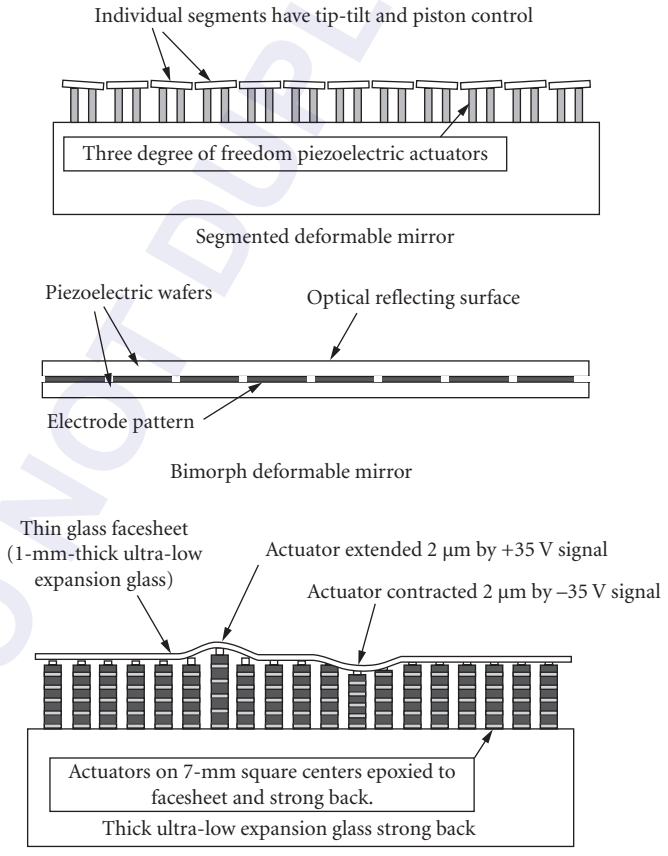

FIGURE 28 Cross sections of three deformable mirror designs.

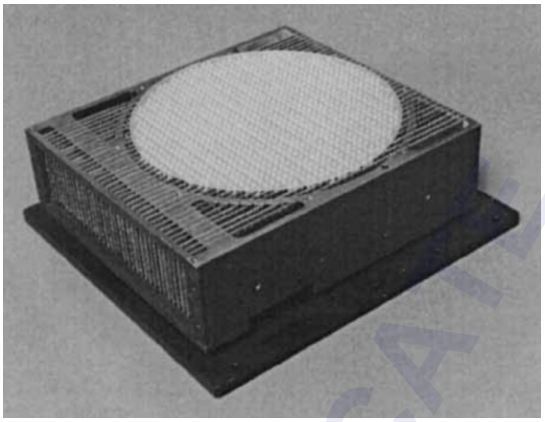

FIGURE 29 The 941-actuator deformable mirror built by Xinetics, Inc., for the SOR 3.5-m telescope.

The stacked actuator deformable mirror is probably the most widely used wavefront corrector. The modern versions are made with lead-magnesium-niobate—a ceramic-like electrostrictive material producing 4 μm of stroke for 70 V of drive.[93] The facesheet of these mirrors is typically 1 mm thick. Mirrors with as many as 2200 actuators have been built. These devices are very stiff structures with first resonant frequencies as high as 25 kHz. They are typically built with actuators spaced as closely as 7 mm. One disadvantage with this design is that it becomes essentially impossible to repair individual actuators once the mirror structure is epoxied together. Actuator failures are becoming less likely with today's refined technology, but a very large mirror may have 1000 actuators, which increases its chances for failures over the small mirrors of times past. Figure 29 is a photograph of the 941-actuator deformable mirror in use at the 3.5-m telescope at the SOR.

New Wavefront Corrector Technologies

Our progress toward good performance at visible wavelengths will depend critically on the technology that is available for high-density actuator wavefront correctors. There is promise in the areas of liquid crystals, MEM devices, and nonlinear-optics processes. However, at least for the next few years, it seems that we will have to rely on conventional mirrors with piezoelectric-type actuators or bimorph mirrors made from sandwiched piezoelectric layers. Nevertheless, there is a significant development in the conventional mirror area that has the potential for making mirrors with very large numbers of actuators that are smaller, more reliable, and much less expensive.

5.6 HOW TO DESIGN AN ADAPTIVE OPTICAL SYSTEM

Adaptive optical systems are complex and their performance is governed by many parameters, some controlled by the user and some controlled by nature. The system designer is faced with selecting parameter values to meet performance requirements. Where does he or she begin? One approach is presented here and consists of the following six steps:

1. Determine the average seeing conditions (the mean value of r_0 and f_G) for the site.
2. Determine the most important range of wavelengths of operation.
3. Decide on the minimum Strehl ratio that is acceptable to the users for these seeing conditions and operating wavelengths.
4. Determine the brightness of available beacons.
5. Given the above requirements, determine the optimum values of the subaperture size and the servo bandwidth to minimize the residual wavefront error at the most important wavelength and minimum beacon brightness. (The most difficult parameters to change after the system is built are the wavefront sensor subaperture and deformable mirror actuator geometries. These parameters need to be chosen carefully to address the highest-priority requirements in terms of seeing conditions, beacon brightness, operating wavelength, and required Strehl ratio.) Determine if the associated Strehl ratio is acceptable.
6. Evaluate the Strehl ratio for other values of the imaging wavelength, beacon brightness, and seeing conditions. If these are unsatisfactory, vary the wavefront sensor and track parameters until an acceptable compromise is reached.

Our objective in this section is to develop some practical formulas that can be implemented and evaluated quickly on desktop or laptop computers using programs like Mathematica™ or MatLab™ that will allow one to iterate the six aforementioned steps to investigate the top-level trade space and optimize system performance for the task at hand.

The most important parameters that the designer has some control over are the subaperture size, the wavefront sensor and track sensor integration times, the latency of data in the higher-order and tracker control loops, and the wavelength of operation. One can find optimum values for these parameters since changing them can either increase or decrease the system Strehl ratio. The parameters that the designer has little or no control over are those that are associated with atmospheric turbulence. On the other hand, there are a few parameters that always make performance better the larger (or smaller) we make the parameter: the quantum efficiency of the wavefront and track sensors, the brightness of the beacon(s), the optical system throughput, and read noise of sensors. We can never make a mistake by making the quantum efficiency as large as physics will allow and the read noise as low as physics will allow. We can never have a beacon too bright, nor can we have too much optical transmission (optical attenuators are easy to install). Unfortunately, it is not practical with current technology to optimize the AO system's performance for changing turbulence conditions, for different spectral regions of operation, for different elevation angle, and for variable target brightness by changing the mechanical and optical design from minute to minute. We must be prepared for some compromises based on our initial design choices.

We will use two system examples to illustrate the process that is outlined in the six aforementioned steps: (1) a 3.5-m telescope at an intracontinental site that is used for visible imaging of low-earth-orbiting artificial satellites, and (2) a 10-m telescope that operates at a site of excellent seeing for near-infrared astronomy.

Establish the Requirements

Table 2 lists a set of requirements that we shall try to meet by trading system design parameters. The values in Table 2 were chosen to highlight how requirements can result in significantly different system designs.

In the 3.5-m telescope example, the seeing is bad, the control bandwidths will be high, the imaging wavelength is short, and the required Strehl ratio is significant. Fortunately, the objects (artificial earth satellites) are bright. The 10-m telescope application is much more forgiving with respect to the seeing and imaging wavelengths, but the beacon brightness is four magnitudes fainter and a high Strehl ratio is still required at the imaging wavelength. We now investigate how these requirements determine an optimum choice for the subaperture size.

TABLE 2 Requirements for Two System Examples

Parameter	3.5-m Requirement	10-m Requirement
C_n^2 profile	Modified HV_{57}	Average Mauna Kea
Wind profile	Slew dominated	Bufton
Average r_0 (0.5 μm)	10 cm	18 cm
Average f_G (0.5 μm)	150 Hz	48 Hz
Imaging wavelength	0.85 μm	1.2–2.2 μm
Elevation angle	45°	45°
Minimum Strehl ratio	0.5	0.5
Beacon brightness	$m_v = 6$	$m_v = 10$

Selecting a Subaperture Size

As was mentioned previously, choosing the subaperture size should be done with care, because once a system is built it is not easily changed. The approach is to develop a mathematical expression for the Strehl ratio as a function of system design parameters and seeing conditions and then to maximize the Strehl ratio by varying the subaperture size for the required operating conditions that are listed in Table 2.

The total-system Strehl ratio is the product of the higher-order and full-aperture tilt Strehl ratios:

$$\mathrm{SR}_{\mathrm{Sys}} = \mathrm{SR}_{\mathrm{HO}} \cdot \mathrm{SR}_{\mathrm{tilt}} \tag{58}$$

The higher-order Strehl ratio can be estimated as

$$\mathrm{SR}_{\mathrm{HO}} = e^{-[E_n^2 + E_f^2 + E_s^2 + E_{\mathrm{FA}}^2]} \tag{59}$$

where E_n^2, E_f^2, E_s^2, and E_{FA}^2 are the mean square phase errors due to wavefront measurement and reconstruction noise, fitting error, servo lag error, and focus anisoplanatism (if a laser beacon is used), respectively. Equation (59) does not properly account for interactions between these effects and could be too conservative in estimating performance. Ultimately, a system design should be evaluated with a detailed computer simulation, which should include wave-optics atmospheric propagations, diffraction in wavefront sensor optics, details of hardware, processing algorithms and time delays, and many other aspects of the system's engineering design. A high-fidelity simulation will properly account for the interaction of all processes and provide a realistic estimate of system performance. For our purposes here, however, we will treat the errors as independent in order to illustrate the processes that are involved in system design and to show when a particular parameter is no longer the dominant contributor to the total error. We will consider tracking effects later [see below Eq. (66)], but for now we need expressions for components of the higher-order errors so that we may determine an optimum subaperture size.

Wavefront Measurement Error, E_n^2 We will consider a Shack-Hartmann sensor for the discussion that follows. The wavefront measurement error contribution, E_n^2, can be computed from the equation[73]

$$E_n^2 = \alpha \left[0.09 \ln (n_{\mathrm{sa}}) \sigma_{\theta_{\mathrm{sa}}}^2 d_s^2 \left(\frac{2\pi}{\lambda_{\mathrm{img}}} \right)^2 \right] \tag{60}$$

where α accounts for control loop averaging and is described below, n_{sa} is the number of subapertures in the wavefront sensor, $\sigma^2_{\theta_{sa}}$ is the angular measurement error over a subaperture, d_s is the length of a side of a square subaperture, and λ_{img} is the imaging wavelength. The angular measurement error in a subaperture is proportional to the angular size of the beacon [normally limited by the seeing for unresolved objects but, in some cases, by the beacon itself (e.g., laser beacons or large astronomical targets)] and is inversely proportional to the signal-to-noise ratio in the wavefront sensor. The value of $\sigma_{\theta_{sa}}$ is given by[94]

$$\sigma_{\theta_{sa}} = \pi\left(\frac{\lambda_b}{d_s}\right)\left[\left(\frac{3}{16}\right)^2 + \left(\frac{\theta_b/2}{4\lambda_b/d_s}\right)^2\right]^{1/2}\left(\frac{1}{n_s} + \frac{4n_e^2}{n_s^2}\right)^{1/2} \tag{61}$$

where λ_b is the center wavelength of the beacon signal, θ_b is the angular size of the beacon, r_0 is the Fried seeing parameter at 0.5 μm at zenith, ψ is the zenith angle of the observing direction, n_s is the number of photodetected electrons per subaperture per sample, and n_e is the read noise in electrons per pixel. We have used the wavelength and zenith scaling laws for r_0 to account for the angular size of the beacon at the observing conditions.

The number of photodetected electrons per subaperture per millisecond, per square meter, per nanometer of spectral width is given by

$$n_s = \frac{(101500)^{\sec\psi}}{(2.51)^{m_v}} d_s^2 T_{ro}\eta_{QE} t_s \Delta\lambda \tag{62}$$

where m_v is the equivalent visual magnitude of the beacon at zenith, d_s is the subaperture size in meters, T_{ro} is the transmissivity of the telescope and wavefront sensor optics, n_{QE} is the quantum efficiency of the wavefront sensor, t_s is the integration time per frame of the wavefront sensor, and $\Delta\lambda$ is the wavefront sensor spectral bandwidth in nanometers.

The parameter α is a factor that comes from the filtering process in the control loop and can be considered the mean square gain of the loop. Ellerbroek[73, 95] has derived an expression (discussed by Milonni et al.[73] and by Ellerbroek[95]) for α using the Z-transform method and a simplified control system model. His result is $\alpha = g/(2-g)$, where $g = 2\pi f_{3dB} t_s$ is the gain, f_{3dB} is the control bandwidth, and t_s is the sensor integration time. For a typical control system, we sample at a rate that is 10 times the control bandwidth, making $t_s = 1/(10 f_{3dB})$, $g = 0.628$, and $\alpha = 0.458$.

Fitting Error, E_f^2 The wavefront sensor has finite-sized subapertures, and the deformable mirror has a finite number of actuators. There is a limit, therefore, to the spatial resolution to which the system can "fit" a distorted wavefront. The mean square phase error due to fitting is proportional to the −5/6th power of the number of actuators and $(D/r_0)^{5/3}$ and is given by

$$E_f^2 = C_f\left(\frac{D}{r_0\left(\dfrac{\lambda_{img}}{0.5\,\mu m}\right)^{6/5}(\cos\psi)^{3/5}}\right)^{5/3} n_a^{-5/6} \tag{63}$$

where C_f is the fitting error coefficient that is determined by the influence function of the deformable mirror and has a value of approximately 0.28 for thin, continuous-facesheet mirrors.

Servo Lag, E_s^2 The mean square wavefront error due to a finite control bandwidth has been described earlier by Eq. (37), which is recast here as

$$E_s^2 = \left(\frac{f_G\left(\dfrac{\lambda_{img}}{0.5\,\mu m}\right)^{-6/5}(\cos\psi)^{-3/5}}{f_{3dB}}\right)^{5/3} \tag{64}$$

where f_G is the Greenwood frequency scaled for the imaging wavelength and a worst-case wind direction for the zenith angle, and $f_{3\text{dB}}$ is the control bandwidth –3-dB error rejection frequency. Barchers[76] has developed an expression from which one can determine $f_{3\text{dB}}$ for a conventional proportional integral controller, given the sensor sample time (t_s), the additional latency from readout and data-processing time (δ_0), and the design gain margin [G_M (a number between 1 and ∞ that represents the minimum gain that will drive the loop unstable)].[96] The phase crossover frequency of a proportional integral controller with a fixed latency is $\omega_{\text{cp}} = \pi/(2\delta)$ rad/s, where $\delta = t_s + \delta_0$ is the total latency, which is made up of the sample period and the sensor readout and processing time, δ_0. The loop gain that achieves the design gain margin is $K = \omega_{\text{cp}}/G_M$ where G_M is the design gain margin. Barchers shows that $f_{3\text{dB}}$ can be found by determining the frequency for which the modulus of the error rejection function is equal to 0.707 or when

$$|S(i\omega_{3\text{dB}})| = \left| \frac{i\omega_{3\text{dB}}}{i\omega_{3\text{dB}} + \dfrac{\pi/2(t_s + \delta_0)}{G_M} e^{-i(t_s+\delta_0)\omega_{3\text{dB}}}} \right| = 0.707 \tag{65}$$

where $f_{3\text{dB}} = \omega_{3\text{dB}}/2\pi$. This equation can be solved graphically or with dedicated iterative routines that find roots, such as Mathematica. Figure 30 shows the error rejection curves for four combinations of t_s, δ_0, and G_M, which are detailed in the caption. Note in particular that decreasing the latency δ_0 from 2 ms to 0.5 ms increased $f_{3\text{dB}}$ from 14 to 30 Hz (compare two curves on the left), illustrating the sensitivity to readout and processing time.

Focus Anisoplanatism, E_{FA}^2 If laser beacons are being used, the effects of focus anisoplanatism, which are discussed in Sec. 5.5, must be considered since this error often dominates the wavefront sensor error budget. Focus anisoplanatism error is given by

$$E_{\text{FA}}^2 = \left(\frac{D}{d_0 \left(\dfrac{\lambda_{\text{img}}}{0.5\,\mu\text{m}} \right)^{6/5} (\cos\psi)^{3/5}} \right)^{5/3} \tag{66}$$

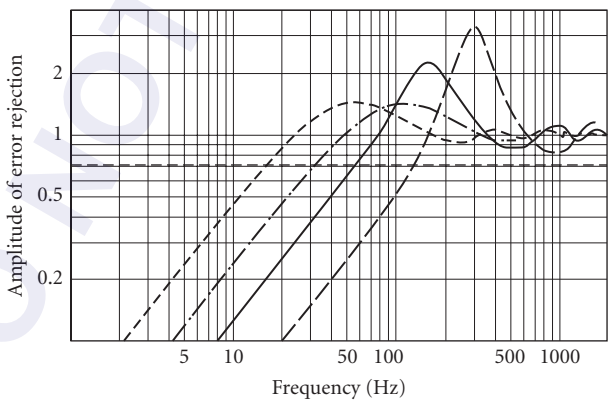

FIGURE 30 Control loop error rejection curves for a proportional integral controller. The curves (left to right) represent the following parameters: dotted ($t_s = 1$ ms, $\delta_0 = 2$ ms, $G_M = 4$); dash-dot ($t_s = 1$ ms, $\delta_0 = 0.5$ ms, $G_M = 4$); solid ($t_s = 667$ μs, $\delta_0 = 640$ μs, $G_M = 2$); dashed ($t_s = 400$ μs, $\delta_0 = 360$ μs, $G_M = 1.5$). $f_{3\text{dB}}$ is determined by the intersection of the horizontal dotted line with each of the three curves and has values of 14, 30, 55, and 130 Hz, respectively.

where d_0 is the section size given by Eqs. (50) and (51), scaled for the imaging wavelength and the zenith angle of observation.

Tracking The tracking system is also very important to the performance of an AO system and should not be overlooked as an insignificant problem. In most instances, a system will contain tilt disturbances that are not easily modeled or analyzed arising most commonly from the telescope mount and its movement and base motions coupled into the telescope from the building and its machinery or other seismic disturbances. As described earlier in Eq. (22), the Strehl ratio due to full-aperture tilt variance, σ_θ^2, is

$$\mathrm{SR}_{\mathrm{tilt}} = \frac{1}{1 + \dfrac{\pi^2}{2}\left(\dfrac{\sigma_\theta}{\lambda/D}\right)^2} \tag{67}$$

As mentioned previously, the total system Strehl ratio is then the product of these and is given by

$$\mathrm{SR}_{\mathrm{Sys}} = \mathrm{SR}_{\mathrm{HO}} \cdot \mathrm{SR}_{\mathrm{tilt}} \tag{68}$$

Results for 3.5-m Telescope AO System

When the preceding equations are evaluated, we can determine the dependence of the system Strehl ratio on d_s for targets of different brightness. Figure 31 shows the Strehl ratio versus subaperture size for four values of target brightness corresponding to (top to bottom) m_v = 5, 6, 7, and 8 and for other system parameters as shown in the figure caption.

Figure 31 shows that we can achieve the required Strehl ratio of 0.5 (see Table 2) for a m_V = 6 target by using a subaperture size of about 11 to 12 cm. We could get slightly more performance (SR = 0.52) by reducing the subaperture size to 8 cm, but at significant cost since we would have nearly twice as many subapertures and deformable mirror actuators. Notice also that for fainter

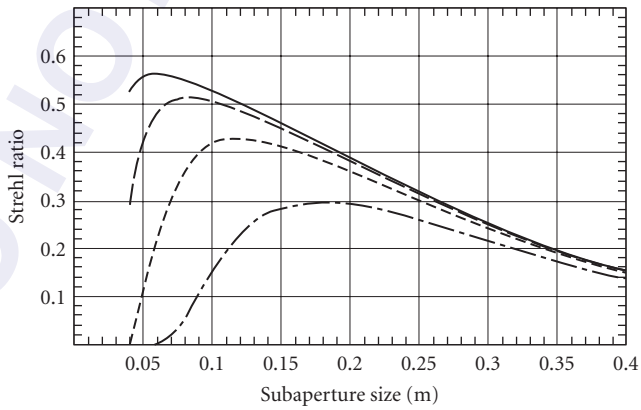

FIGURE 31 System Strehl ratio as a function of subaperture size for the 3.5-m telescope example. Values of m_V are (top to bottom) 5, 6, 7, and 8. Other parameters are: $r_0 = 10$ cm, $f_G = 150$ Hz, $t_s = 400$ μs, $\delta_0 = 360$ μs, $G_M = 1.5$, $f_{3\mathrm{dB}} = 127$ Hz, $\lambda_{\mathrm{img}} = 0.85$ μm, $\psi = 45°$, $T_{\mathrm{ro}} = 0.25$, $\eta_{\mathrm{QE}} = 0.90$, $\Delta\lambda = 400$ nm.

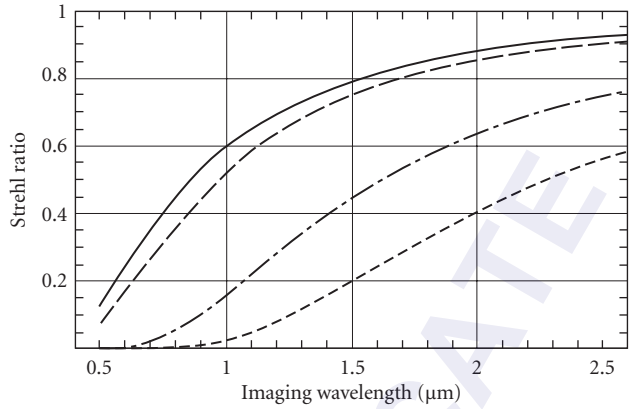

FIGURE 32 System Strehl ratio as a function of imaging wavelength for the 3.5-m telescope example. Curves are for (top to bottom) $m_V = 6$, $d_s = 12$ cm; $m_y = 6$, $d_s = 18$ cm; $m_V = 8$, $d_s = 18$ cm; $m_V = 8$, $d_s = 12$ cm. Other parameters are: $r_0 = 10$ cm, $f_G = 150$ Hz, $t_s = 400$ μs, $\delta_0 = 360$ μs, $G_M = 1.5$, $f_{3dB} = 127$ Hz, $\psi = 45°$, $T_{ro} = 0.25$, $\eta_{QE} = 0.90$, $\Delta\lambda = 400$ nm.

objects, a larger subaperture (18 cm) would be optimum for an $m_V = 8$ target, but the SR would be down to 0.4 for the $m_V = 6$ target and would not meet the requirement.

Figure 32 shows the performance of the system for sixth- and eighth-magnitude targets as a function of wavelength. The top two curves in this figure are for 12-cm subapertures (solid curve) and 18-cm subapertures (dashed curve) for the $m_V = 6$ target. Notice that the 12-cm subapertures have better performance at all wavelengths with the biggest difference in the visible. The bottom two curves are for 18-cm subapertures (dash-dot curve) and 12-cm subapertures (dotted curve) for the $m_V = 8$ target. These curves show quantitatively the trade-off between two subaperture sizes and target brightness.

Figure 33 shows how the system will perform for different seeing conditions (values of r_0) and as a function of target brightness. These curves are for a subaperture choice of 12 cm. The curves in

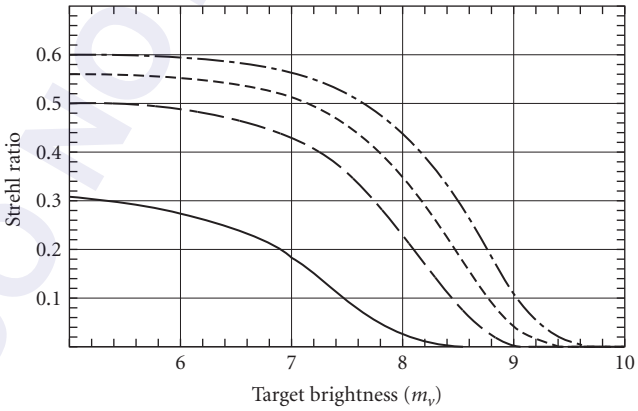

FIGURE 33 System Strehl ratio as a function of target brightness for the 3.5-m telescope example. Curves are for values of r_0 of (top to bottom) 25, 15, 10, and 5 cm. Other parameters are: $d_s = 12$ cm, $f_G = 150$ Hz, $t_s = 400$ μs, $\delta_0 = 360$ μs, $G_M = 1.5$, $f_{3dB} = 127$ Hz, $\lambda_{img} = 0.85$ μm, $\psi = 45°$, $T_{ro} = 0.25$, $\eta_{QE} = 0.90$, $\Delta\lambda = 400$ nm.

Figs. 31 through 33 give designers a good feel of what to expect and how to do top-level system trades for those conditions and parameters for which only they and the users can set the priorities. These curves are easily and quickly generated with modern mathematics packages.

Results for the 10-m AO Telescope System

Similar design considerations for the 10-m telescope example lead to Figs. 34 through 36. Figure 34 shows the Strehl ratio for an imaging wavelength of 1.2 μm versus the subaperture size for four

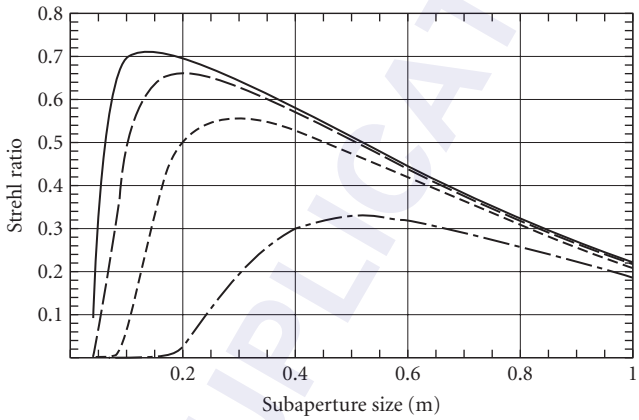

FIGURE 34 System Strehl ratio as a function of subaperture size for the 10-m telescope example. Values of m_V are (top of bottom) 8, 9, 10, and 11. Other parameters are: $r_0 = 18\,\text{cm}$, $f_G = 48\,\text{Hz}$, $t_s = 1000\,\mu\text{s}$, $\delta_0 = 1000\,\mu\text{s}$, $G_M = 2$, $f_{3\text{dB}} = 39\,\text{Hz}$, $\lambda_{\text{img}} = 1.2\,\mu\text{m}$, $\psi = 45°$, $T_{\text{ro}} = 0.25$, $\eta_{\text{QE}} = 0.90$, $\Delta\lambda = 400\,\text{nm}$.

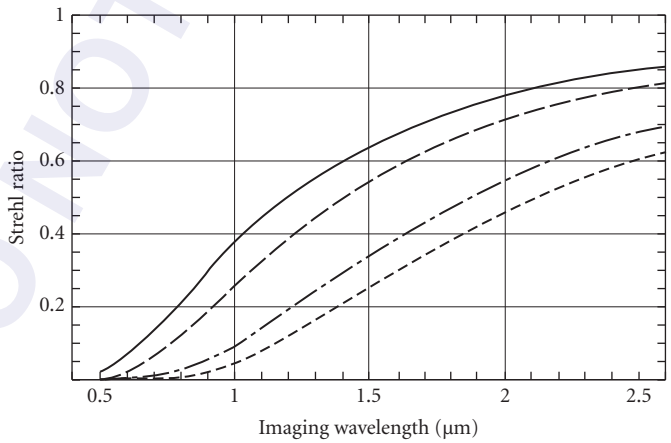

FIGURE 35 System Strehl ratio as a function of imaging wavelength for the 10-cm telescope example. Curves are for (top to bottom) $m_V = 10$, $d_s = 45\,\text{cm}$; $m_v = 10$, $d_s = 65\,\text{cm}$; $m_v = 12$, $d_s = 65\,\text{cm}$; $m_v = 12$, $d_s = 45\,\text{cm}$. Other parameters are: $r_0 = 18\,\text{cm}$, $f_G = 48\,\text{Hz}$, $t_s = 1000\,\mu\text{s}$, $\delta_0 = 1000\,\mu\text{s}$, $G_M = 2$, $f_{3\text{dB}} = 39\,\text{Hz}$, $\psi = 45°$, $T_{\text{ro}} = 0.25$, $\eta_{\text{QE}} = 0.90$, $\Delta\lambda = 400\,\text{nm}$.

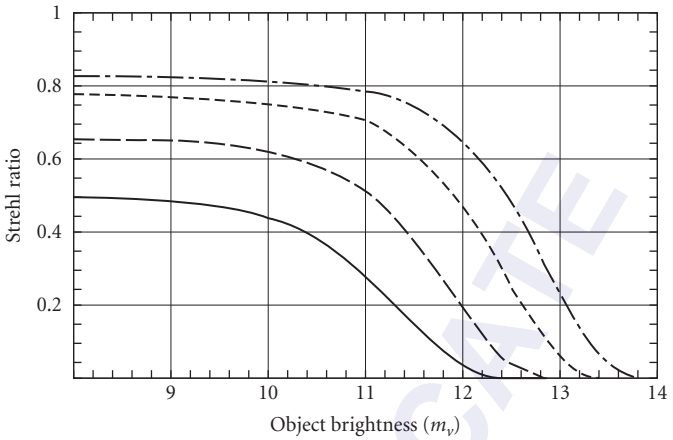

FIGURE 36 System Strehl ratio as a function of target brightness for the 10-m telescope example. Curves are for values of r_0 of (top to bottom) 40, 25, 15, and 10 cm. Other parameters are: $d_s = 45\,\text{cm}$, $f_G = 48\,\text{Hz}, t_s = 1000\,\mu\text{s}$, $\delta_0 = 1000\ \mu\text{s}, G_M = 2, f_{3\text{dB}} = 39\ \text{Hz}$, $\lambda_{\text{img}} = 1.6\ \mu\text{m}$, $\psi = 45°$, $T_{\text{ro}} = 0.25, \eta_{\text{QE}} = 0.90, \Delta\lambda = 400\,\text{nm}$.

values of beacon brightness corresponding to (top to bottom) m_V = 8, 9, 10, and 11. Other system parameters are listed in the figure caption. These curves show that we can achieve the required Strehl ratio of 0.5 for the m_v = 10 beacon with subapertures in the range of 20 to 45 cm. Optimum performance at 1.2 μm produces a Strehl ratio of 0.56, with a subaperture size of 30 cm. Nearly 400 actuators are needed in the deformable mirror for 45-cm subapertures, and nearly 900 actuators are needed for 30-cm subapertures. Furthermore, Fig. 34 shows that 45 cm is a better choice than 30 cm in the sense that it provides near-optimal performance for the m_V = 11 beacon, whereas the Strehl ratio is down to 0.2 for the 30-cm subapertures.

Figure 35 shows system performance as a function of imaging wavelength. The top two curves are for the m_V = 10 beacon, with d_s = 45 and 65 cm, respectively. Note that the 45-cm subaperture gives excellent performance with a Strehl ratio of 0.8 at 2.2 μm (the upper end of the required spectral range) and a very useful Strehl ratio of 0.3 at 0.8 μm. A choice of d_s = 65 cm provides poorer performance for m_V = 10 (in fact, it does not satisfy the requirement) than does d_s = 45 cm due to fitting error, whereas a choice of $d_s = 65\,\text{cm}$ provides better performance for $m_V = 12$ due to improved wavefront sensor signal-to-noise ratio.

Figure 36 shows system performance in different seeing conditions as a function of beacon brightness for an intermediate imaging wavelength of 1.6 μm. These curves are for a subaperture size of 45 cm. This chart predicts that in exceptional seeing, a Strehl ratio of 0.5 μm can be achieved using an $m_V = 12.5$ beacon.

As in the 3.5-m telescope case, these curves and others like them with different parameters can be useful in performing top-level design trades and in selecting a short list of design candidates for further detailed analysis and simulation.

5.7 ACKNOWLEDGMENTS

I would like to thank David L. Fried, Earl Spillar, Jeff Barchers, John Anderson, Bill Lowrey, and Greg Peisert for reading the manuscript and making constructive suggestions that improved the content and style of this chapter. I would especially like to acknowledge the efforts of my editor, Bill Wolfe, who relentlessly kept me on course from the first pitiful draft.

Accord Optics
Sunnyvale, California

6.1 GLOSSARY

$\delta\theta_o$, $\delta\theta_a$	divergence: optical, acoustic
ΔB_m	impermeability tensor
Δf, ΔF	bandwidth, normalized bandwidth
Δn	birefringence
$\Delta\theta$	deflection angle
λ_o, λ	optical wavelength (in vacuum/medium)
Λ	acoustic wavelength
ρ	density
τ	acoustic transit time
ψ	phase mismatch function
A	optical to acoustic divergence ratio
a	optical to acoustic wavelength ratio
D	optical aperture
$\mathbf{E}_i$, $\mathbf{E}_d$	electric field, incident, diffracted light
f, F	acoustic frequency, normalized acoustic frequency
H	acoustic beam height
$\mathbf{k}_i$, $\mathbf{k}_d$, $\mathbf{k}_a$	wavevector: incident, diffracted light, acoustic wave
L, l	interaction length, normalized interaction length
L_o	characteristic length
M	figure of merit
n_o, n_e	refractive index: ordinary, extraordinary
P_a, P_d	acoustic power, acoustic power density
p, p_{mn}, p_{ijkl}	elasto-optic coefficient

$\mathbf{S}, S_I$	strain, strain tensor components
t_r, T	rise time scan time
V	acoustic velocity
W	bandpass function

6.2 INTRODUCTION

When an acoustic wave propagates in an optically transparent medium, it produces a periodic modulation of the index of refraction via the elasto-optical effect. This provides a moving phase grating which may diffract portions of an incident light into one or more directions. This phenomenon, known as the acousto-optic (AO) diffraction, has led to a variety of optical devices that can be broadly grouped into AO deflectors, modulators, and tunable filters to perform spatial, temporal, and spectral modulations of light. These devices have been used in optical systems for light-beam control, optical signal processing, and optical spectrometry applications.

Historically, the diffraction of light by acoustic waves was first predicted by Brillouin[1] in 1921. Nearly a decade later, Debye and Sears[2] and Lucas and Biquard[3] experimentally observed the effect. In contrast to Brillouin's prediction of a single diffraction order, a large number of diffraction orders were observed. This discrepancy was later explained by the theoretical work of Raman and Nath.[4] They derived a set of coupled wave equations that fully described the AO diffraction in unbounded isotropic media. The theory predicts two diffraction regimes; the Raman-Nath regime, characterized by the multiple of diffraction orders, and the Bragg regime, characterized by a single diffraction order. Discussion of the early work on AO diffraction can be found in Ref. 5.

The earlier theoretically work tend to treat AO diffraction from a mathematical point of view, and for decades, solving the multiple-order Raman-Nath diffraction has been the primary interest on acousto-optics research. As such, the early development did not lead to any AO devices for practical applications prior to the invention of the laser. It was the need of optical devices for laser beam modulation and deflection that stimulated extensive research on the theory and practice of AO devices. Significant progress has been made in the decade from 1966 to 1976, due to the development of superior AO materials and efficient broadband ultrasonic transducers. During this period several important research results of AO devices and techniques were reported. These include the works of Gordon[6] on the theory of AO diffraction in finite interaction geometry, by Korpel et al. on the use of acoustic beam steering,[7] the study of AO interaction in anisotropic media by Dixon;[8] and the invention of AO tunable filter by Harris and Wallace[9] and Chang.[10] As a result of these basic theoretical works, various AO devices were developed and demonstrated its use for laser beam control and optical spectrometer applications. Several review papers during this period are listed in Refs. 11 to 14.

Intensive research programs in the 1980s and early 1990s further advanced the AO technology in order to explore the unique potential as real-time spatial light modulators (SLMs) for optical signal processing and remote sensing applications. By 1995, the technology had matured, and a wide range of high performance AO devices operating from UV to IR spectral regions had become commercially available. These AO devices have been integrated with other photonic components and deployed into optical systems with electronic technology in diverse applications.

It is the purpose of this chapter to review the theory and practice of bulk-wave AO devices and their applications. In addition to bulk AO, there have also been studies based on the interaction of optical guided waves and surface acoustic waves (SAW). Since the basic AO interaction structure and fabrication process is significantly different from that of the bulk acousto-optics, this subject is treated separately in Chap. 7.

This chapter is organized as follows: Section 6.3 discusses the theory of acousto-optic interaction. It provides the necessary background for the design of acousto-optic devices. The subject of acousto-optic materials is discussed in Sec. 6.4. The next three sections deal with the three basic types of acousto-optic devices. Detailed discussion of AO deflectors, modulators, and tunable filters are presented in Section 6.5, 6.6, and 6.7, respectively.

6.3 THEORY OF ACOUSTO-OPTIC INTERACTION

Elasto-Optic Effect

The elasto-optic effect is the basic mechanism responsible for the AO interaction. It describes the change of refractive index of an optical medium due to the presence of an acoustic wave. To describe the effect in crystals, we need to introduce the elasto-optic tensor based on Pockels' phenomenological theory.[15]

An elastic wave propagating in a crystalline medium is generally described by the strain tensor **S**, which is defined as the symmetric part of the deformation gradient

$$S_{ij} = \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \Big/ 2 \qquad i, j = 1 \text{ to } 3 \tag{1}$$

where u_i is the displacement. Since the strain tensor is symmetric, there are only six independent components. It is customary to express the strain tensor in the contracted notation

$$S_1 = S_{11} \qquad S_2 = S_{22} \qquad S_3 = S_{33} \qquad S_4 = S_{23} \qquad S_5 = S_{13} \qquad S_6 = S_{12} \tag{2}$$

The conventional elasto-optic effect introduced by Pockels states that the change of the impermeability tensor ΔB_{ij} is linearly proportional to the symmetric strain tensor.

$$\Delta B_{ij} = p_{ijkl} S_{kl} \tag{3}$$

where p_{ijkl} is the elasto-optic tensor. In the contracted notation

$$\Delta B_m = p_{mn} S_n \qquad m, n = 1 \text{ to } 6 \tag{4}$$

Most generally, there are 36 components. For the more common crystals of higher symmetry, only a few of the elasto-optic tensor components are nonzero.

In the above classical Pockels' theory, the elasto-optic effect is defined in terms of the change of the impermeability tensor ΔB_{ij}. In the more recent theoretical work on AO interactions, analysis of the elasto-optic effect has been more convenient in terms of the nonlinear polarization resulting from the change of dielectric tensor $\Delta \varepsilon_{ij}$. We need to derive the proper relationship that connects the two formulations.

Given the inverse relationship of ε_{ij} and B_{ij} in a principal axis system $\Delta \varepsilon_{ij}$ is

$$\Delta \varepsilon_{ij} = -\varepsilon_{ii} \Delta B_{ij} \varepsilon_{jj} = -n_i^2 n_j^2 \Delta B_{ij} \tag{5}$$

where n_i is the refractive index. Substituting Eq. (3) into Eq. (5), we can write

$$\Delta \varepsilon_{ij} = \chi_{ijkl} S_{kl} \tag{6}$$

where we have introduced the elasto-optic susceptibility tensor

$$\chi_{ijkl} = -n_i^2 n_j^2 p_{ijkl} \tag{7}$$

For completeness, two additional modifications of the basic elasto-optic effect are discussed as follows.

Roto-Optic Effect Nelson and Lax[16] discovered that the classical formulation of elasto-optic effect was inadequate for birefringent crystals. They pointed out that there exists an additional roto-optic susceptibility due to the antisymmetric rotation part of the deformation gradient.

$$\Delta B'_{ij} = p'_{ijkl} R_{kl} \tag{8}$$

where $R_{ij} = (S_{ij} - S_{ji})/2$.

It turns out that the roto-optic tensor components can be predicted analytically. The coefficient of $\mathbf{p}_{ijkl}$ is antisymmetric in kl and vanishes except for shear waves in birefringent crystals. In a uniaxial crystal the only nonvanishing components are $p_{2323} = p_{2313} = (n_o^{-2} - n_e^{-2})/2$, where n_o and n_e are the principal refractive indices for the ordinary and extraordinary wave, respectively. Thus, the roto-optic effect can be ignored except when the birefringence is large.

Indirect Elasto-Optic Effect In the piezoelectric crystal, an indirect elasto-optic effect occurs as the result of the piezoelectric effect and electro-optic effect in succession. The effective elasto-optic tensor for the indirect elasto-optic effect is given by[17]

$$p^*_{ij} = p_{ij} - \frac{r_{im} S_m e_{jn} S_n}{\varepsilon_{mn} S_m S_n} \tag{9}$$

where p_{ij} is the direct elasto-optic tensor, r_{im} is the electro-optic tensor, e_{jn} is the piezoelectric tensor, ε_{mn} is the dielectric tensor, and S_m is the unit acoustic wavevector. The effective elasto-optic tensor thus depends on the direction of the acoustic mode. In most crystals the indirect effect is negligible. A notable exception is $LiNbO_3$. For instance, along the z axis, $r_{33} = 31 \times 10^{-12}$ m/v, $e_{33} = 1.3$ c/m^2, $E^s_{33} = 29$, thus $p^* = 0.088$, which differs notably from the contribution $p_{33} = 0.248$.

Plane Wave Analysis of Acousto-Optic Interaction

We now consider the diffraction of light by acoustic waves in an optically transparent medium. As pointed out before, in the early development, the AO diffraction in isotropic media was described by a set of coupled wave equations known as the Raman-Nath equations.[4] In this model, the incident light is assumed to be a plane wave of infinite extent. It is diffracted by a rectangular sound column into a number of plane waves propagating along different directions. Solution of the Raman-Nath equations gives the amplitudes of these various orders of diffracted optical waves.

In general, the Raman-Nath equations can be solved only numerically and judicious approximations are required to obtain analytic solutions. Using a numerical procedure computation Klein and Cook[18] calculated the diffracted light intensities for various diffraction orders in this regime. Depending on the interaction length L relative to a characteristic length $L_o = n\Lambda^2/\lambda_o$, where n is the refractive index and Λ and λ_o are wavelengths of the acoustic and optical waves, respectively, solutions of the Raman-Nath equations can be classified into three different regimes.

In the Raman-Nath regime, where $L << L_o$, the AO diffraction appears as a large number of different orders. The diffraction is similar to that of a thin phase grating. The direction of the various diffraction orders are given by the familiar grating equation, $\sin \theta_m = m\lambda_o/n\Lambda$, where m is the diffraction order. Solution of the Raman-Nath equations shows that the amplitude of the mth-order diffracted light is proportional to the mth-order Bessel functions. The maximum intensity of the first-order diffracted light (relative to the incident light) is about 34 percent. Due to this relatively low efficiency, AO diffraction in the Raman-Nath regime is of little interest to practical device applications.

In the opposite limit, $L >> L_o$, the AO diffraction appears as a predominant first order and is said to be in the Bragg regime. The effect is called Bragg diffraction since it is similar to that of the x-ray diffraction in crystals. In the Bragg regime the acoustic column is essentially a plane wave of infinite extent. An important feature of the Bragg diffraction is that the maximum first-order diffraction efficiency obtainable is 100 percent. Therefore, practically all of today's AO devices are designed to operate in the Bragg regime.

In the immediate case, $L \le L_o$, the AO diffraction appears as a few dominant orders. This region is referred as the near Bragg region since the solutions can be explained based on the near field effect of the finite length and height of the acoustic transducer.

Many modern AO devices are based on the light diffraction in anisotropic media. The Raman-Nath equations are no longer adequate and a new formulation is required. We have previously presented a plane wave analysis of AO interaction in anisotropic media.[13] The analysis was patterned after that of Klienman[19] used in the theory of nonlinear optics. Unlike the Raman-Nath equations wherein the optical plane waves are diffracted by an acoustic column, the analysis assumes that the acoustic wave is also a plane wave of infinite extent. Results of the plane wave AO interaction in anisotropic media are summarized as follows.

The AO interaction can be viewed as a parametric process where the incident optical plane wave mixes with the acoustic wave to generate a number of polarization waves, which in turn generate new optical plane waves at various diffraction orders. Let the angular frequency and optical wavevector of the incident optical wave be denoted by ω_m and $\vec{k}_o$, respectively, and those of the acoustic waves by ω_a and $\vec{k}_a$. The polarization waves and the diffracted optical waves consist of waves with angular frequencies $\omega_m = \omega_o + m\omega_a$ and wavevectors $\vec{K}_m = \vec{k}_o + m\vec{k}_a$ ($m \pm 1, \pm 2, \ldots$). The diffracted optical waves are new normal modes of the interaction medium with the angular frequencies $\omega_m = \omega_o + m\omega_a$ and wavevectors $\vec{k}_m$ making angles θ_m with the z axis.

The total electric field of the incident and diffracted light be expanded in plane waves as

$$\vec{E}(r,t) = \frac{1}{2}\sum \hat{e}_m E_m(z) \exp j(\omega_m t - \vec{k}_m \cdot \vec{r}) + \text{c.c.} \tag{10}$$

where $\hat{e}_m$ is a unit vector of the electric field of the mth wave, E_m is the slowly varying amplitude of the electric field and c.c. stands for the complex conjugate. The electric field of the optical wave satisfies the wave equation,

$$\nabla \times \nabla \times \vec{E} + \frac{1}{c^2}\left(\ddot{\varepsilon} \cdot \frac{\partial^2 \vec{E}}{\partial t^2}\right) = -\mu_o \frac{\partial^2 \vec{P}}{\partial t^2} \tag{11}$$

where $\ddot{\varepsilon}$ is the relative dielectric tensor and $\vec{P}$ is the acoustically induced polarization. Based on Pockels' theory of the elasto-optic effect,

$$\vec{P}(r,t) = \varepsilon_o \ddot{\chi} \vec{S}(r,t) \vec{E}(r,t) \tag{12}$$

where $\ddot{\chi}$ is the elasto-optical susceptibility tensor defined in Eq. (7). $\vec{S}(r,t)$ is the strain of the acoustic wave

$$\vec{S}(r,t) = 1/2(\hat{s} S e^{j(\omega_a t - \vec{k}_a \cdot \vec{r})} + \text{c.c}) \tag{13}$$

where $\hat{s}$ is a unit strain tensor of the acoustic wave and S is the acoustic wave amplitude. Substituting Eqs. (10), (12), and (13) into Eq. (11) and neglecting the second-order derivatives of electric-field amplitudes, we obtain the coupled wave equations for AO Bragg diffraction.

$$\frac{dE_m}{dz} = \frac{j(\omega_o/c)^2}{4k_m \cos\gamma_m}\left(\chi_m S E_{m-1} e^{-j\Delta\vec{k}_m \cdot \vec{r}} + \chi_{m+1} S^* E_{m+1} e^{j\Delta\vec{k}_{m+1} \cdot \vec{r}}\right) \tag{14}$$

where $\chi_m = n_m^2 n_{m-1}^2 p_m$, $p_m = \hat{e}_m \cdot \ddot{p} \cdot \ddot{s} \cdot \hat{e}_{m-1}$, γ_m is the angle between $\vec{k}_m$ and the z axis, and $\Delta\vec{k}_m = \vec{K}_m - \vec{k}_m = \vec{k}_o + m\vec{k}_a - \vec{k}_m$ is the momentum mismatch between the optical polarization waves and mth-order normal modes of the medium. Equation (14) is the coupled wave equation describing the AO interaction in an anisotropic medium. Solution of the equation gives the field of the optical waves in various diffraction orders.

Two-Wave AO Interaction In the Bragg limit, the coupled wave equation reduces to the two-wave interaction between the incident and the first-order diffracted light ($m = 0, 1$):

$$\frac{dE_d}{dz} = \frac{j\pi n_i^2 n_d p_e}{2\lambda_o \cos\gamma_o} S E_i e^{j\Delta\vec{k}\cdot\hat{z}} \tag{15}$$

$$\frac{dE_i}{dz} = \frac{j\pi n_d^2 n_i p_e}{2\lambda_o \cos\gamma_o} S^* E_d e^{-j\Delta\vec{k}\cdot\hat{z}} \tag{16}$$

where n_i and n_d are the refractive indices for the incident and diffracted light, $p_e = \hat{e}_d \cdot \hat{p} \cdot \hat{s} \cdot \hat{e}_i$ is the effective elasto-optic constant for the particular mode of AO interaction, γ_o is the angle between the z axis and the median of incident and diffracted light and, $\Delta\vec{k} \cdot \hat{z} = \Delta k_z$ is the component of the momentum mismatch $\Delta\vec{k}$ along the z axis, and $\Delta\vec{k}$ is the momentum mismatch between the polarization wave $\vec{K}_d$ and the free wave $\vec{k}_d$ of the diffracted light.

$$\Delta\vec{k} = \vec{K}_d - \vec{k}_d = \vec{k}_i + \vec{k}_a - \vec{k}_d \tag{17}$$

Equations (15) and (16) admit simple analytic solutions. At $z = L$, the intensity of the first-order diffracted light (normalized to the incident light) is

$$I_1 = \frac{I_d(L)}{I_i(0)} = \eta\,\mathrm{sinc}^2 \frac{1}{\pi}\left(\eta + \left(\frac{\Delta k_z L}{2}\right)^2\right)^{1/2} \tag{18}$$

where $\mathrm{sinc}\,(x) = (\sin\pi x)/\pi x$, and

$$\eta = \frac{\pi^2}{2\lambda_o^2}\left(\frac{n^6 p^2}{2}\right) S^2 L^2 = \frac{\pi^2}{2\lambda_o^2} M_2 P_a \left(\frac{L}{H}\right) \tag{19}$$

In the above equation, we have used the relation $P_a = \rho V^3 S^2 LH/2$, where P_a is the acoustic power, H is the acoustic beam height, ρ is the mass density, V is the acoustic wave velocity, and $M_2 = n^6 p^2/\rho V^3$ is a material figure of merit.

Far Bragg Regime Equation (18) shows that in the far-field limit ($L \to \infty$) the diffracted light will build up finite amplitude only when the exact phase matching is met. When $\Delta k = 0$, the diffracted light intensity becomes

$$I_1 = \sin^2\sqrt{\eta} \tag{20}$$

where $\eta << 1$, $I_1 \approx \eta$ and the diffraction efficiency is linearly proportional to acoustic power. This is referred to as the weak interaction approximation (or low efficiency regime). As acoustic power increases, the diffraction efficiency approaches 100 percent. However, the acoustic power required is about 2.5 times that predicted by the low efficiency regime.

Near Bragg Regime In the near field the growth of the diffraction is determined by the accumulated phase mismatch over the interaction length. The fractional diffracted light I_1 can be approximated by

$$I_1 = \eta\,\mathrm{sin}\,c^2\,\psi \tag{21}$$

where $\psi = \Delta k_z L/2\pi$ is the phase mismatch (normalized to 2π). In the following, we shall discuss first AO diffraction in the far Bragg limit, that is, when exact phase matching is satisfied.

Phase Matching

Particle Picture of AO Diffraction In the far Bragg limit ($L \to \infty$), the diffracted light will build up finite amplitude only when the exact phase matching is met.

$$\vec{k}_d = \vec{k}_i \pm \vec{k}_a \tag{22}$$

In this limit case, the AO diffraction can be viewed as the interaction of optical and acoustic plane waves of infinite extent. To analyze AO interaction, it is more conveniently to use the particle picture of plane waves. The optical and acoustic plane waves can be thought of as made of photons and phonons of well-defined momentum and energy. Equation (22) simply states the principle of conservation of total momentum in the collision process. The principle of conservation of energy may be written as

$$\omega_d = \omega_i \pm \omega_a \tag{23}$$

The optical frequency of the diffracted light is shifted by the frequency of the acoustic wave. In analog to the Doppler effect, the optical frequency is up or down shifted if the direction of the acoustic wave is the same as or opposite to that of light wave.

In the following, we shall apply the conservation principles to derive the basic characteristics of light diffraction by acoustic wave in the plane wave formulation. For the general case of AO interaction in an anisotropic medium, the magnitudes of the incident optical wavevector can be written as

$$k_i = \frac{2\pi n_i}{n_o \lambda} \qquad k_d = \frac{2\pi n_d}{n_o \lambda} \qquad k_a = \frac{2\pi}{\Lambda} \tag{24}$$

where $\lambda = \lambda_o/n_o$ is the wavelength of the o-wave in the medium, n_i and n_d are refractive indices for the incident and diffracted light, $\Lambda = V/f$ is the acoustic wavelength and V and f are the acoustic velocity and frequency, respectively. Since the acoustic frequency is typically below 10^{-4} of the optical frequency, the small optical frequency difference (due to acoustic frequency shift) of the incident and diffracted light beams are neglected in Eq. (24).

Isotropic Diffraction Consider first the case of isotropic diffraction. Figure 1*a* shows the wavevector interaction geometry in the interaction plane. The loci of the incident and diffracted optical wavevectors fall on a circle of radius n_o. The principle of momentum conservation requires that the acoustic and optical wavevectors form a closed triangle. For isotropic AO diffraction the triangle is isosceles, and the incident and diffracted optical wavevectors make the same angle with the acoustic wavefront at the Bragg angle θ_b

$$\sin\theta_b = \frac{\lambda}{2\Lambda} = \frac{\lambda_o f}{2n_o V} \tag{25}$$

Consider, for example, the diffraction of a laser beam at 633 nm by a longitudinal mode acoustic wave in TeO_2, $n = 2.216$, $V = 4.2$ mm/μsec, Eq. (25) yields $\theta_b = 1.9°$ at an acoustic frequency $f = 500$ MHz. For all practical purpose the Bragg angle θ_b is small and the incident optical beam is always nearly

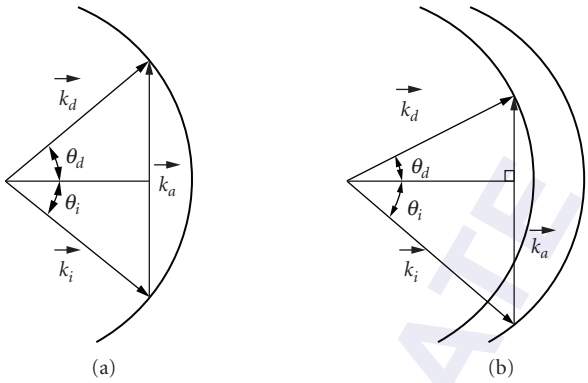

FIGURE 1 Vector diagram of acousto-optic interaction: (*a*) isotropic diffraction and (*b*) birefringent diffraction.

perpendicular to the acoustic wavefront. Thus, for an isotropic AO diffraction the primary effect of the acoustically driving polarization is to provide a transverse spatial light modulation (SLM). Similar to a grating, the transverse SLM acts as an acoustically driven optical beam deflector that scans the output light beam as the acoustic frequency is changed. The deflection angle θ_D, defined as the angle of separation between the incident and diffraction light, is given by (in the small-angle approximation)

$$\theta_D = \frac{\lambda}{\Lambda} = \frac{\lambda f}{V} \tag{26}$$

Anisotropic Diffraction Next, consider the AO diffraction in an optically anisotropic medium such as a birefringent crystal. In this case there are two distinct loci of the optical wavevectors (normal surfaces), an ordinary optical wave (polarized perpendicular to the *c* axis) and an extraordinary optical wave (polarized parallel to the *c* axis). The refraction indices are in general dependent on the propagation direction and polarization of the optical wave. The acoustic wave could couple the incident and diffracted optical wave of the same polarization ($o \leftrightarrow o$, $e \leftrightarrow e$) or orthogonal polarization ($o \leftrightarrow e$). In the latter case, the AO diffraction occurs between two loci of unequal refractive indices; this process is referred as the birefringent diffraction.

Phase Matching Equations Consider the AO interaction in a positive uniaxial crystal. Figure 1*b* shows the wavevector diagram for $o \leftrightarrow e$ type birefringent diffraction in the interaction plane. Applying the law of cosine to the triangle yields the following pair of equations for the incident and diffraction angle.

$$\sin\theta_i = \frac{\lambda_o}{2n_i\Lambda}\left[1 + \frac{\Lambda^2}{\lambda_o^2}\left(n_i^2 - n_d^2\right)\right] \tag{27}$$

$$\sin\theta_d = \frac{\lambda_o}{2n_d\Lambda}\left[1 - \frac{\Lambda^2}{\lambda_o^2}\left(n_i^2 - n_d^2\right)\right] \tag{28}$$

where n_i and n_d are the refractive indices for the incident and diffracted light, respectively. Equations (27) and (28) were first derived by Dixon[8] for AO diffraction in a uniaxial crystal wherein the interaction plane is perpendicular to the *c* axis. The wavevector loci for the ordinary polarized light (*o*-wave) and the extraordinary polarized light (*e*-wave) are concentric circles; thus the two

equations can be separately solved. In general the refractive index for an extraordinary polarized light (*e*-wave) is a function of the polar angle of the incident and diffracted light. Thus, Dixon's equations are not applicable in practice since Eqs. (27) and (28) are coupled.

In order to decouple the input and diffracted angles from this pair of equations, we have chosen to express the wavevectors in the exact momentum matching condition using an elliptical parametric representation. Since the polarization is switched in the birefringent diffraction, the output characteristics of the diffracted light are same as the input characteristics of the incident light with the orthogonal polarization. Therefore, we need to consider only the input frequency-angle characteristics of the birefringent diffraction. The phase matching equations may be written in a form similar to the Dixon equations

$$e \rightarrow o: \qquad \hat{s}_e \cdot \hat{s}_a = \frac{\lambda}{2\mu_e \Lambda}\left[1 + \frac{\Lambda^2}{\lambda^2}(\mu_e^{\,2} - 1)\right] \tag{29}$$

$$o \rightarrow e: \qquad \vec{\sigma}_o \cdot \vec{\sigma}_a = \frac{\lambda}{2\Lambda}\left[\vec{\sigma}_a^{\,2} + \frac{\Lambda^2}{\lambda^2}(\vec{\sigma}_o^{\,2} - 1)\right] \tag{30}$$

where

$$\hat{s}_a = (\cos\theta_a, \sin\theta_a) \qquad \hat{s}_e = (\cos\theta_e, \sin\theta_e) \qquad \mu_e = (\cos^2\theta_e + e^{-2}\sin^2\theta_e)^{-1/2}$$

$$\vec{\sigma}_a = (\cos\theta_a, e^{-1}\sin\theta_a) \qquad \vec{\sigma}_o = (\cos\theta_o, e^{-1}\sin\theta_o) \tag{31}$$

where $e = n_c/n_o$ is the ratio of the principal refractive indices, θ_a, θ_o, and θ_e are the polar angles of the acoustic wave, ordinary, and extraordinary optical wave, respectively. The phase matching Eqs. (29) and (30) are the basic equations for AO diffraction in the Bragg regime.

To proceed with the analysis we introduce a dimensionless parameter *a*, defined as the ratio of optical wavelength (inside the medium) to the acoustic wavelength, $a = \lambda/\Lambda$. In terms of the wavelength ratio Eqs. (29) and (30) can be written in the form of quadratic equations.

$$q_{eo}(a) = a^2 - 2a\mu_e(\hat{s}_e \cdot \hat{s}_a) + \mu_e^2 - 1 = 0 \tag{32}$$

$$q_{oe}(a) = \vec{\sigma}_a^{\,2}a^2 - 2a(\vec{\sigma}_a \cdot \vec{\sigma}_o) + \vec{\sigma}_o^2 - 1 = 0 \tag{33}$$

Equations (32) and (33) may be considered the dispersion relations for the acousto-optic "grating" for an extraordinary and ordinary light input, respectively. Consider, for example, the diffraction of an extraordinary wave into an ordinary wave in a uniaxial crystal. Solving the quadratic equation [Eq. (32)] yields the wavelength ratio a for the $e \rightarrow o$ type diffraction

$$a = \mu_e\left\{\sin\theta_i \pm \sqrt{\sin^2\theta_i - (1 - \mu_e^{\,-2})}\right\} \tag{34}$$

where $\theta_i = \theta_e - \theta_a - \pi/2$ is the incidence angle. Equation (34) admits two real roots if $|\sin\theta_i| \geq \sqrt{1 - \mu_e^{\,-2}}$. Depending on the separation of the two roots, the AO diffraction can be classified into two regimes; referred as transverse and longitudinal spatial modulation.[20]

Transverse Spatial Modulation By selecting the incidence angle near its critical value, the two roots are close to each other. This happens when direction of the acoustic wave is nearly perpendicular to that of the optical waves. The acoustically driven polarization provides a transverse spatial modulation (TSM) to the incident light beam. Similar to isotropic AO diffraction, the TSM acts as an optical beam deflector.

The characteristics birefringent diffraction can be utilized to provide significant performance advantages for of the AO deflector are. For instance, when the light beam is chosen to incident at the critical angle, Eq. (32) yields two equal roots and the acoustic roots. The AO diffraction is said to operate at the tangential phase matching (TPM) since acoustic wavevector is tangential to the locus of the diffracted wavevector. At TPM the AO deflector acquires a wideband frequency characteristics since a range of acoustic frequencies nearly satisfy the exact phase matching condition. The optic and acoustic wavelengths at TPM are related by

$$\lambda_o = \Lambda_t \sqrt{\mu_e^2 - 1} \approx \Lambda_t \sqrt{2n_o \Delta n} \sin\theta_e \tag{35}$$

where $\Delta n = n_o(e-1)$ is the birefringence. At $\theta_e = 90°$, the acoustic frequency reaches a maximum value.

$$\lambda_o \approx \Lambda_t \sqrt{2n_o \Delta n} \tag{36}$$

Longitudinal Spatial Modulation By selecting the optical incidence much larger than the critical angle, the two terms in Eq. (34) are about equal. Only the solution that corresponds to the difference of the two terms yields a low acoustic frequency near its minimum value. In this case the acoustic wavevector has a larger component along the direction of the optical wave, the AO diffraction thus provides a longitudinal spatial modulation (LSM) to the incident light. Unlike the previous case the LSM acts as an acoustically tuned optical bandpass filter. When the acoustic frequency is changed, the passband wavelength is tuned accordingly while the diffracted optical beam remains at a fixed deflection. This LSM-based AO device forms the basis of the acousto-optic tunable filter (AOTF).

Since the wavelength ratio is small, in this case the second order in Eq. (32) or (33) can be neglected. For an incident light with either polarization, an approximate solution of the center wavelength the AOTF passband is

$$\lambda_o \approx \frac{\Lambda \Delta n \sin^2\theta_o}{\cos(\theta_a - \theta_o)} \tag{37}$$

where $\Delta n = n_e - n_o$ is the birefringence. At $\theta_a = 90°$, the incident and diffracted optical waves are collinear with the acoustic wave, Eq. (37) reduced to

$$\lambda_o = \Lambda \Delta n \tag{38}$$

Equation (38) is the momentum-matching condition for the collinear AOTF.

Frequency Characteristics of AO Interaction

In the near-Bragg regime, the AO diffraction is determined by the z-component of phase mismatch function $\psi = \Delta k_z L/2\pi = \Delta\sigma_z L$. In our analysis, this z-component mismatch is caused by the deviation of the light incidence from exact momentum matching. Based on this model it can be shown that the momentum mismatch (normalized to 2π) is $\Delta\sigma_z = (n_o/2)q$, where q is defined in Eqs. (32) and (33) for $e \rightarrow o$ and $o \rightarrow e$ type diffraction, respectively. Substituting $\psi = Ln_o q/2$ from Eq. (32) or (33) into Eq. (21), the bandpass function of AO diffraction can be expressed as a function of the variation of the acoustic angle θ_a and acoustic frequency f. It is convenient to normalize the acoustic frequency to a center frequency f_o (wavelength Λ_o). In terms of the normalized acoustic frequency ($F = f/f_o$), the phase mismatch ψ can be written as

$$\psi = \frac{l}{2}(F^2 - FF_m + F_t^2) \tag{39}$$

where

$$l = L/L_o \qquad L_o = n_o\Lambda^2/\lambda_o \qquad F_m = 2(n_o\Lambda_o/\lambda_o)\mu_e \sin\theta_i \qquad F_t = f_t/f_o \tag{40}$$

Isotropic Diffraction Bandshape By choosing $F_m = 1 + (\Delta F/2)^2$, the bandshape function $W(\psi)$ has equal loss at the two ends of the passband $F_1 = 1 + (\Delta F/2)$, where ΔF is the fractional bandwidth of the AO interaction. The diffraction efficiency reduces to 0.5, where $\psi = 0.45$. This corresponds to a fractional bandwidth

$$\Delta F = 1.8/l \tag{41}$$

To realize octave bandwidth, ($\Delta F = 2/3$) for instance, the normalized interaction length l is equal to 2.7. Figure 2*a* shows the bandshape of isotropic AO diffraction.

Birefringent Diffraction Bandshape For $e \rightarrow o$ diffraction, it is possible to obtain a wide bandpass response by operating near tangential phase matching (TPM). At TPM the two

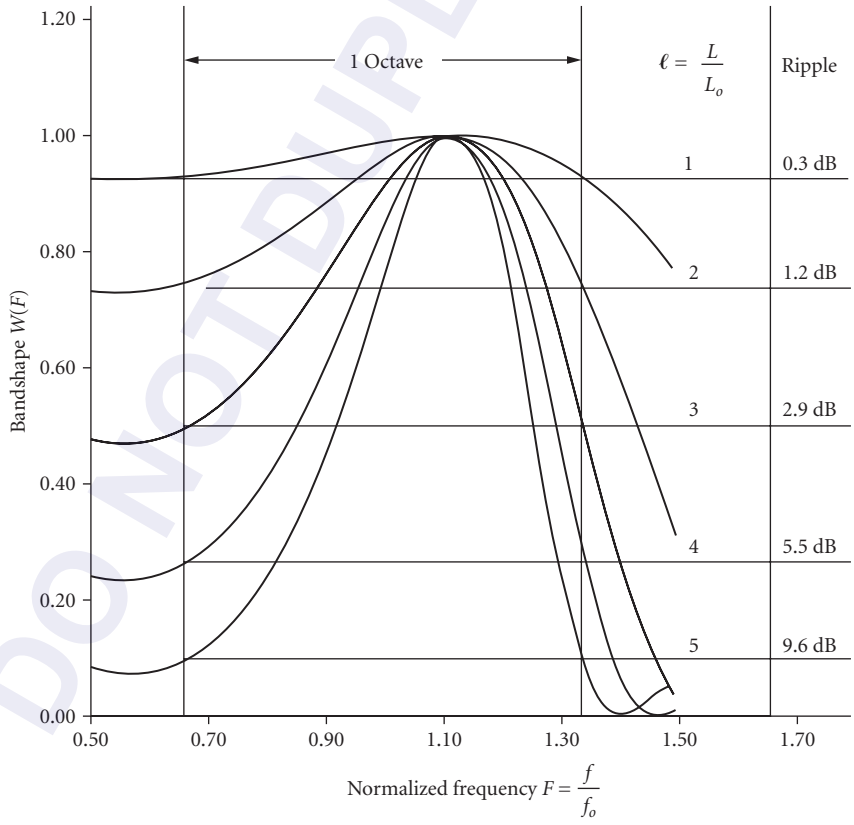

FIGURE 2 Acousto-optic bandshapes: (*a*) isotropic diffraction and (*b*) birefringent diffraction.

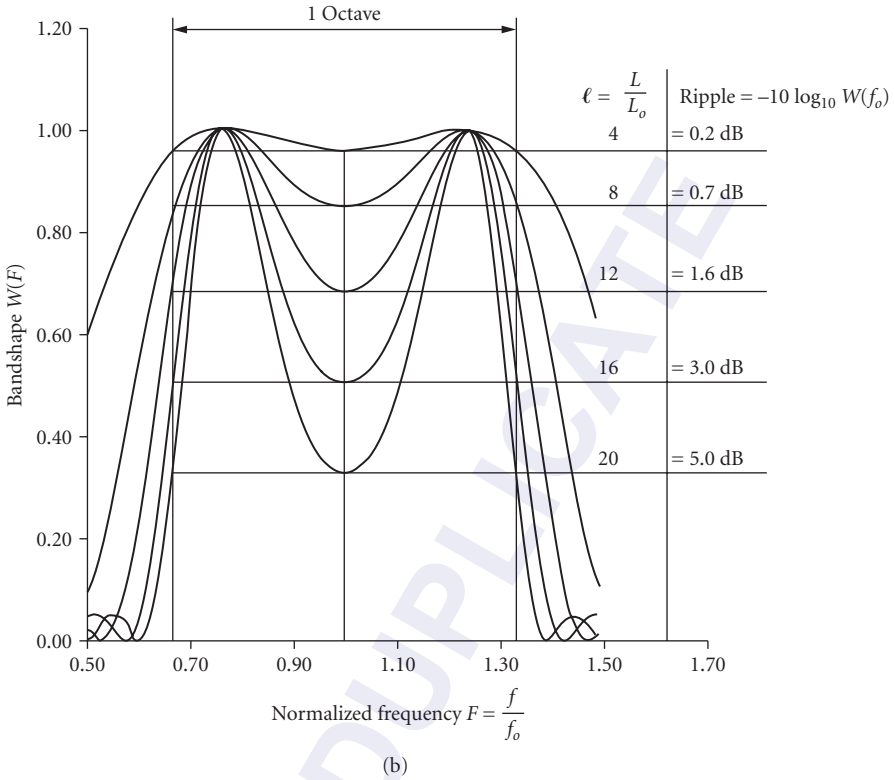

FIGURE 2 (*Continued*)

phase-matching frequencies coincide and the AO bandpass exhibits a flat-top shape with a bandwidth

$$\Delta F = \frac{\Delta f}{f} \approx \left(\frac{3.6}{l}\right)^{1/2} \tag{42}$$

For octave bandwidth ($\Delta F = 2/3$) the normalized interaction length l is equal to 8.1. This represents an efficiency advantage factor of 3 compared to isotropic AO diffraction. Figure 2*b* shows the bandshape of the birefringent AO diffraction.

Acousto-Optic Interaction of Finite Geometry

The plane wave analysis of AO interaction in the Bragg regime appears to be inadequate for real devices since the interaction geometry usually involves optical and acoustic beams of finite sizes with nonuniform amplitude distributions, for example, a Gaussian optical beam and a divergent acoustic beam. Gordon[6] considered the AO diffraction in finite interaction geometry using the Green's function solution for the wave equation. To make the approach analytically tractable, the first-order Born's approximation is used, which is same as the weak interaction assumption.

Instead of the Green's function solution, an equivalent approach is to decompose the optical and acoustic waves into angular spectrum of plane waves (ASW) and add all the spatial frequency components of the

diffracted light that satisfy the exact phase-matching condition.[21,22] Since the AO interaction is modeled as a filtering process in the spatial frequency domain, this approach is referred to as the frequency domain analysis.

As an example we use the frequency domain approach to determine the frequency and angular characteristics of an AO deflector. To simplify the analysis we will make a two-dimensional model for AO interaction in the interaction (*x*-*z*) plane. The reduction of diffraction efficiency in the height (*y*-*z*) plane will be calculated in the real domain as an overlapping integral of the acoustic and optical beams in the transverse plane along the height direction.

In the case of weak interaction, there is negligible depletion of the incident light. Assume that the incident light amplitude is a constant, Eq. (15) can be integrated to yield

$$E_d(\vec{\sigma}) = j\kappa S(\vec{\sigma}_a)E_i(\vec{\sigma}_i)\delta(\vec{\sigma} - \vec{\sigma}_i - \vec{k}_a) = j\kappa S(\vec{\sigma}_a)E_i(\sigma - \vec{\sigma}_a) \tag{43}$$

where $\vec{\sigma}$, $\vec{\sigma}_i$, and $\vec{\sigma}_a$ are the wavevector components in the interaction plane for the diffracted light, incident light and the acoustic waves, respectively.

We assume that the acoustic beam consists of acoustic plane waves propagating along the *x* axis in the interaction (*x*-*z*) plane. It is generated by an acoustic transducer with a top electrode of effective length *L* along the *z* axis and height *H* along the *y* axis. We also assume that the incident light beam consists of optical plane waves propagating in the *x*-*z* plane at an angle of incidence γ_i with the *z* axis. The incident light beam has a Gaussian with a beam waist $2\omega_1$ and $2\omega_2$ at e^{-2} of the intensity profile in the interaction and height plane, respectively. By expanding the optical and acoustic field in terms of their spatial frequency components in the interaction plane and applying Eq. (43), the total power spectrum of the diffracted light intensity can be written as

$$I_d(F, \xi) = \eta W(F)\ U(\xi) \bullet J \tag{44}$$

where η is the small signal diffraction efficiency given by Eq. (19). The next three multiplying factors are briefly discussed as fellows.

Overlapping Integral The overlapping integral *J* of optical and acoustic profile in the height plane is given by

$$J = \frac{2}{\pi\omega_1\omega_2}\int_0^D\int_{-H/2}^{H/2} \left|V(x,y)\right|^2 e^{-y^2/\omega_2^2} e^{-(x-D/2)^2/\omega_1^2}\, dy\, dx \tag{45}$$

where $V(x, y)$ is the acoustic field distribution and can be determined by the Fresnel integral

$$V(x,y) = \int_{-H/2}^{H/2} \frac{1}{\sqrt{jB\Lambda x}}\left[\exp\left(\frac{j\pi(y_o - y)^2}{B\Lambda x}\right)\right] dy_o \tag{46}$$

where *B* is the curvature of the acoustic slowness surface in the transverse plane. The overlapping integral represents a reduction of diffraction efficiency of the AO diffraction due to acoustic diffraction in the transverse plane along the height direction. For a transducer of height *H*, the acoustic radiation in a region near the transducer is approximately collimated. This collimated region, known as the near field, extends a distance *D* from transducer and is given by

$$H_o = \sqrt{B\Lambda D} = V\sqrt{\tau B/f} \tag{47}$$

Numerical calculation of the overlapping integral *J* in Eq. (43) shows its value is on the order of unity if the transducer height *H* is chosen to be equal to H_o given by Eq. (47).

Bandpass Response The bandpass function $W(F)$ as a function of the normalized frequency *F* is equal to the magnitude square of the Fourier transform, that is, the power spectrum of the acoustic

field along the z axis. For a standard rectangular window of the transducer field, the bandpass function is same as that given by

$$W(\psi) = \text{sinc}^2(\psi) \tag{48}$$

where $\psi = \Delta\sigma_z L = (n_o/2)q$ is the phase mismatch along optical direction (z axis) and is given by Eq. (39) as a function of the normalized frequency F.

Spatial Frequency Spectrum The spatial frequency spectrum $U(\xi)$ expressed as a function of spatial frequency component ξ signal direction (x axis) is determined by the power spectrum of the incident optical beam profile along the x axis, the direction perpendicular to the optical direction. For input Gaussian light with a beam waist $2\omega_1$ along the z axis in the interaction plane, the spatial frequency spectrum $U(\xi)$ is given by

$$U(\xi) = \exp -(\Delta\sigma_x^2/\pi^2\omega_1^2) \tag{49}$$

where $\Delta\sigma_x = \xi - \sigma_i \sin\theta_i - \sigma_a$, ξ is the spatial frequency of the diffracted light along x axis.

6.4 ACOUSTO-OPTIC MATERIALS

The significant progress of AO devices has been due largely to the development of superior materials such as TeO_2 and GaP. In this section we shall review the material issues related to AO device applications. A comprehensive list of tables summarizing the properties of AO materials is presented at the end of this section. The AO material issues and the selection guidelines have been discussed in a previous publication.[12]

The selection of AO materials depends on the specific device application.[23] An AO material suited for one type of device may not even be applicable for another. For example, GaP is perhaps the best choice for making wideband AO deflectors or modulators. However, since GaP is optically isotropic, it cannot be used for tunable filter purposes.

Some of the requirements for materials' properties apply to the more general cases of optical device applications, for example, high optical transparency over wavelength range of interest, availability in large single crystals, and the like. We shall restrict the discussion to material properties that are particularly required for AO device applications

Acousto-Optic Figures of Merit

A large AO figure of merit is desired for device applications. There are several AO figures of merit that have been used for judging the usefulness of an AO material. The relevant one to be used depends on the specific applications. Several AO figures of merit are defined in the literature. These include

$$M_1 = \frac{n^7 p^2}{\rho V} \qquad M_2 = \frac{n^6 p^2}{\rho V^3} \qquad M_3 = \frac{n^7 p^2}{\rho V^2} \qquad M_4 = \frac{n^8 p^2 V}{\rho} \qquad M_5 = \frac{n^8 p^2}{\rho V^3} \tag{50}$$

where n is the index of refraction, p is the relevant elasto-optic coefficient, ρ is the density, and V is the acoustic wave velocity. These figures of merit are generally listed as the normalized quantities M (normalized to values for fused silica).

The figure of merit M_2 relates the diffraction efficiency η, to the acoustic power P_a for a given device aspect ratio L/H in accordance with Eq. (18). M_2 is the AO figure of merit most often referred to in the literature and is widely used for the comparison of AO materials. This is a misconception, since from the viewpoint of device applications, M_2 is usually not appropriate. Comparison of AO materials (or modes) based on M_2 can lead to erroneous conclusions. M_2 is used only when efficiency is the only parameter of

concern. In most practical cases, other parameters such as bandwidth and resolution must also be considered. To optimize the efficiency bandwidth product, the relevant figure of merit is $M_1 = nV^2M_2$.

In the design of AO deflectors, or Bragg cells, besides efficiency and bandwidth, a third parameter of interest is the aperture time τ. A minimum acoustic beam height H must be chosen to ensure that the aperture is within the near field of the acoustic radiation. With is choice, the relevant figure of merit for optimized efficiency for a specified bandwidth and aperture time is $M_3 = nVM_2$.

For wideband AO modulators, the acoustic power density P_d is often the limiting factor. The appropriate AO figure of merit is then M_4, that is, $M_4 = nV^2M_1$.

In the design of AO tunable filters, the parameters to be optimized are the product of efficiency η, the resolving power $\lambda_o/\Delta\lambda$, and the solid angular aperture $\Delta\Omega$. In this case the appropriate AO figure of merit is $M_5 = n^2M_2$.

Acoustic Propagation and Attenuation

The performance of AO devices also depends on the acoustic properties of the interaction medium. As seen from the figures of merit listed above, a low acoustic velocity is one of the most important desired material parameters for AO devices. It not only provides the advantage of lower drive power, but it also allows the realization of large resolution for AO deflectors and tunable filters for a specified maximum crystal length.

The anisotropic acoustic propagation characteristic also plays an important role in the performance of AO devices. For instance, the small curvature of slowness surface of the transverse plane in GaP allows a smaller transducer height and greatly lowers the drive power. The use of large acoustic beam walk-off in TeO_2 allows the realization of a preferred interaction geometry to extend interaction length or optical aperture.

A low acoustic attenuation is also desired for increased resolution of deflectors or aperture of tunable filters. Generally, at room temperature $\omega\tau_{th} << 1$, where ω is the angular frequency of the acoustic wave and τ_{th} is the thermal phonon relaxation, the dominant contribution to acoustic attenuation is due to Akhieser loss caused by relaxation of the thermal phonon distribution toward equilibrium. A widely used result of this theory is the relation derived by Woodruff and Erhenrich. It states that acoustic attenuation measured in nepers per unit time is given by[12] $\alpha = \gamma^2 f^2 \kappa T/\rho V^4$, where γ is the Grüneisen constant, T is the temperature, and κ is the thermal conductivity. From this relation, it is seen that the AO figure of merit and the acoustic attenuation approximately follow an inverse relation. Notice also that the acoustic attenuation has a quadratic frequency-dependence for most crystals. In practice, in some crystals (such as GaP), it has been found that the frequency dependence of attenuation $a \sim f^n$, where n varies from 1 to 2 as the frequency increases ranges. The deviation from a quadratic dependence may be attributed to the additional extrinsic attenuation caused by scattering from lattice imperfections.

Optical Birefringence

Optical birefringence is a requirement for materials used in AO tunable filters. The requirement is met by optically birefringent crystals so that the AO filter interaction can operate as a longitudinal spatial modulator (LSM). For AO deflectors and modulators, optical birefringence is not necessary. AO devices with high efficiency, wide bandwidth, and large resolution are realizable with superior isotropic materials such as GaP. However, in an optically birefringent crystal it is possible to operate at tangential phase matching (TPM), which provides an enhancement of interaction length l for a given fractional bandwidth. The optical birefringence in $LiNbO_3$ and TeO_2 has been largely responsible for the superior device performance.

Tabulation of Acousto-Optic Material Properties

To aid in the selection of AO materials, the relevant properties of some promising materials are listed below. Table 1 lists the values of elasto-optical tensor components. Table 2, taken from Ref. 24

TABLE 1 Elasto-Optic Coefficients of Materials

$$M_1 = 7.83 \times 10^{-7} \quad [\text{cm}^2\text{sg}^{-1}]$$
$$M_2 = 1.51 \times 10^{-18} \quad [\text{s}^3\text{g}^{-1}]$$
$$M_3 = 1.3 \times 10^{-12} \quad [\text{cm}^2\text{s}^2\text{g}^{-1}]$$

6.5 ACOUSTO-OPTIC DEFLECTOR

Acousto-optic interaction provides a simple means to deflect an optical beam in a sequential or random-access manner. As the driving frequency of the acoustic wave is changed, the direction of the diffracted beam can also be varied. The angle between the first-order diffracted beam and the incident beam for a frequency range Δf is approximately given by

$$\Delta\theta_d = \frac{\lambda \Delta f}{V} \tag{51}$$

In a deflector, the most important performance parameters are resolution and speed. The resolution, or the maximum number of resolvable spots, is defined as the ratio of the range of deflection angle divided by the angular spread of the diffracted beam, that is,

$$N = \frac{\Delta\theta_d}{\delta\theta_o} \tag{52}$$

The angular divergence of the incident optical beam is given by

$$\delta\theta_o = \xi \frac{\lambda}{D} \tag{53}$$

where D is the width of the incident beam and ξ is the a factor (near unity) that depends on the incident beam's amplitude distribution. For a nontruncated Gaussian beam $\xi = 4/\pi$. From Eqs. (51), (52), and (53) it follows

$$N \approx \tau \Delta f \tag{54}$$

where $\tau = D/V \cos \theta_o$ is the acoustic-transit time across the optical aperture. Notice that the acoustic-transit time also represents the (random) access time and is a measure of the speed of the deflector. Equation (54) shows that the resolution is equal to time (aperture) bandwidth product. This is the basic tradeoff relation between resolution and speed (or bandwidth) of AO deflectors.

It is instructive to specify the interaction geometry for AO deflectors using a dimensionless parameter A, the ratio of divergence angle between the optical and acoustic beams. For an acoustic wave generated from a flat transducer of width L, the acoustic beam divergence is given by

$$\delta\theta_a = \frac{\Lambda}{L} \tag{55}$$

TABLE 3 Interaction Geometry and Performance of AO Deflectors

Type I-Laser beam scanner
Regime of AO diffraction: Transverse SLM
Divergence ratio: A << 1, N >> 1
Primary performance: High resolution, high peak efficiency
Type II-Signal processing Bragg cell
Regime of AO diffraction: Transverse SLM
Divergence ratio/Resolution: A << 1, N >> 1
Primary performance: Wide bandwidth, large dynamic range

From the above equations, the divergence ratio A and resolution N are related by

$$A = \frac{\delta\theta_o}{\delta\theta_a} = \frac{l\Delta F}{N} \tag{56}$$

where $l = L/L_o$ is the normalized interaction length and $\Delta F = \Delta f/f_o$ is the fractional bandwidth. For isotropic AO diffraction F, $l\Delta F = 1.8$. Thus, an AO deflector is characterized by the requirement $A << 1$. As an example, to realize a high resolution AO deflector with 1000 resolvable spots, the divergence ratio must be less than 0.002. The use of expanded incident beam with diffracted limited optics becomes the most critical requirement in the design high-resolution AO deflectors.

In summary, the AO deflector can be viewed as a transverse spatial light modulator (SLM) with a large number of resolvable angular channels. Based on the primary performance goals and the interaction geometry the AO deflector can be further divided into type I-laser beam scanners and type II-signal processing Bragg cells. Table 3 lists the range of the divergence ratio and the key performance requirements for the two types of AO deflectors.

Deflector Interaction Geometry

Principle of Operation

Isotropic AO diffraction In the following we consider the design of AO deflectors.[25] Figure 3*a* and *b* shows the device geometry of an AO deflector in the interaction plane and transverse plane, respectively. A piezoelectric transducer is bonded to the appropriate face of a selected AO medium, oriented for efficient interaction. A top electrode deposited on the transducer defines the active area with equivalent acoustic beam length L and height H. An optical beam generally truncated to an aperture width, D is incident in the interaction plane at a proper Bragg angle with respect to the acoustic wavefront. The incident beam has a Gaussian profile with a beam waist $2\omega_1$ at $1/e^2$ of the intensity in the interaction plane and a beam waist $2\omega_2$ at $1/e^2$ intensity in the transverse plane.

In accordance to Eqs. (19) and (44) the peak diffraction efficiency of an AO diffraction under the weak interaction approximation is given by

$$\eta = \frac{\pi^2}{2\lambda_o^{\,2}} M_2 P_a \left(\frac{L}{H}\right) \cdot J \tag{57}$$

where L and H are the equivalent acoustic beam length and height and J is the overlapping integral given by Eq. (45). As an example, assume an optical Gaussian beam with a truncation ratio of 1.5 and a rectangular shaped electrode, numerical calculation shows when the electrode height is chosen to be equal to H_o so that the interaction region coincide with the acoustic near field. With this choice by Eq. (47), so that the AO interaction regionextends from the transducer to the acoustic near field, the peak diffraction efficiency becomes

$$\eta_o = \frac{\pi^2 P_a}{2\lambda_o^3 f^{3/2} \tau^{1/2}} \left(\frac{M_3}{\sqrt{B}}\right) \cdot l \tag{58}$$

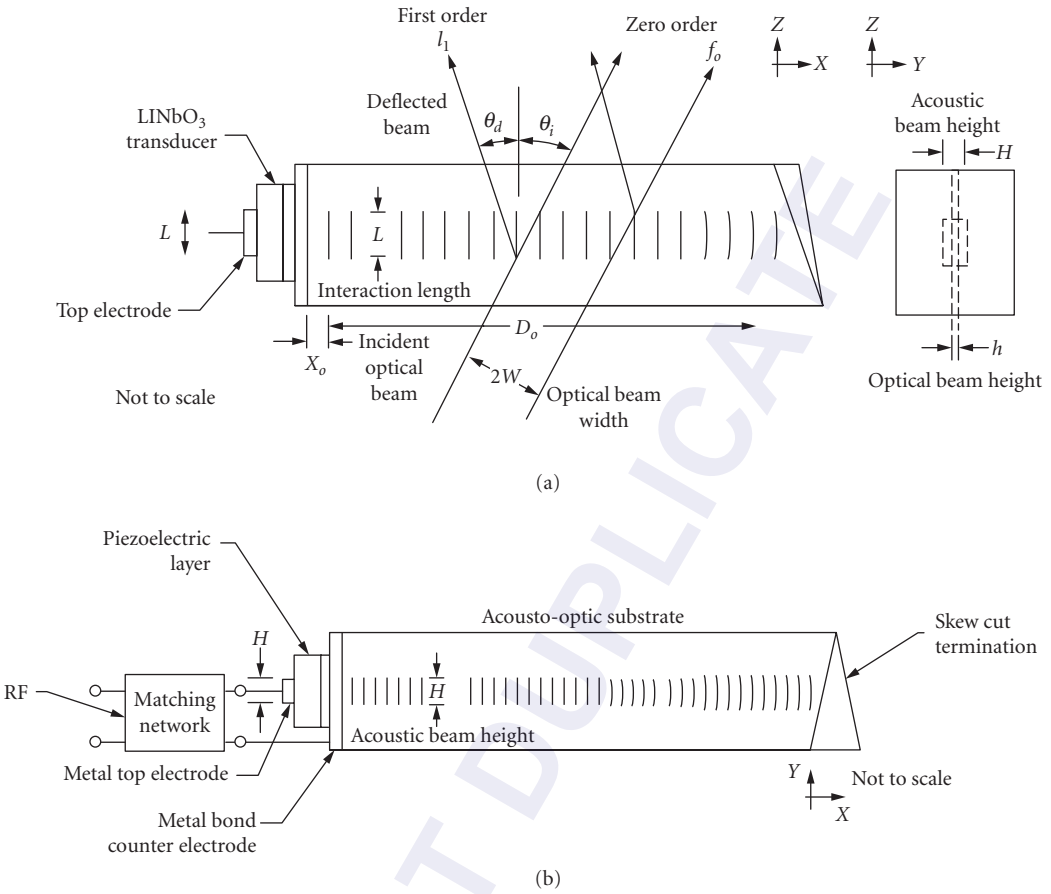

FIGURE 3 Acousto-optic deflector configuration: (*a*) interaction plane and (*b*) transverse plane.

Equation (58) is the basic equation for the design of the deflector. The multiplying factor *J/h* in Eq. (58) depends on the the optical beam geometry and the transducer electrode pattern in the transverse plane. For example, for an optical Gaussian beam with a truncation ratio $D/2\omega_1 = 1.5$, and rectangular electrode, the value of *J/h* exhibits a broad maximum about unity when $h \approx 0.7$. The choice of normalized interaction length $l = L/L_o$ is determined by the specified bandwidth. For isotropic diffraction it is related to the fractional bandwidth by, from Eq. (41):

$$l = \frac{1.8}{\Delta F} \tag{59}$$

With the selection of *l*, all the key performance parameters can be determined. The frequency response and spatial frequency distribution are obtained from Eqs. (48) and (49).

Anisotropic acoustic beam collimation Equation (58) shows that increased diffraction efficiency can be obtained by selecting AO materials and modes with small slowness curvature *B*. This is referred to as anisotropic acoustic beam collimation. An example is the shear mode in GaP propagating

along [110] direction.[26] In this case $B = 0.026$. Compared to an acoustically isotropic direction, the transducer height can be reduced by a factor of 6.2.

Resolution The resolution of the AO deflector obtainable is limited by the maximum available crystal size, requirement of large optics, and acoustic attenuation across the aperture. For most crystalline solids, the acoustic attenuation is proportional to f^2. If we allow a change of average attenuation of £ (dB) across the band, the maximum deflector resolution is given by

$$N_{\max} = \frac{£}{\alpha_o f_o} \tag{60}$$

where α_o (dB/μsec-GHz^2) is the acoustic attenuation coefficient.

It is instructive to estimate the maximum resolution achievable of AO deflectors. Consider, for example, a slow shear wave TeO_2 AO deflector with the following parameters: the octave bandwidth $f_o = 1.5\,\Delta f$, acoustic velocity $V = 0.62$ mm/μsec, acoustic attenuation coefficient $\alpha_o = 17.9$ (dB/μsec-GHz^2), maximum acoustic loss £ = 4 dB, aperture size $D = 5$ cm. From Eq. (60), the maximum resolution $N_{\max}$ is estimated to be about 3000 resolvable spots. This is close to the limit of a practical single stage AO deflector.

Birefringent tangential phase matching The maximum interaction length is limited by the bandwidth requirement. One approach of increasing while maintaining the fractional bandwidth ΔF is the use of birefringent diffraction. It was shown in Sec. 6.3 that by choosing the birefringent AO interaction near the tangential phase matching (TPM), a large band of acoustic frequencies will simultaneously satisfy the momentum matching condition. Equivalently a larger l can be used without narrowing the bandwidth. Under the birefringent TPM condition l is related to the fractional bandwidth by, from Eq. (42):

$$l = \frac{3.6}{\Delta F^2} \tag{61}$$

Compared to isotropic diffraction, the birefringent phase matching achieves an efficiency advantage factor of $2/\Delta F$, which becomes particularly significant for smaller fractional bandwidths. For instance, at 50 percent fractional bandwidth, the birefringent phase matching has an advantage factor of 4.

Since the first report on the use of birefringent TPM,[27] this performance enhancement technique has been used in the design of high resolution AO deflectors. All of these TPM deflectors are based on the birefringent diffraction in TeO_2 by a slow shear wave propagating on or near the [110] axis. Because of the exceptional low velocity and large figure of merit, these TeO_2 deflectors can achieve a large number of resolvable spots with a relatively low drive power.

The birefringent TPM deflectors can be classified as on-axis, optically rotated (OR) and acoustically rotated (AR) types. The design of these high resolution (HR) AO deflectors shown are briefly discussed as follows.

ON-axis TPM The first TPM type of AO deflector uses a slow shear wave propagating along the [110] axis of the TeO_2 crystal. This is referred as 90° or on-axis design, since the acoustic angle θ_a is chosen to be equal to 90°. For lowering TPM frequency, the AO diffraction birefringent diffraction uses circular birefringence in the TeO_2 crystal along the c axis.[28] Due to the slow velocity $V = 0.62$ mm/μsec, large resolution is obtainable with a relatively small size crystal. For instance, a 70-μsec cell realize more than 2000 resolvable spots with an optical aperture size of only 4.3 cm.

The on-axis design has several drawbacks. First, operation of this mode requires the use of circular polarizers. Second, the tangential frequency f_t is fixed and thus other performance parameters such as figure of merit cannot be independently chosen. Third, at the tangential phase-matching frequency, the second-order diffraction is also matched. The first-order diffracted light is rediffracted into the second order and results in a dip at the middle of the deflector passband.

To resolve this, two types of birefringent phase matching (TPM) are proposed. These include optically rotated (OR)[25] and acoustically rotated (AR)[29] TPM. For both types of phase-matching schemes the tangential matching frequency, $f_t = F_t f_o$, is given by, from Eq. (35):

$$f_t \approx \frac{V(\theta_a)}{\lambda_o}\sqrt{2n_o \Delta n}\sin\theta_e \tag{62}$$

Figure 4 shows the wavevector diagram for the two types of tangential phase matching.

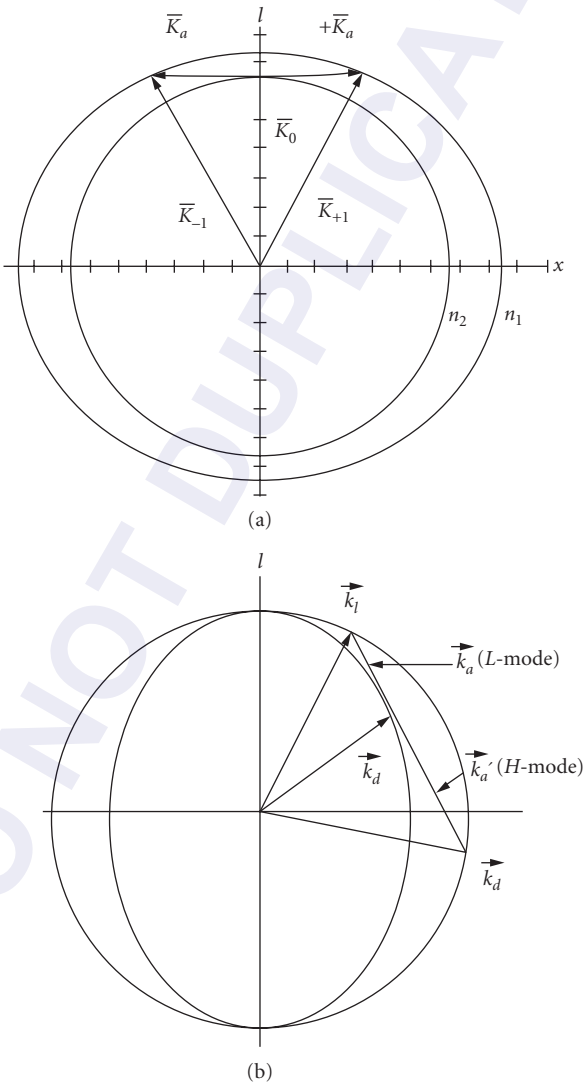

FIGURE 4 Wavevector diagram for tangential phase matching: (*a*) optically rotated geometry and (*b*) acoustically rotated geometry.

Optically rotated TPM The wavevector diagram shown in Fig. 4*a* describes the OR tangential phase matching. In this case the acoustic wavevector is chosen to be perpendicular to the optic axis. The incident light wavevector is allowed to rotate in different polar angles to achieve TPM at the selected frequency. Operation of this cell is more convenient than the on-axis device since the optical beam is linearly polarized. The OR type can realize long time aperture and higher efficiency since the acoustic wave is propagating along the isotropic direction. However, rediffraction into second order occurs since optical locus is symmetrical to the acoustic wave direction, the peak maximum efficiency remains limited by the dip in the center of the frequency response.

Acoustically rotated TPM Figure 4*b* shows the wavevector diagram for AR type of tangential phase matching. The constant azimuth plane is chosen as the interaction plane and the acoustic wavevector is rotated in the plane to be tangential to the locus of the diffracted light wavevector. Because of the rotation of the acoustic wavevector, the asymmetry of optical wavevector locus removes the degeneracy of the second-order diffraction. The dip in the bandpass is eliminated and thus can operate at the high-efficiency regime. This is the major advantage of the AR type cell. Since the acoustic wave is propagating along an anisotropic path, the large walk-off will reduce the optical aperture and thus limits the maximum resolution. A higher TPM frequency is chosen in order to achieve 2000 resolvable spots.

Phase array beam steering The birefringent type of tangential phase-matching technique is limited to AO diffraction in birefringent crystals. For isotropic materials such as wideband GaP Bragg cells an alternate technique for realizing TPM is to use acoustic beam steering.[7] In this approach, a phase array of transducers is used so that the composite acoustic wavefront will effectively track the Bragg angle. The simplest phase array employs a fixed inter-relevant phase difference that corresponds to an acoustic delay of $P\Lambda/2$, where P is an integer. This is referred to as first-order beam steering and can be realized in either a stepped array[7,30] or a planar configuration.[31] The two types of phased array configuration are shown in Fig. 5. The stepped array configuration is more efficient, but fabrication difficulty makes it less practical. The following analysis addresses only the planar configuration of first-order beam steering.

Consider the simplest geometry of a planar first-order beam-steered transducer array where each element is driven with an inter-element phase difference of 180°. The acousto-optic bandpass response of this transmitter configuration is equal to the single-element bandshape multiplied by the interference (array) function,[25]

$$W(F) = \left(\frac{\sin \pi X}{\pi X}\right)^2 \left(\frac{\sin N\pi Y}{N \sin \pi Y}\right)^2 \tag{63}$$

$$X = \frac{l_e F}{2}(F_b - F) \tag{64}$$

$$Y = \frac{d}{2}\left\{F(F_b - F) + \frac{1}{d}\right\} \tag{65}$$

where $l_e = L_e/L_o$, $d = D/L_o$, L_e is the length of one element, N is the number of elements, and D is the center-to-center distance between adjacent elements. Since radiation pattern for a single element is broad, the bandpass function is primarily determined by the array functions. The bandpass characteristics of the phased array are similar to birefringent diffraction with an equivalent interaction length $\ell = Nd$ and tangential matching frequency $F_t = 1/\sqrt{d}$.

Referring to Eq. (59), notice that at the peak of the grating lobe for the phase-array radiation, the value of the single element radiation $\text{sinc}^2 x$ is approximately equal to 0.5. There is thus an additional 3 dB loss due to the planar phase array. This is the major disadvantage of the phase array approach.

Since the power density is proportional to ℓ^2 for both types of TPM techniques, the increase of ℓ will significantly reduce the power density. This is of practical importance, since high power density

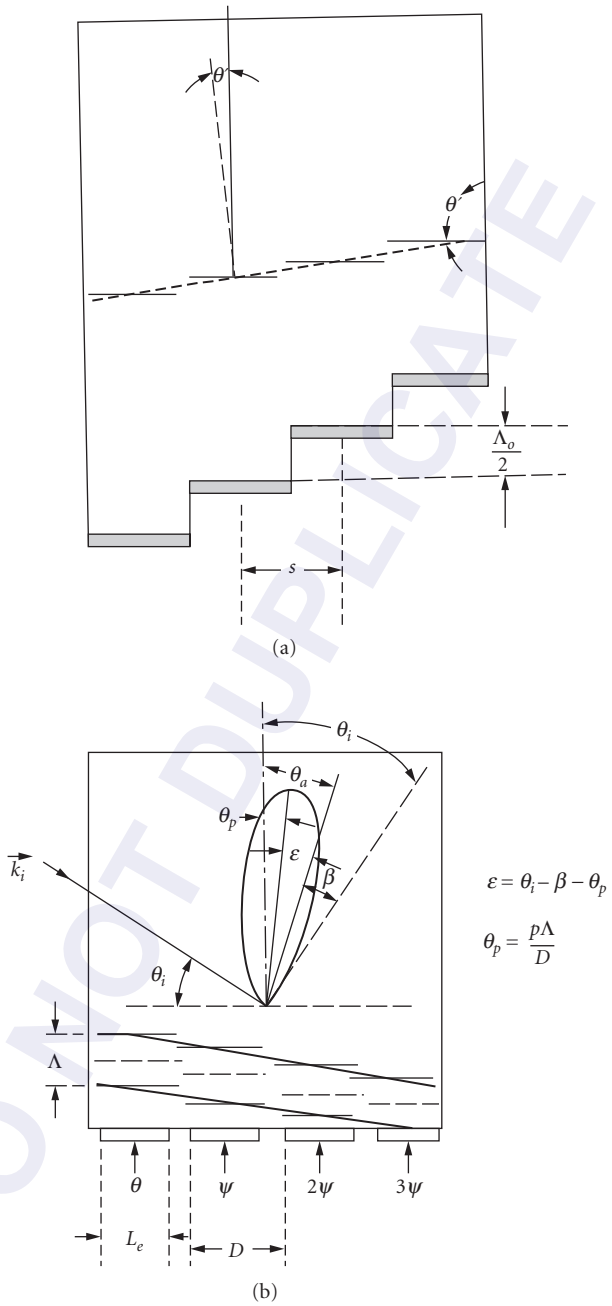

FIGURE 5 Acoustic beam steering using phased array: (*a*) stepped phased array and (*b*) planar phased array.

has been the dominant factor for performance degradation and even catastrophic device failure due to thermal gradient, nonlinear acoustics and overheating of transducers.

Birefringent phased array An interesting design combining the two performance enhancement techniques was reported in birefringent AO device using phased-array transducers.[32] Theoretical analysis of the new interaction geometry was described and experimentally demonstrated in a wide-band Bragg cell. The new approach provides design flexibility in the choice of acoustic and optic modes for increased efficiency, bandwidth, suppression of nonlinear effects, and optimizing other performance characteristics. The approach was further explored in the design of AO deflectors for specific performance improvement. By applying the birefringent phased array design to on-axis,[33] OR and AR configuration,[34] some of the deficiencies in each configuration can be removed. The design flexibility of this approach was also utilized to improve other key performance features, including, for example, the development of wide angle AO Bragg cells.[35]

AO Laser Beam Scanner The early development of AO deflectors was aimed at laser beam scanning applications. The primary goal is to provide a simple solid-state laser scanner that eliminates the inherent drawbacks of mechanical scanners due to moving parts, such as facet errors and the requirement of realignment because of bearing wear. For certain applications, such as beam-addressed optical memory, the rapid random access capability of AO deflectors offers a distinct advantage.

High Resolution AO Deflector The AO device for laser beam scanning is referred as the high resolution (HR) or type I AO deflector. As shown in Table 3, the primary design objective is to realize high resolution with the choice of a long-time aperture. Another key performance specification is high throughput or peak diffraction efficiency. Table 4 lists the performance of a few representative HR AO deflectors operated in the visible range. To satisfy the high peak efficiency specification, the degradation due to in-band dip must be minimized if OR type TPM rediffraction at high efficiency.

Resolution and Scan Rate In the design of the AO deflector for linear scanning, the most important system specification is the resolution, or maximum number of resolvable spots, N. Another key system parameter to specify is the scan time required to scan a single line and the flyback time. The acoustic transit time across the optical aperture sets the minimum flyback time for the scanner. The finite scan rate also degrades the resolution of the AO deflector. When the acoustic transit time τ (which is equal to flyback time) becomes an appreciable portion of the scan time T, there is a reduction of the effective aperture by the factor $1 - \tau/T$. This results in a resolvable number of spots for the scanning mode

$$N = \tau \Delta f [1 - \tau/(T + \tau)] \tag{66}$$

To minimize the loss of resolution, the transit time τ should be much less than the scan time T.

TABLE 4 Performance of High Resolution AO Deflectors

Material (Mode)	Center Frequency (MHz)	Bandwidth (MHz)	Aperture (μs)	TB Product	Efficiency (%/W)
TeO_2(S)	50	30	70	2100	200
TeO_2(S)	90	50	40	2000	110
TeO_2(S)	160	100	20	2000	95
GaP(S)	300	200	2.5	500	50

Resolution Enhancement One early design for increased resolution involves the use of cascaded deflectors.[36] Another technique is to use higher-order AO diffraction. One interesting design was to utilize the second-order diffraction in an OR-type birefringent cell.[37] Since both the first- and second-order diffractions are degenerately phase-matched, efficient rediffraction of the first order into the second order was obtained. However, the use of the second-order diffraction allows the deflector resolution to be doubled for a given bandwidth and time aperture.

AO Signal Processing Bragg Cell The deflection of an incident optical wave according to a single RF frequency input is just one of the characteristics of the acoustically driven transverse spatial modulator (TSM). More generally, the TSM encodes the light beam with the complete spectrum information contained in the RF signal. An AO deflector simultaneously driven by multifrequencies provides a simple but powerful technique for processing wideband electronic signals. This multifrequency AO device used for signal processing is referred to as the AO Bragg cell.

Dynamic Range The design of Bragg cells is similar to that of the AO deflector. However, instead of optimization of the peak diffraction efficiency, the primary objective of the Bragg cell design is to achieve a large dynamic range rather than the peak diffraction. The dynamic range is defined as the ratio of the intensity of the diffracted light to the intensity of the spurious light in the Bragg cell. The spurious optical beams are caused by the nonlinear mixing of various diffraction orders when multiple frequencies are simultaneously present. Hecht[38] analyzed isotropic AO diffraction with multiple acoustic waves with different carrier frequencies based on the coupled wave theory. His analysis shows that the dominant in-band nonlinear signals for two simultaneous signals at f_1 and f_2 are the third-order intermodulation (IM) products occurring at $2f_1 - f_2$ and $2f_2 - f_1$. The magnitude of this spurious signal due to multiple AO diffraction is

$$I_{\mathrm{AO}}(2,-1) = \frac{I_1^2 I_2}{36} \tag{67}$$

where I_1 and I_2 are the diffracted light efficiency at f_1 and f_2, respectively. To obtain a spurious-free dynamic range of 40 dB, for instance, the Bragg cell must be operated with diffraction efficiency less than 5 percent.

In our experimental work on wideband Bragg cells, we have found another type of IM product in the nonlinear response of Bragg cells.[39] This second source of TM products is caused by the nonlinear acoustic (NA) interaction that occurs at high acoustic power densities. A key parameter for the NA type IM products process is the critical interaction length $L_c = (\pi \gamma_2 f \tau)$, where γ_2 is the ratio of second-order nonlinear elastic coefficient to the first-order elastic coefficient. The dominant NA modes are second harmonics and two-tone third-order IM product, which grow according to $(L_c/L)^2 P_1^2/4$ and $(L_c/L)^4 P_1^2 P_2/9$, respectively. Based on the new theory, the AO type of IM products dominates when the ratio L_c/L is small, as the acoustic power increases. The dynamic range of the Bragg cell is reduced by the NA type of IM product, initially by the successive AO diffraction from fundamental and second harmonics and finally by the single AO diffraction from the acoustic IM product.

Wideband Bragg Cell Two candidate materials for wideband Bragg cells are GaP and $LiNbO_3$. Both have very low acoustic attenuation and large M_3^*, making them ideal for this purpose. A number of high performance wideband cells using these two materials have been developed with bandwidth in excess of 1000 MHz. These include the AR-type birefringent $LiNbO_3$ cell[40] and the phased-array GaP cell.[41] The best-known design is a $LiNbO_3$ device, which uses a *y-z* propagating off-axis *x*-polarized shear wave. The device demonstrated an overall bandwidth of 2 GHz, a peak diffraction efficiency of 6 percent per watt and about 600 resolvable spots. A summary of the representative wideband AO Bragg cells is shown in Table 5.

Multichannel Cell As an extension to the usual single-channel configuration there has been considerable activity in the development of multichannel Bragg cells (MCBC). The MCBC uses a pattern

TABLE 5 Performance of Acousto-Optic Bragg Cells ($\lambda_o = 830$ nm)

Material (Mode)	Center Frequency (MHz)	Bandwidth (MHz)	Aperture (μs)	TB Product	Efficiency (%/W)

of multiple individually addressed transducer electrodes in the transverse plane. In addition to the design rules used for single-channel cells, other performance parameters such as crosstalk, amplitude, and phase tracking must be considered.

Early work on MCBC uses the *y-z* cut shear-wave wideband $LiNbO_3$ cell design.[42] Good amplitude and phase tracking were obtained over the operating bandwidth of 1 GHz. The channel-to-channel isolation, typically about 25 dB, was limited by RF cross talk. In a later development of GaP MCBC,[43] reduction of electrical crosstalk (to –40 dB) was obtained by using stripline interconnection structures. The use of the anisotropic collimating modes in GaP also brings the advantage of lowering acoustic crosstalk.

6.6 ACOUSTO-OPTIC MODULATOR

Acousto-optic interaction has also been used to modulate light. The AO modulator uses the transverse spatial modulation (TSM) of AO interaction to convert an amplitude modulated RF signal into an intensity modulation light beam. Unlike AO deflectors, however, at the output end the diffracted light spectral components are focused into one channel to reproduce the video information via a collinear mixing process. Functionally the most important requirement for the AO modulators is its temporal response. Thus a basic design consideration for AO modulator is the limitation of temporal response caused by the finite acoustic transit time across the light beam. To reduce the transit time effect on the fidelity of the input video information, the AO modulator is operated in a focused beam geometry.

Following similar design procedure as the deflectors, we shall describe the characteristics of AO modulator by the basic parameters. As a modulator the key performance parameters are rise time or video modulation bandwidth, contrast ratio or rejection against the undeflected light beam, and the optical throughput, the diffracted light intensity integrated over the acceptance angular aperture. A thorough discussion on the tradeoff of key performance parameters of AO modulators is reviewed by Johnson.[44]

Based on the optics configuration AO modulators can be divided into type-I focused beam modulator and type II-wide beam modulator. Table 6 lists the interaction geometry and key performance requirement for the two types of AO modulators.

TABLE 6 Interaction geometry and key performance parameters of AO modulators

Type I: Focused beam modulator
- Regime of AO diffraction: Transverse SLM
- Divergence ratio/Resolution: A = 1, N = 2
- Primary performance: Wide modulation bandwidth, large optical throughput

Type II: Wide beam modulator
- Regime of AO diffraction: Transverse SLM
- Divergence ratio: A << 1, N >> 1
- Prime performance: High peak efficiency, high rejection ratio

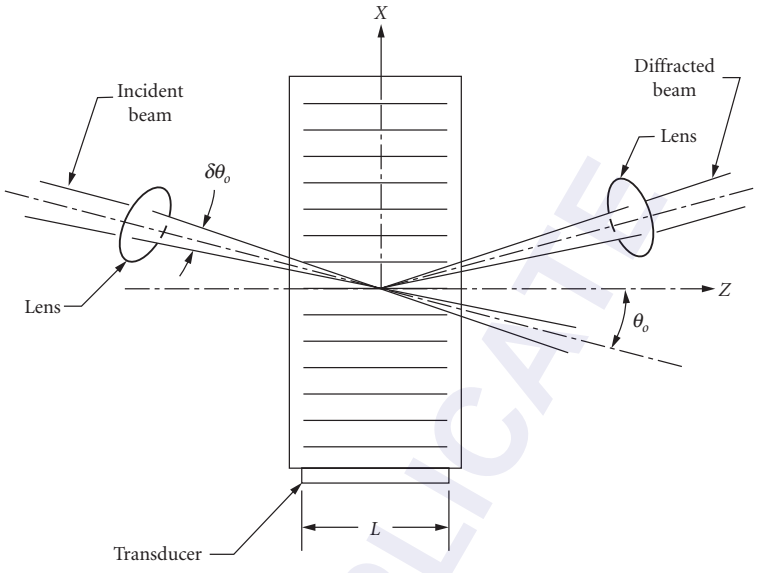

FIGURE 6 Diffraction geometry of acousto-optic modulator.

Principle of Operation Figure 6 shows the diffraction geometry of a focused-beam AO modulator. Unlike the AO deflector the optical beam is focused in both directions into the interaction region near the transducer. For an incident Gaussian beam with a beam waist d, ideally the rise time (10 to 90 percent) of the AO modulator response to a step function input pulse is given by

$$t_r = 0.64\tau \tag{68}$$

where $\tau = d/V$ is the acoustic transit time across the optical beam. To reduce rise time, the optical beam is focused to a spot size as small as possible. However, focusing of the optical beam will increase the optical beam divergence $\delta\theta_o$, which may exceed the acoustic beam divergence $\delta\theta_a$, $A > 1$. This will result in a decrease of the diffracted light since the Bragg condition will no longer be satisfied. To make a compromise between the frequency response (spatial frequency bandwidth) and temporal response (rise time or modulation bandwidth) the optical and acoustic divergence should be approximately equal, $A = \delta\theta_o/\delta\theta_a \approx 1$. The actual value of the divergence ratio depends on the tradeoff between key performance parameters as dictated by the specific application.

Analog Modulation In the following, we shall consider the design of a focused beam AO modulator for analog modulation, the diffraction of an incident Gaussian beam by an amplitude-modulated (AM) acoustic wave. The carrier, upper, and lower sidebands of the AM acoustic wave will generate three correspondingly diffracted light waves traveling in separate directions. The modulated light intensity is determined by the overlapping collinear heterodyning of the diffracted optical carrier beam and the two sidebands. Using the frequency domain analysis, the diffracted light amplitudes of an AO modulator were calculated. The numerical results are summarized in the plot of modulation bandwidth and peak diffracted light intensity as a function of the optical to acoustic divergence ratio A.[13] Design of the AO modulator based on the choice of the divergence ratio is discussed below.

Unity Divergence Ratio ($A \leq 1$) The characteristics of the AO modulator can be best described by the modulation transfer function (MTF), defined as the frequency domain response to a sinusoidal video signal. In the limit of $A \leq 1$, the MTF takes a simple form:

$$\text{MTF}(f) = \exp - (\pi f \tau)^2/8 \tag{69}$$

The modulation bandwidth f_m, the frequency at –3 dB is given by

$$f_m = \frac{0.75}{\tau} \tag{70}$$

From Eqs. (62) and (64), the modulator rise time and the modulation bandwidth are related by

$$f_m t_r = 0.48 \tag{71}$$

Minimum Profile Distortion (0.5 < A < 0.67) Equation (70) shows that the modulation bandwidth can be increased by further reducing the acoustic transit time τ. When the optical divergence $\delta\theta_o$ exceeds the acoustic divergence $\delta\theta_a$, that is, $A > 1$, the Bragg condition is no longer satisfied for all the optical plane waves. The light at the edges of the incident light beam will not be diffracted. This will result in an elliptically shaped diffracted beam. In many laser modulation systems this distortion of the optical beam is not acceptable. The effect of the parameter A on the eccentricity of the diffracted beam was analyzed based on numerical calculation.[45] The result shows that to limit the eccentricity to less than 10 percent, the divergence ratio value for A is about 0.67.

This distortion of the diffracted beam profile is caused by the finite acceptance angle of the isotropic AO diffraction. The limited angular aperture also results in the lowering the optical throughput. Based on curve fitting the numerical results the peak optical throughput can be expressed as a function of the divergence ratio[44]

$$I_1(A) = 1 - 0.211A^2 + 0.026A^4 \tag{72}$$

As an example, at $A = 0.67$, the peak throughput I_1 is about 94.9 percent. However, with the choice of unity divergence ratio, $A = 1$, it reduces to 81.5 percent.

Digital Modulation (1.5 < A <2) Another important case is the digital, or pulse modulation. Maydan[46] calculated the rise time and efficiency of pulsed AO modulators. His results show that an optimized choice of A is equal to 1.5, and that the corresponding rise time (10 to 90 percent) is

$$t_r = 0.85\tau \tag{73}$$

Contrast Ratio Another key performance parameter for AO modulator is the extinction ratio or the rejection against the undeflected light. To obtain an adequate extinction ratio, 30 dB, for instance, the angle of separation θ_D is chosen to be equal to twice that of the optical beam divergence. It follows that the acoustic frequency must be greater than

$$f_o = \frac{8}{\pi\tau} \tag{74}$$

Comparing to Eq. (70), the center frequency of the AO modulator is about 4 times that of the modulation frequency.

Birefringent Modulation In the above analysis of focused beam modulator it is assumed that the AO modulator is operated in the isotropic diffraction mode. Similar to the deflector case a large frequency bandwidth can be obtained by using birefringent diffraction. However, the input angular aperture according to Eq. (55) is proportional to 1/L, an increase of L will in effect reduce the modulation bandwidth as well as the optical throughput. Based on this argument, it was well recognized that the birefringent diffraction offers no advantage for AO modulators. A careful reexamination of this basic limitation shows that a wide angle AO modulation is obtainable if the birefringent diffraction satisfies the noncritical phase matching (NPM) condition.[48] The concept of NPM will be discussed in Sec. 6.7, "Acousto-Optic Tunable Filter."

TABLE 7 Performance of Acousto-Optic Modulators

Material	Wavelength (μm)	Center Frequency (MHz)	Modulation Bandwidth (MHz)	Rise Time (nsec)	Efficiency (%)
TeO_2	0.44–0.64	200	40	10	80
GaP	0.63–0.83	200	40	10	80
GaP	1.06	160	32	15	70
GaAs	1.3–1.55	120	24	20	70
Ge	10.6	100	20	25	70

Focused Beam AO Modulator

Intensity modulator Simple intensity AO modulators using the focused beam interaction geometry have been standard approach for external modulation of lasers. Since the development of laser diode with wideband internal modulation capability, the use of AO modulators has been limited to gas and solid-state lasers for moderate modulation bandwidth f_m. Because of the high power requirement, in practice f_m of AO modulators is limited to about 50 MHz. Table 7 lists a few selected AO modulators and typical performances.

Intracavity modulator Since AO diffraction occurs in all crystal or amorphous solids, high optical quality, low optical absorption AO materials are readily available for intracavity applications. These intracavity modulator applications include Q-switching, mode locker, and cavity dumping. All of these intracavity AO modulator have been discussed in the early review paper.[13] In the following we shall only briefly discuss the AO Q-switches.

Q-switching of YAG and other similar solid state lasers has been an importance requirement for indutral applications such as cutting, scribing, marking, and other material processing process. In a Q-switching operation, the optical loss introduced by the intracavity AO modulator keeps the laser below threhold. When the loss is suddenly removed by switching off the acoustic pulse, the laser bursts into a short pulse with extremely high intensity. During Q-switching, the AO modulator should add minimum loss to the laser cavity.

Besides low loss, other key performance requirement of the AO Q-switch include (a) high damage threshold, (b) fast pulse rise time, (c) good thermal and mechanical property, and (d) polarization-insensitive. The last requirement is due to a special characteristics of YAG lasers that it reaches maximum gain when operated in a unploarized mode. To meet these requirement the standard design for high power laser is a shear wave AO modulator using UV grade fused silica as the interaction medium. Longitudinal mode Q-switch will have the advantage of lower drive power and faster rise time; however, since the diffracted efficiency for perpendicular polarization is five times that of the parallel polarization. the TAG laser will tend to operate in the mode with the lower diffraction efficiency. Thus the use of longitidinal mode Q-switch is limited to lower power polarized laser. More efficient materials such as $PbMoO_4$ or TeO_2 have been used but because of lower damage threshold these crystal Q-switch is also limited to low power lasers.

Widebeam AO Modulator

Image (Scophony) AO Modulator The focused-beam-type AO modulator has certain disadvantages. The diffraction spread associated with the narrow optical beam tends to lower the diffraction efficiency. More importantly, the focusing of the incident beam results in high peak intensity that can cause optical damage for even relatively low laser power levels. For these reasons, it is desirable to open up the optical aperture. Due to the basic issue of acoustic transit time, the temporal bandwidth of the wide-beam AO modulator will be severely degraded.

In certain applications, such as the laser display system, it is possible to use a much broader optical beam in the modulator than that which would be allowed by the transit time limitation. The operation of the wide-beam modulator is based on the ingenious technique of Scophony light modulation. A brief description of the Scophony light modulator is given below; refer to Johnson[47] for a thorough treatment.

The Scophony technique is applicable to any system that scans a line at a uniform scan velocity. The basic idea is to illuminate a number of picture elements, or pixels, in the modulator (window) onto the output line, such that the moving video signal in the modulator produces a corresponding image of the pixels that travels across the beam at sound velocity. The image can be made stationary by directing the image through a deflector that scans with equal and opposite velocity. Now, if the window contains N spots, then N picture elements can be simultaneously exposed in the image at any instant, and each picture element will be built up over the access time of the window that is equal to N times the spot time. Since the spots are immobilized, there is no loss of resolution in the image, provided that the modulator bandwidth is sufficient to produce the required resolution. The design of the wide-beam AO modulator is thus the same as that of the Bragg cell.

Acousto-Optic Frequency Shifters Because of the frequency shift associated with the acousto-optic diffraction, the AO frequency shifter (AOFS) provides a capability of shifting the optical frequency of an incident light beam, a unique ability shared by no other technique. Usually the frequency shift specified is either fixed or tunable over a small frequency range. Since the AOFS is often intended for use in interferometry, an important requirement is to minimize the distortion of diffracted light beam profile. For isotropic AO diffraction the use of an input optics design with low divergence ratio $A << 1$ is the preferred choice.

Another important requirement is the rejection of incident light, other diffraction order with opposite frequency shift, as well as various spurious signals caused by multiple acoustic reflections within the AO medium. To achieve high suppression of the residual AM components and obtain the ideal spectral purity, the acoustic wave reflection and diffraction in the medium must be considered in the device design and fabrications of the AOFS. Similar to focused beam AO modulator the wide angle design using birefringent phase array can provide large degree of freedom in the optimization of performance parameters such as the optical throughput. The use of crossed polarizers also provides the advantage of increased rejection ratio.

In the design of AOFS, the desired frequency shift f_s is generally chosen to be near the center frequency f_o. This constraint is obviously impractical for small frequency shift $f_s << f_o$. The AOFS in this case is typically constructed by putting two copropagating AO cells in cascade so that the two frequencies subtract to give the small frequency shift. The cascaded AO cells configuration can also be used to obtain variable frequency shifts without change of direction. For example, two counterpropagating AO cells can be configured so that the two frequencies are added while the directions cancel each other.

6.7 ACOUSTO-OPTIC TUNABLE FILTER

The acousto-optic tunable filter (AOTF) is an all-solid-state optical filter that operates on the principle of acousto-optic diffraction in an anisotropic medium. The center wavelength of the filter passband can be rapidly tuned across a wide spectral range by changing the frequency of the applied radio frequency (RF) signal. In addition to the electronic tunability, other outstanding features of the AOTF include large angular aperture while maintaining high spectral resolution, inherent intensity, and wavelength modulation capability.

The first AOTF, proposed by Harris and Wallace[9] used a configuration in which the interacting optical and acoustic waves were collinear. Later, Chang[10] extended the AOTF concept to a noncollinear configuration. The theory and practice of the AOTF have been discussed in a review paper.[49]

Based on the viewpoint of device physics, the AOTF is a new AO device of a fundamentally different nature compared to AO deflectors and modulators. It operates on longitudinal spatial light modulation (SLM) that occurs only in an anisotropic medium. In accordance with the interaction geometry

TABLE 8 Interaction Geometry and Key Performance Goals of AO Tunable Filters

Regime of AO diffraction: Longitudinal SLM
Divergence ratio: a >> 1, R >> 1
Primary performance: Large angular aperture, high optical throughput
Type II Critical phase matching (CPM) AOTF
Regime of AO diffraction: Longitudinal SPM
Primary performance requirement: High resolution, low drive power

and primary performance requirement the AOTF can be divided into two types. Type I noncritical phase matching (NPM) AOTF exhibits large angular aperture and high optical throughput, is best suited for spectral imaging applications. Type II critical phase matching (CPF) AOTF emphasizes high spectral resolution and low drive power, has shown to be best suited for use as a dynamic-wavelength division multiplexing (WDM) component. Table 8 shows the range of divergence ratio and key performance requirements for the two types of AOTFs.

Principle of Operation

Collinear acousto-optic tunable filter Consider the collinear AO interaction in a birefringent crystal, a linearly polarized light beam will be diffracted into the orthogonal polarization if the momentum matching condition is satisfied. For a given acoustic frequency the diffracted light beam contains only for a small band of optical frequencies centered at the passband wavelength,

$$\lambda_o = \frac{V\Delta n}{f} \tag{75}$$

where Δn is the birefringence. Equation (75) shows that the passband wavelength of the filter can be tuned simply by changing the frequency of the RF signal. To separate the filtered light from the broadband incident light, a pair of orthogonal polarizers is used at the input and output of the filter. The spectral resolution of the collinear AOTF is given by

$$R = \frac{\Delta nL}{\lambda_o} \tag{76}$$

A significant feature of this type of electronically tunable filter is that the spectral resolution is maintained over a relatively large angular distribution of incident light. The total angular aperture (outside the medium) is

$$\Delta\psi = 2n\sqrt{\frac{\lambda_o}{\Delta nL}} \tag{77}$$

where n is the refractive index for the incident light wave.

This unique capability of collinear AOTF for obtaining high spectral resolution within a large angular aperture was experimentally demonstrated using a transmissive-type configuration shown in Fig. 7.[50] A longitudinal wave is mode converted at the prism interface into a shear wave that propagates down along the x axis of the $CaMoO_4$ crystal. An incident light with a wavelength satisfying Eq. (75) is diffracted into the orthogonal polarization and is coupled out by the output polarizer. The center wavelength of the filter passband was changed from 400 to 700 nm when the RF frequency was tuned from 114 to 38 MHz. The full width at half-maximum (FWHM) of the filter passband was measured to be 8 Å with an input light cone angle of ±4.8° (F/6). This angular aperture is more than one order of magnitude larger than that of a grating for the same spectral resolution.

Considering the potential of making electronically driven rapid-scan spectrometers, a dedicated effort was initiated to develop collinear AOTFs for the UV using quartz as the filter medium.[51] Because of the collinear structure quartz AOTF demonstrated very high spectral resolution. With a 5-cm-long crystal, a filter

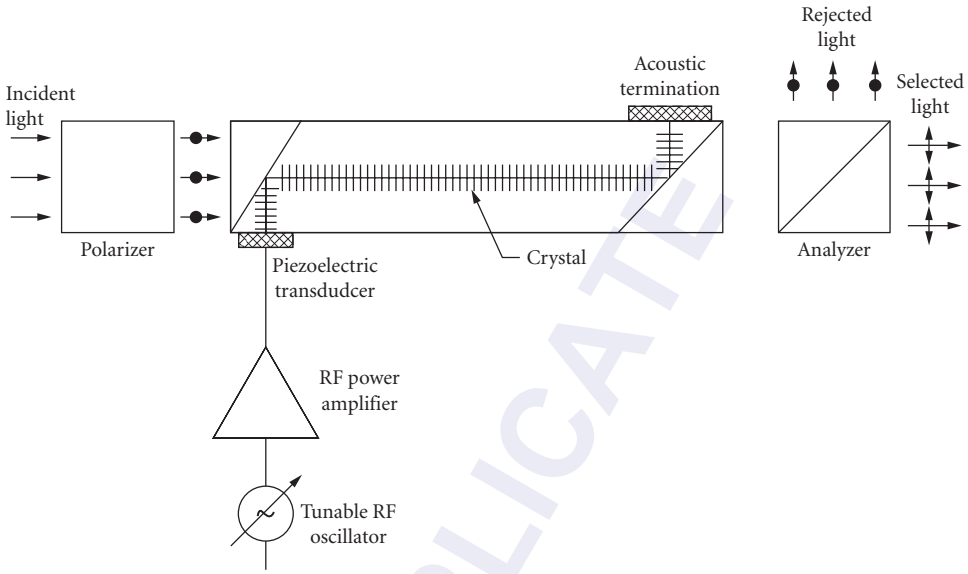

FIGURE 7 Collinear acousto-optic tunable filter with transmissive configuration.

bandwidth of 0.39 nm was obtained at 250 nm. One limitation of this mode conversion type configuration is the complicated fabrication procedures in the filter construction. To resolve this issue, a simpler configuration using acoustic beam walk-off was proposed and demonstrated.[52] The walk-off AOTF allows the use of multiple transducers and thus could realize a wide tuning range. Experimentally, the passband wavelength was tunable from about 250 to 650 nm by changing the acoustic frequency from 174 to 54 MHz. The simple structure of the walk-off filter is particularly attractive for manufacturing.

Noncollinear AOTF The collinearity requirement limits the AOTF materials to rather restricted classes of crystals. Some of the most efficient AO materials (e.g., TeO_2) are excluded since the pertinent elasto-optic coefficient for collinear AO interaction is zero. Early work has demonstrated a noncollinear TeO_2 AOTF operation using a S[110] on-axis design. However, since the phase-matching condition of the noncollinear AO interaction is critically dependent on the direction of the incident angle of the light beam, this type of filter has a very small angular aperture (on the order of milliradians), and its use must be restricted to well-collimated light sources. To overcome this deficiency, a new method was proposed to obtain a large-angle filter operation in a noncollinear configuration.

The basic concept of the noncollinear AOTF is shown in the wavevector diagram in Fig. 8. The acoustic wavevector is chosen so that the tangents to the incident and diffracted light wavevector loci are parallel. When the parallel tangents condition is met, the phase mismatch due to the change of angle incidence is compensated for by the angular change of birefringence. The AO diffraction thus becomes relatively insensitive to the angle of light incidence, a process referred to as the noncritical phase-matching (NPM) condition. The figure also shows the wavevector diagram for the collinear AOTF as a special case of noncritical phase-matching.

Figure 9 shows the schematic of a noncollinear acousto-optic tunable filter. The first experimental demonstration of the noncollinear AOTF was reported for the visible spectral region using TeO_2 as the filter medium. The filter had a FWHM of 4 nm at an *F*/6 aperture. The center wavelength is tunable from 700 to 450 nm as the RF frequency is changed from 100 to 180 MHz. Nearly 100 percent of the incident light is diffracted with a drive power of 120 mW. The filtered beam is separated from the incident beam with an angle of about 6°. The experimental result is in agreement

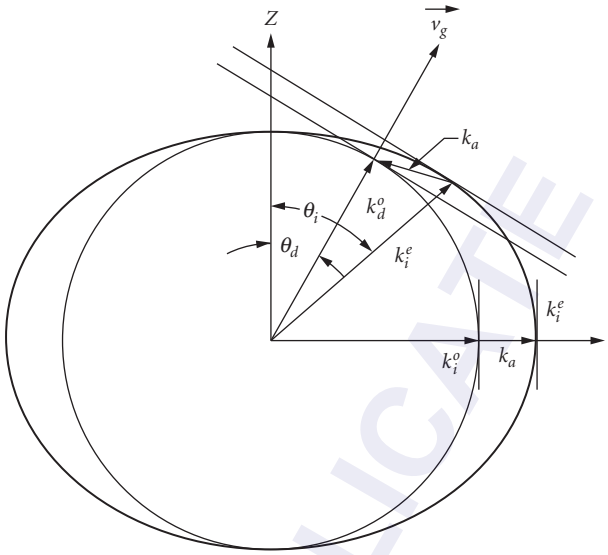

FIGURE 8 Wavevector diagram for noncollinear AOTF showing noncritical phase matching.

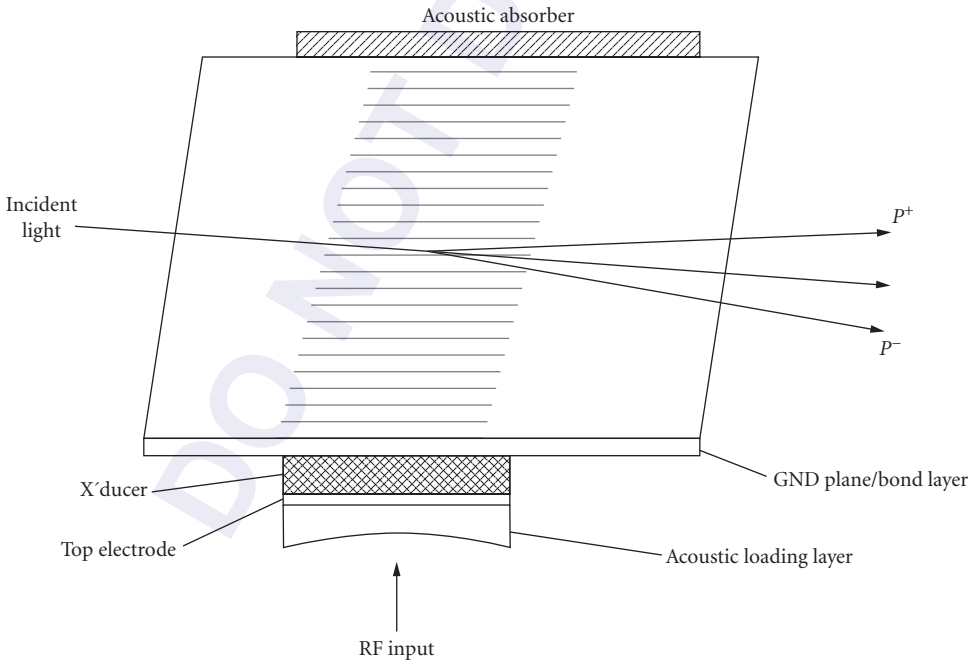

FIGURE 9 Schematic of noncollinear AOTF.

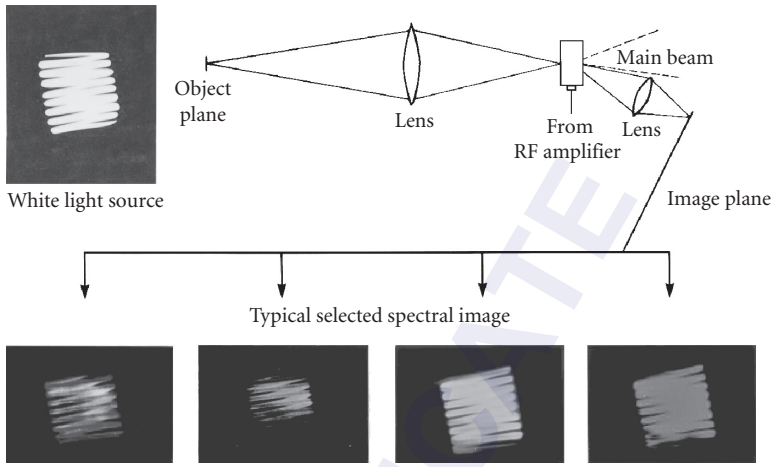

FIGURE 10 Color images of lamp filament through the first noncollinear AOTF.

with a theoretical analysis.[53] The early work on the theory and practice of the AOTF is given in a review paper.[54]

After the first noncollinear TeO_2 AOTF, it was recognized that because of its larger aperture and simpler optical geometry, this new type of AOTF would be better suited to spectral imaging applications. A multispectral spectral experiment using a TeO_2 AOTF was performed in the visible region.[55] The white light beam was spatially separated from the filtered light and blocked by an aperture stop in the immediate frequency plane. A resolution target was imaged through the AOTF and relayed onto the camera. At a few wavelengths in the visible region selected by the driving RF frequencies, the spectral imaging of the resolution was measured. The finest bar target had a horizontal resolution of 144 lines/mm and a vertical resolution of 72 lines/mm. Figure 10 shows the measured spectral images of the lamp filament through the AOTF at a few selected wavelengths in the visible.

Other application concepts of the new AOTF have also been demonstrated. These include the detection of weak laser lines in the strong incoherent background radiation using the extreme difference in the temporal coherence[56] and the operation of multiwavelength AOTF driven by multifrequencies simultaneously.[57]

It is instructive to summarize the advantages of the noncollinear AOTF: (a) it uses efficient AO materials; (b) it affords the design freedom of choosing the direction of optical and acoustic wave for optimizing efficiency, resolution, angular aperture, and so on; (c) it can be operated without the use of polarizers; and (d) it allows simple filter construction ease for manufacturing. As a result, practically all AOTFs are noncollinear types satisfying the NPM condition.

Noncritical Phase-Matching AOTF

AOTF characteristics The key performance characteristics of the AOTF operated in the noncritical phase-matching (NPM) mode will be reviewed. These characteristics include tuning relation, angle of deflection and imaging resolution, passband response, spectral resolution, angular aperture, transmission and drive power, out-of-band rejection, and sidelobe suppression.

Tuning relation For an AOTF operated at NPM, the tangents to the incident and diffracted optical wavevector surfaces must be parallel. The parallel tangent condition implies that the diffracted extraordinary ray is collinear with the incident ordinary ray,[19]

$$\tan \theta_e = e^2 \tan \theta_o \tag{78}$$

For a given incident light angle θ_i, the diffracted light angle θ_d is readily determined from the above equation. Thus, without loss of generality we can assume the incident optical beam to be either ordinary or extraordinary polarized. To minimize wavelength dispersion an ordinary polarized light (*o*-wave) is chosen as the incident light in the following analysis.

Substituting Eq. (78) into the phase matching Eq. (22), the acoustic wave direction and center wavelength of the passband can be expressed as a function of the incident light angle.

$$\tan \theta_a = (\cos \theta_o + \rho_o)/\sin \theta_o \tag{79}$$

$$\lambda_o = [n_o V(\theta_a)/f_a][(\rho_o - 1)^2 \cos^2\theta_0 + (\delta\rho_o - 1)^2 \sin^2\theta_o]^{1/2} \tag{80}$$

where $\rho_o = (1 + \delta \sin^2\theta_o)^{1/2}$ and $\delta = (e^2 - 1)/2$. The above expressions are exact. For small birefringence $\Delta n = n_o |\delta| << n_o$, Eqs. (81) and (82) yield the approximate solution for the acoustic wave direction and acoustic frequency:

$$\tan \theta_a = 2/\tan \theta_o - (1 + \delta) \tan \theta_o \tag{81}$$

$$\lambda_o = (V \Delta n/f_a)(\sin^4\theta_o + \sin^2 2\theta_o)^{1/2} \tag{82}$$

Angle of deflection In a noncollinear AOTF the diffracted light is spatially separated from the incident light. The deflection angle θ_D is defined as the deviation of the diffracted light from that of the incident light. For small birefringence, θ_D is approximately given by

$$\theta_D \approx \Delta n \sin 2\theta_o \tag{83}$$

Equation (83) shows that θ_D depends only on the input optical angle. It reaches maximum value Δn when $\theta_o = 45°$. For instance, in a TeO_2 AOTF operated at 633 nm, $\Delta n \approx 0.15$, the maximum deflection angle for TeO_2 AOTF is about 8.6°. As a result of the finite angle of deflection angle the noncollinear AOTF can operate without the use of polarizers.

Bandpass response For an acoustic column of uniform amplitude, the bandpass response is given by $T(\lambda_o) = T_o \text{sinc}^2 \Delta\sigma L$, where T_o is the peak transmission at exact momentum matching, L is the interaction length, and $\Delta\sigma$ is the momentum mismatch. It can be shown[19] that

$$\Delta\sigma = -b\sin^2\theta_i(\Delta\lambda/\lambda_o^2) + (\Delta n/2\lambda_o)[F_1(\Delta\theta)^2 + F_2(\sin\theta_i\Delta\phi)^2 + F_3(\Delta\theta)^3] \tag{84}$$

where

$$F_1 = 2 - 3\sin^2\theta_o \qquad F_2 = 2 - \sin^2\theta_o \qquad F_3 = -\sin 2\theta_o \tag{85}$$

$\Delta\lambda$, $\Delta\theta$, and $\Delta\phi$ are deviations in wavelength, polar, and azimuth angles of the incident light beam, b is the dispersion constant defined by $b = \Delta n - \lambda_o \delta(\Delta n)/\delta\lambda_o$.

Resolution Equation (84) shows that half peak transmission occurs when $\Delta\sigma L \approx 0.44$. The full width at half-maximum (FWHM) of the AOTF is given by

$$\Delta\lambda = 0.9\lambda_o^2/bL\sin^2\theta_i \tag{86}$$

The spectral resolution (i.e., longitudinal resolution) of the AOTF is given by

$$R_l = \lambda_o/\Delta\lambda = \Delta n L \sin^2\theta_i/\lambda_o \tag{87}$$

Angular aperture The acceptance (half) angles in the polar plane ($\theta_o \neq 54.7$) and azimuth planes are given by

$$\Delta\theta = \pm n(\lambda_o/\Delta nLF_1)^{1/2} \tag{88}$$

$$\Delta\phi = \pm n(\lambda_o/\Delta nLF_2)^{1/2} \tag{89}$$

At $\theta_o \approx 54.7$, $F_1 = 0$, and the angular aperture in the polar plane reaches a maximum.

$$\Delta\theta = \pm n(\lambda_o/\Delta nL)^{1/3} \tag{90}$$

As a general rule, the noncollinear AOTF is operated without the use of polarizers. Thus the deflection angle θ_D sets the upper limit for the angular aperture for the AOTF. Assuming the incident is a rectangular beam of width D. This yields a transverse or imaging resolution

$$R_t = \frac{\theta_D}{\delta\theta_o} = \frac{D\Delta n}{\lambda_o}\sin 2\theta_o \tag{91}$$

Optical throughput The filter transmission for normalized input light distribution $I(\theta_i, \phi_i)$ is obtained by integrating the plane-wave transmission over the solid angle aperture

$$I_d(\Delta\lambda) = \int_{\alpha_i,\beta_i} T(\Delta\lambda,\theta_i,\varphi_i) I(\theta_i,\varphi_i)\sin\theta_i\, d\theta_i, d\varphi_i \tag{92}$$

Transmission and drive power The peak transmission of an AOTF is given by

$$T_o = \sin^2\left(\frac{\pi^2}{2\lambda_o^2} M_2 P_d L^2\right)^{1/2} \tag{93}$$

where P_d is the acoustic power density. Maximum transmission occurs when the drive power reaches the value

$$p_a = \frac{\lambda_o^2 A}{2M_2 L^2} \tag{94}$$

where A is the optical aperture. Because of the λ_o^2 dependence, the drive power of an AOTF increases rapidly as the wavelength increases. For instance, at $\lambda_o = 4$ μm, the required acoustic power for a 1 cm infrared TeO_2 AOTF exceeds about 10 W. The required high drive power is perhaps the most severe limitation of the infrared AOTF.

Sidelobe suppression As an optical filter, one of the most undesired characteristics of the AOTF is the nonuniform in-band frequency response and the high sidelobes/fall-off shape near the edge of the passband. The AOTF bandpass response is proportional to the amplitude square of the Fourier transform of the acoustic field. For uniform acoustic excitation, the AOTF exhibits a sinc^2-type bandpass characteristic with many sidelobes. The nearest sidelobe is only about 13 dB below the main lobe. A more serious problem is that the envelope of the sidelobe decays slowly at a fall-off rate of –6 dB per octave. In principle, suppression of the high sidelobes can be obtained by the technique of amplitude apodization, a process that slowly reduces the acoustic amplitude profile at the transducer according to a prescribed weighting function. The real problem is the practicality of implementing the apodization. A number of transducer apodization techniques have been experimentally investigated.[58] These include (1) the use of segmented transducers weighted with designed resistive coupling or varying electrode area; and (2) tapered windows with an air gap or dielectric layer.

The effectiveness of each method varies depending on the size and thickness of the acoustic frequency, among other factors. Typically, the highest sidelobes of apodized devices are about 20 to 25 db below main peak. However, the result is very sensitive to the fabrication tolerance and design parameters. The price to pay is the reliability and high cost of the fabrication.

Spectral Tuning Range Prior to 1980, both the collinear and noncollinear types of AOTFs have been successfully demonstrated covering the spectral range from ultraviolet (UV) to long-wave infrared (LWIR). However, due to the various performance limitations such as polarization dependence, limited optical aperture and resolution and in particular high drive power, the TeO_2 AOTF is the only type that has been deployed in practical optical systems. Considerable effort were devoted to overcome the basic limitations of AOTF technology and extend the usable spectral range.[58] The progress of AOTFs for the various spectral regions are summarized as follows.

Ultraviolet (UV) AOTF Until recently, collinear quartz AOTF has been the only type for the UV region. The performance limitations of the quartz filter include (1) limited UV operating range: due to the optical absorption of calcite polarizers, the short wavelength cutoff of the UV AOTF is about 240 nm, (2) high drive power: because of the small figure of merit, the drive power is typically above 10 W; and (3) low optical throughput: the fixed on-axis of the collinear interaction geometry lacks the design flexibility with typically small solid angle x aperture characteristics. To overcome these drawbacks, two noncollinear UV AOTFs were developed.[59]

These include (1) A KDP UV AOTF operated without polarizers was demonstrated at 253.7 nm using a Hg lamp. The device was tunable from 190 to 340 nm. The measured result include a full-width at half-maximum (FWHM) of 0.79 nm and a peak diffraction efficiency of 50 percent at 1.3 W input power. The deflection angle of the filtered light separated from the broadband incident light is 1.9°. (2) A Far UV AOTF made of MgF_2 was tested at 196.03 nm from a hollow cathode lamp. A Brewster-type polarizer made of a pile of thin MgF_2 plates was used in the test. The FWHM of the AOTF was about 3 nm. The diffracted light intensity was about 45 percent at a drive power of 6 W. Because of the UV transmission, the AOTF is extendable to 150 nm.

Mid-infrared AOTF The most severe technological issues that limit the extension of spectral range to thermal infrared region are (1) high drive power requirement due to the λ^2 dependence and (2) catastrophic device failure when operated at low temperatures. To resolve these critical issues a number of the TeO_2 AOTFs feasibility models for the mid-wave infrared (MWIR) have been built and tested.[60] Performance characteristics of the 1 cm^2 size acoustically resonant AOTFs measured at 3.39 μm include tuning range: 2.5 to 5 μm, bandwidth 15 nm, and drive power (at 80 percent efficiency) less than 0.5 W, with a resonance gain about 20. Repeated operation of the low-power MWIR AOTF was obtainable for temperature above 150 K. However, because of the power thermal conductivity of TeO_2 below the critical temperature the crystal or the transducer may crack. The reliability of the resonant AOTF operated at cryogenic temperature remains a major engineering issue.

Long wave infrared AOTF Operation of the AOTF were demonstrated in the LWIR region of 8 to 12 μm were demonstrated prior to 1980. Stimulated by the important potential application for hyperspectral imaging, there has been considerable effort to develop practical LWIR AOTF for optical remote sensing systems.

For AOTF operated in the long-wave infrared (LWIR) the high drive power is even a much serious problem. Because of its high figure of merit Tl_3AsSe_3 (TAS) is considered to be the best LWIR AOTF material. Even with its exceedingly large AO figure of merit (>2000), the TAS AOTF has to operate on pulsed basis with low duty cycle. However, because of extremely low thermal conductivity and the brittle nature of the TAS crystals, the potential of practical TAS AOTF operated at low temperature does not appear promising.

Performance of NPM AOTF The AOTF possesses many salient features that make it attractive for a variety of optical system applications. To realize the benefits of these merits the limitations of the AOTF must be considered when compared with the competing technologies. Based on the

TABLE 9 Broadband and High Resolution Type NPM AOTF

Type	Broadband (8 × 8 mm)		High-Resolution AOTF	
Aperture	10 × 10 mm		5 × 5 mm	
Wavelength	400–1100	700–2500	400–650	650–1100
Bandwidth (cm^1)	25	20	5	7
$\Delta\lambda$ (nm)	1	5	0.12	0.5
At λ_o (μm)	633	1550	442	830
Efficiency (%)	80	70	95	95
RF power (W)	1	2	1	2

previous discussion of the usable spectral range, it appears that with the exception of possible new development in the UV, only the TeO_2 AOTFs operated in the visible to SWIR can be considered as a matured technology ready for system deployment. Considering the primary niche, it is pertinent to improve the basic performance of the AOTFs for meeting the system requirement. Table 9 shows two selected high performance NPM AOTFs. These include (1) broadband imaging AOTF with two octave tuning range in a single unit and (2) high resolution high efficiency AOTF suited as rapid random access laser tuner.

The AOTF has the unique capability of being able to simultaneously and independently add or drop multiwavelength signals. As such, it can serve as a WDM cross-connect for routing multiwavelength optical signals along a prescribed connection path determined by the signal's wavelength. Because of this unique attractive feature, the AOTF appears to be suited for use as dynamical reconfigurable components for the WDM network. However, due to the relatively high drive power and low resolution requirement, the AOTF has not been able to meet the requirement for dense wavelength division multiplexing (DWDM) applications. This basic drawback of the AOTF is the result of finite interaction length limited by the large acoustic beam walk-off in the TeO_2 crystal. To overcome this intrinsic limitation, a new type of noncollinear AOTF showing significant improvement of resolution and diffraction efficiency was proposed and demonstrated.[60,61] The filter is referred to as the collinear beam (CB) AOTF, since the group velocity of the acoustic wave and light beams are chosen to be collinear. An extended interaction length was realized in a TeO_2 AOTF with narrow bandwidth and significantly lower drive power. Figure 11 shows the schematic of an in-line TeO_2 CBAOTF using internal mode conversion.

An initial test of the CBAOTF was performed at 1532 nm using a HeNe laser as the light source.[61] Figure 12 shows the bandpass response of the CBAOTF obtained by monitoring the diffracted light intensity as the acoustic frequency was swept through the laser line. As shown in the figure, the slowly decaying bandpass response appears to be a Lorentzian shape with observable sidelobes. However, the falloff rate of the bandpass at –6 dB per octave wavelength change is the same as the envelope of the $sinc^2$ response of the conventional AOTF.

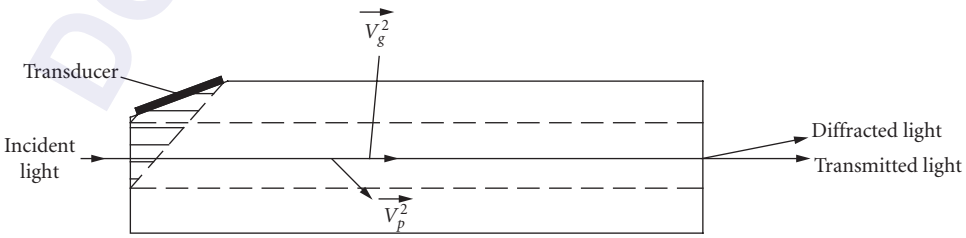

FIGURE 11 Collinear beam AOTF using internal mode conversion.

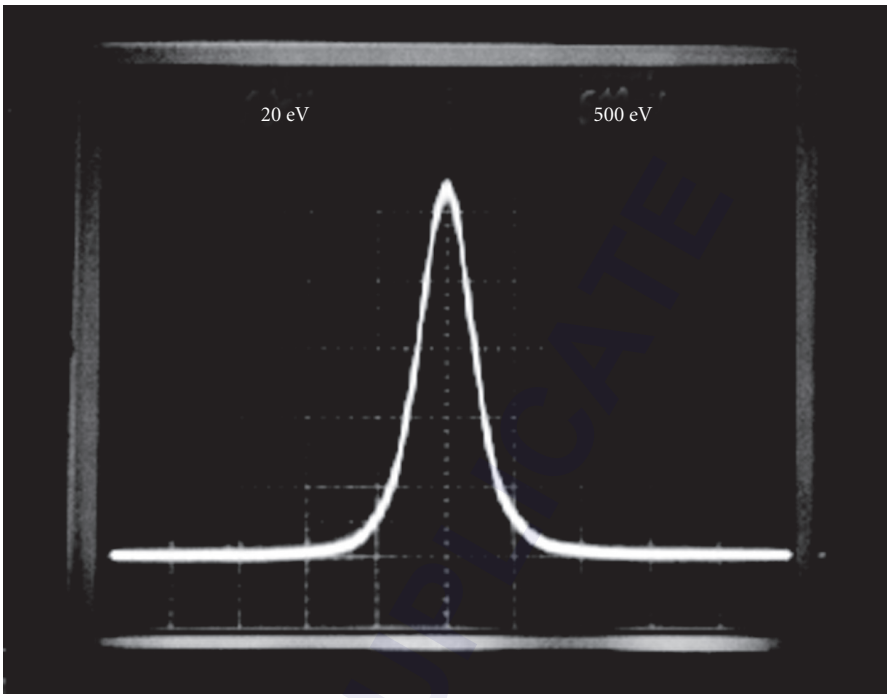

FIGURE 12 Bandpass of CBAOTF (RF swept through a 1.550-μm laser line).

The half-power bandwidth was measured to be 25 kHz, which corresponds to an optical FWHM of 1 nm or 4.3 cm^{-1}. The diffracted light reaches a peak value of 95 percent when the drive power is increased to about 55 mW. Compared to the state-of-the-art high resolution NPM, the measured result showed that the drive power was about 50 times smaller. The low drive power advantage of the CBAOTF is most important for WDM application, which requires simultaneously a large number of channels.

Although the CBAOTF has resolved the most basic limitation of high drive power requirement, to be used as a dynamic DWDM component, there still remains several critical technical bottleneck. For a 100-GHz (0.8 nm at 1550 nm) wavelength spacing system, the AOTF has to satisfy a set of performance goals. These include: polarization independent operation, full width at half-maximum (FWHM) of 0.4 nm, drive power of 150 mW per signal, and the sidelobe must be suppressed to be lower than at least 30 dB at 100 GHz away from the center wavelength. Significant progress has been made in the effort to overcome these critical issues. These are discussed below.

Polarization independence The operation of AOTF is critically dependent on the polarization state of the incoming light beam. To make it polarization-independent, polarization diversity configurations (PDL) are used.[62] The scheme achieves polarization independence by dividing into two beams of orthogonal polarization, o- and e-rays with a polarization beam splitter (PBS) passing through two single polarization AOTFs in two paths, then combing the two diffracted o- and e-rays of selected wavelengths with a second PBS. Half-wave plates are used to convert the polarization of the light beam so that o-rays are incident onto the AOTF.

Sidelobe suppression Due to low crosstalk requirement, the sidelobe at the channel must be sufficiently low (~35 dB). This is the most basic limitation and as such it will be discussed in some detail. There are three kinds of crosstalk. These include the interchannel crosstalk caused by the

TABLE 10 Measured Performance of CBAOTF

Tuning range	1300–1600 nm
Measured wavelength	1550 nm
FWHM (3 dB)	0.4 nm @ 1.55 nm
Sidelobe @ ch. spacing	–20 dB @ –0.8 nm
Sidelobe @ ch. spacing	–25 dB @ +0.8 nm
Peak efficiency	95(%)
Drive power	80 mW

sidelobe level of the AOTF bandpass; and the extinction ratio, an intrachannel crosstalk due to the finite extinction ratio. The most severe crosstalk is the coherent type that originates from the mixing of sidelobe of light beam λ_1 shifted by frequencies f_1 and f_2. The optical interference of the two light beams will result in an amplitude-modulated type crosstalk at the difference frequency of $f_1 - f_2$. This type of interchannel crosstalk is much more severe since the modulation is proportional to the amplitude or square root of the sidelobe power level.

Several apodization techniques have been developed in order to suppress the high sidelobe. A simple approach of tilted configuration to simulate a various weighting function appears to be most practical.[58] A major advantage of this approach is the design flexibility to obtain a desired tradeoff between sidelobe suppression and bandwidth.

Another technique for reducing the sidelobe is to use two or more AOTFs in an incoherent optical cascade. The bandpass response of the incoherently cascaded AOTFs is equal to the product of the single stage and thus can realize a significantly reduced sidelobe. This doubling of sidelevel by cascaded cells has been experimentally demonstrated.[58]

A number of prototype devices of polarization independent (PI) CBAOTF using the tilt configuration have been built. Typical measured results at 1550 nm include 1.0 nm FWHM, peak efficiency 95 percent at 80 mW drive power insertion loss; –3 dB polarization-independent loss; 0.1 dB polarization mode dispersion (PDL); 1 psec, and sidelobe below –27 dB at 3 nm from the center wavelength.[58]

To further reduce the half power bandwidth, a higher angle cut design was chosen in the follow-on experimental work. A 65°, apodized CBAOTF was designed and fabricated. The primary design goal was to meet the specified narrow bandwidth and accept the sidelobe level based on the tradeoff relation. Test results of the 65° devices measured at 1550 are summarized in Table 10. Except the sidelobe suppression goal, the 65° device essentially satisfies all other specifications. The specified sidelobe level of –35 dB for the 100-GHz channel spacing can be met by using two CBAOTFs in cascade.

In conclusion, it is instructive to emphasize the unique advantage of the AOTF. Because of its random access wavelength tunability over large spectral range, the CBAOTF provides a low-cost implementation of a dynamic multiwavelength component for DWDM and other noncommunication type of application with nonuniform distribution of wavelengths.

7.1 GLOSSARY

A, [**A**]	general symmetric matrix
[a]	orthogonal transformation matrix
b	electrode separation of the electro-optic modulator
D	displacement vector
d	width of the electro-optic crystal
E	electric field
H	magnetic field
IL	insertion loss
k	wavevector, direction of phase propagation
L	length of the electro-optic crystal
L/b	aspect ratio
N	number of resolvable spots
n_m	refractive index of modulation field
n_x, n_y, n_z	principal indices of refraction
r_{ijk}	third-rank linear electro-optic coefficient tensor
S	Poynting (ray) vector, direction of energy flow
S_{ijkl}	fourth-rank quadratic electro-optic coefficient tensor
T	transmission or transmissivity
V	applied voltage
V_π	half-wave voltage
v_π	phase velocity
v_m	modulation phase velocity

v_s	ray velocity
w	beamwidth
w_o	resonant frequency of an electro-optic modulator circuit
$\mathbf{X}$	position vector in cartesian coordinates
X'	electrically perturbed position vector in cartesian coordinates
(x, y, z)	unperturbed principal dielectric coordinate system
(x', y', z')	new electro-optically perturbed principal dielectric coordinate system
(x'', y'', z'')	wavevector coordinate system
(x''', y''', z''')	eigenpolarization coordinate system
β_1	polarization angle between x''' and x''
β_2	polarization angle between y''' and x''
Γ	phase retardation
Γ_m	amplitude modulation index
$\Delta\eta$	electro-optically induced change in the index of refraction or birefringence
$\Delta(1/\eta^2)$	electro-optically induced change in an impermeability tensor element
$\Delta\phi$	angular displacement of beam
$\Delta\nu$	bandwidth of a lumped electro-optic modulator
δ	phase modulation index
$[\boldsymbol{\varepsilon}]$	permittivity tensor
ε_0	permittivity of free space
$[\boldsymbol{\varepsilon}]^{-1}$	inverse permittivity tensor
$\varepsilon_x, \varepsilon_y, \varepsilon_z$	principal permittivities
$[\epsilon]$	dielectric constant tensor
$[\epsilon]^{-1}$	inverse dielectric constant tensor
$\epsilon_x, \epsilon_y, \epsilon_z$	principal dielectric constants
η_m	extinction ratio
θ	half-angle divergence
θ_k, ϕ_k	orientation angles of the wavevector in the (x, y, z) coordinate system
ϑ	optic axis angle in biaxial crystals
λ	wavelength of the light
$[\lambda]$	diagonal matrix
ν_{tw}	bandwidth of a traveling wave modulator
ξ	modulation efficiency
ρ	modulation index reduction factor
τ	transit time of modulation signal
ϕ	phase of the optical field
Ω	plane rotation angle
ϖ	beam parameter for bulk scanners
ω_d	frequency deviation
ω_e	stored electric energy density
ω_m	modulation radian frequency
$[1/n^2]'$	electro-optically perturbed impermeability tensor
$[1/n^2]$	inverse dielectric constant (impermeability) tensor
Γ_{wg}	overlap correction factor
β	waveguide effective propagation constant

7.2 INTRODUCTION

Electro-optic modulators are used to control the amplitude, phase, polarization state, or position of an optical beam, or light wave carrier, by application of an electric field. The electro-optic effect is one of several means to impose information on, or modulate, the light wave. Other means include acousto optic, magneto optic, thermo optic, electroabsorption, mechanical shutters, and moving mirror modulation and are not addressed in this chapter, although the fundamentals presented in this chapter may be applied to other crystal optics driven modulation techniques.

There are basically two types of modulators: bulk and integrated optic. Bulk modulators are made of single pieces of optical crystals, whereas the integrated optic modulators are constructed using waveguides fabricated within or adjacent to the electro-optic material. Electro-optic devices have been developed for application in communications,[1–4] analog and digital signal processing,[5] information processing,[6] optical computing,[6,7] and sensing.[5,7] Example devices include phase and amplitude modulators, multiplexers, switch arrays, couplers, polarization controllers, and deflectors.[1,2] Given are rotation devices,[8] correlators,[9] A/D converters,[10] multichannel processors,[11] matrix-matrix and matrix-vector multipliers,[11] sensors for detecting temperature, humidity, radio-frequency electrical signals,[5,7] and electro-optic sampling in ultrashort laser applications.[12,13] The electro-optic effect allows for much higher modulation frequencies than other methods, such as mechanical shutters, moving mirrors, or acousto-optic devices, due to a faster electronic response time of the material.

The basic idea behind electro-optic devices is to alter the optical properties of a material with an applied voltage in a controlled way. The direction dependent, electrically induced physical changes in the optical properties are mathematically described by changes in the second rank permittivity tensor. The tensor can be geometrically interpreted using the index ellipsoid, which is specifically used to determine the refractive indices and polarization states for a given direction of phase propagation. The changes in the tensor properties translate into a modification of some parameter of a light wave carrier, such as phase, amplitude, frequency, polarization, or position of the light as it propagates through the device. Therefore, understanding how light propagates in these materials is necessary for the design and analysis of electro-optic devices. The following section gives an overview of light propagation in anisotropic materials that are homogeneous, nonmagnetic, lossless, optically inactive, and nonconducting. Section 7.4 gives a geometrical and mathematical description of the linear and quadratic electro-optic effects. This section illustrates how the optical properties described by the index ellipsoid change with applied voltage. A mathematical approach is offered to determine the electrically perturbed principal dielectric axes and indices of refraction of any electro-optic material for any direction of the applied electric field as well as the phase velocity indices and eigenpolarization orientations for a given wavevector direction. Sections 7.5 and 7.6 describe basic bulk electro-optic modulators and integrated optic modulators, respectively. Finally, example applications, common materials, design considerations, and performance criteria are discussed.

The discussion presented in this chapter applies to any electro-optic material, any direction of the applied voltage, and any direction of the wavevector. Therefore, no specific materials are described explicitly, although materials such as lithium niobate ($LiNbO_3$), potassium dihydrogen phosphate (KDP), and gallium arsenide (GaAs) are just a few materials commonly used. Emphasis is placed on the general fundamentals of the electro-optic effect, bulk modulator devices, and practical applications.

7.3 CRYSTAL OPTICS AND THE INDEX ELLIPSOID

With an applied electric field, a material's anisotropic optical properties will be modified, or an isotropic material may become optically anisotropic. Therefore, it is necessary to understand light propagation in these materials. For any anisotropic (optically inactive) crystal class there are two allowed orthogonal linearly polarized waves propagating with differing phase velocities for a given wavevector **k**. Biaxial crystals represent the general case of anisotropy. Generally, the allowed waves exhibit *extraordinary-like* behavior; the wavevector and ray (Poynting) vector directions differ.

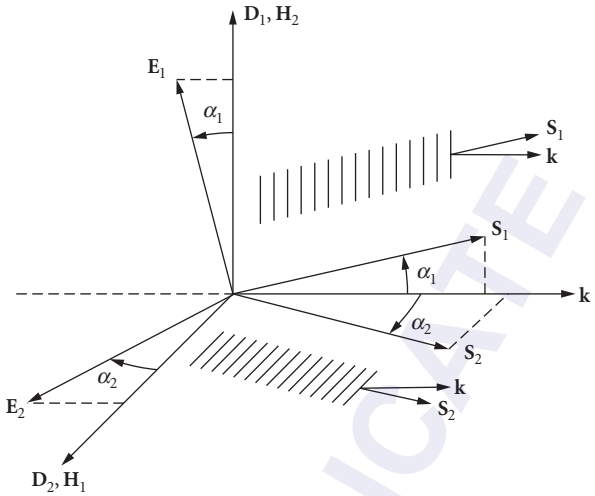

FIGURE 1 The geometric relationships of the electric quantities **D** and **E** and the magnetic quantities **B** and **H** to the wavevector **k** and the ray vector **S** are shown for the two allowed extraordinary-like waves propagating in an anisotropic medium.[14]

In addition, the phase velocity, polarization orientation, and ray vector of each wave change distinctly with wavevector direction. For each allowed wave, the electric field **E** is not parallel to the displacement vector **D** (which defines polarization orientation) and, therefore, the ray vector **S** is not parallel to the wavevector **k** as shown in Fig. 1. The angle α_1 between **D** and **E** is the same as the angle between **k** and **S**, but for a given **k,** $\alpha_1 \neq \alpha_2$**.** Furthermore, for each wave **D** $\perp$ **k** $\perp$ **H** and **E** $\perp$ **S** $\perp$ **H**, forming orthogonal sets of vectors. The vectors **D**, **E**, **k**, and **S** are coplanar for each wave.[14]

The propagation characteristics of the two allowed orthogonal waves are directly related to the fact that the optical properties of an anisotropic material depend on direction. These properties are represented by the constitutive relation $\mathbf{D} = [\varepsilon]\,\mathbf{E}$**,** where $[\varepsilon]$ is the permittivity tensor of the medium and **E** is the corresponding optical electric field vector. For a homogeneous, nonmagnetic, lossless, optically inactive, and nonconducting medium, the permittivity tensor has only real components. Moreover, the permittivity tensor and its inverse, $[\varepsilon]^{-1} = 1/\varepsilon_0[1/n^2]$, where n is the refractive index, are symmetric for all crystal classes and for any orientation of the dielectric axes.[15–17] Therefore the matrix representation of the permittivity tensor can be diagonalized, and in principal coordinates the constitutive equation has the form

$$\begin{pmatrix} D_x \\ D_y \\ D_z \end{pmatrix} = \begin{pmatrix} \varepsilon_x & 0 & 0 \\ 0 & \varepsilon_y & 0 \\ 0 & 0 & \varepsilon_z \end{pmatrix} \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix} \tag{1}$$

where reduced subscript notation is used. The principal permittivities lie on the diagonal of $[\varepsilon]$.

The index ellipsoid is a construct with geometric characteristics representing the phase velocities and the vibration directions of **D** of the two allowed plane waves corresponding to a given optical wave-normal direction **k** in a crystal. The index ellipsoid is a quadric surface of the stored electric energy density ω_e of a dielectric,[15,18]

$$\omega_e = \frac{1}{2}\mathbf{E} \times \mathbf{D} = \frac{1}{2}\sum_i \sum_j E_i \varepsilon_{ij} E_j = \frac{1}{2}\varepsilon_0 \mathbf{E}^T[\epsilon]\mathbf{E} \qquad i, j = x, y, z \tag{2a}$$

where T indicates the transpose.

In principal coordinates, that is, when the dielectric principal axes are parallel to the reference coordinate system, the ellipsoid is simply

$$\omega_e = \frac{1}{2}\varepsilon_0(E_x^2\varepsilon_x + E_y^2\varepsilon_y + E_z^2\epsilon_z) \tag{2b}$$

where the convention for the dielectric constant subscript is $\varepsilon_{xx} = \varepsilon_x$, and so on. The stored energy density is positive for any value of electric field; therefore, the quadric surface is always given by an ellipsoid.[15,18–20]

Substituting the constitutive equation, Eq. (2*b*) assumes the form $(D_x^2/\varepsilon_x) + (D_y^2/\varepsilon_y) + (D_z^2/\epsilon_z) = 2\omega_e\varepsilon$. By substituting $x = D_x/(2\omega_e\varepsilon_0)^{1/2}$ and $n_x^2 = \varepsilon_x$ and similarly for y and z, the ellipsoid is expressed in cartesian principal coordinates as

$$\frac{x^2}{n_x^2} + \frac{y^2}{n_y^2} + \frac{z^2}{n_z^2} = 1 \tag{3a}$$

In a general orthogonal coordinate system, that is, when the reference coordinate system is not aligned with the principal dielectric coordinate system, the index ellipsoid of Eq. (3*a*) can be written in summation or matrix notation as

$$\sum_i \sum_j X_i(1/n_{ij}^2)X_j = \mathbf{X}^T[1/n^2]\mathbf{X} = (x\ y\ z)\begin{pmatrix} 1/n_{xx}^2 & 1/n_{xy}^2 & 1/n_{xz}^2 \\ 1/n_{xy}^2 & 1/n_{yy}^2 & 1/n_{yz}^2 \\ 1/n_{xz}^2 & 1/n_{yz}^2 & 1/n_{zz}^2 \end{pmatrix}\begin{pmatrix} x \\ y \\ z \end{pmatrix} \tag{3b}$$

where $\mathbf{X} = [x, y, z]^T$, and all nine elements of the inverse dielectric constant tensor, or impermeability tensor, may be present. For sections that follow, the index ellipsoid in matrix notation will be particularly useful.

Equation (3*b*) is the general index ellipsoid for an optically biaxial crystal. If $n_{xx} = n_{yy}$, the surface becomes an ellipsoid of revolution, representing a uniaxial crystal. In this crystal, one of the two allowed eigenpolarizations will always be an *ordinary* wave with its Poynting vector parallel to the wavevector and **E** parallel to **D** for any direction of propagation. An isotropic crystal ($n_{xx} = n_{yy} = n_{zz}$) is represented by a sphere with the principal axes having equal length. Any wave propagating in this crystal will exhibit ordinary characteristics. The index ellipsoid for each of these three optical symmetries is shown in Fig. 2.

For a general direction of phase propagation **k**, a cross section of the ellipsoid through the origin perpendicular to **k** is an ellipse, as shown in Fig. 2. The major and minor axes of the ellipse represent the

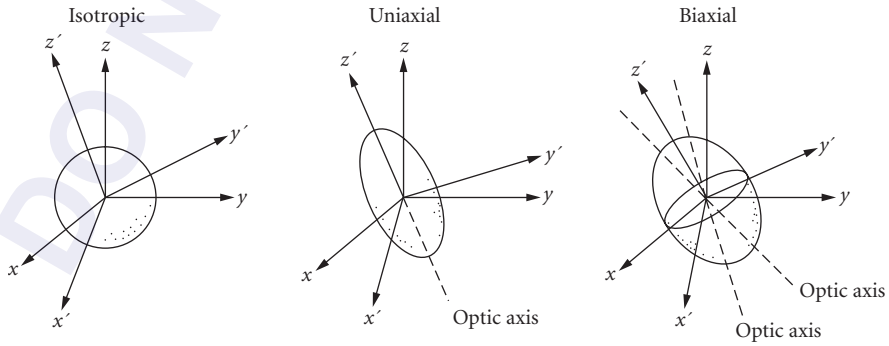

FIGURE 2 The index ellipsoids for the three crystal symmetries are shown in nonprincipal coordinates (x', y', z') relative to the principal coordinates (x, y, z). For isotropic crystals, the surface is a sphere. For uniaxial crystals, it is an ellipsoid of revolution. For biaxial crystals, it is a general ellipsoid.[21]

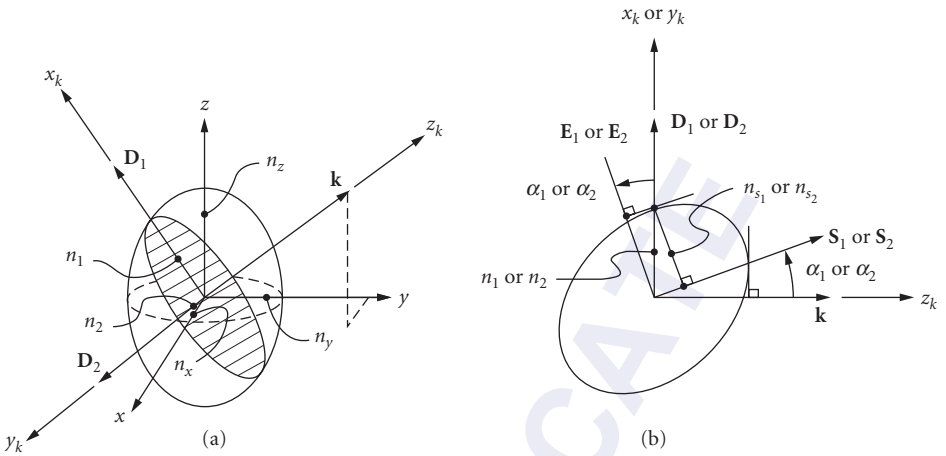

FIGURE 3 (*a*) The index ellipsoid cross section (crosshatched) that is normal to the wavevector **k** has the shape of an ellipse. The major and minor axes of this ellipse represent the directions of the allowed polarizations $\mathbf{D}_1$ and $\mathbf{D}_2$ and (*b*) for each eigenpolarization (1 or 2) the vectors **D**, **E**, **S**, and **k** are coplanar.[21]

orthogonal vibration directions of **D** for that particular direction of propagation. The lengths of these axes correspond to the phase velocity refractive indices. They are, therefore, referred to as the "fast" and "slow" axes. Figure 3*b* illustrates the field relationships with respect to the index ellipsoid. The line in the $(\mathbf{k}, \mathbf{D}_i)$ plane ($i = 1$ or 2) that is tangent to the ellipsoid at $\mathbf{D}_i$ is parallel to the ray vector $\mathbf{S}_i$; the electric field $\mathbf{E}_i$ also lies in the $(\mathbf{k}, \mathbf{D}_i)$ plane and is normal to $\mathbf{S}_i$. The line length denoted by n_{S_i} gives the ray velocity as $v_{s_i} = c/n_{s_i}$ for $\mathbf{S}_i$. The same relationships hold for either vibration, $\mathbf{D}_1$ or $\mathbf{D}_2$.

In the general ellipsoid for a biaxial crystal there are two cross sections passing through the center that are circular. The normals to these cross sections are called the *optic axes* (denoted in Fig. 2 in a nonprincipal coordinate system), and they are coplanar and symmetric about the z principal axis in the x-z plane. The angle ϑ of an optic axis with respect to the z axis in the x-z plane is

$$\tan \vartheta = \frac{n_z}{n_x} \sqrt{\frac{n_y^2 - n_x^2}{n_z^2 - n_y^2}} \tag{4}$$

The phase velocities for $\mathbf{D}_1$ and $\mathbf{D}_2$ are equal for these two directions: $v_1 = v_2 = c/n_y$. In an ellipsoid of revolution for a uniaxial crystal, there is one circular cross section perpendicular to the z principal axis. Therefore, the z axis is the optic axis, and $\vartheta = 0°$ in this case.

7.4 THE ELECTRO-OPTIC EFFECT

At an atomic level, an electric field applied to certain crystals causes a redistribution of bond charges and possibly a slight deformation of the crystal lattice.[16] In general, these alterations are not isotropic; that is, the changes vary with direction in the crystal. Therefore, the dielectric tensor and its inverse, the impermeability tensor, change accordingly. The linear electro-optic effect, or Pockels, is a change in the impermeability tensor elements that is proportional to the magnitude of the externally applied electric field. Only crystals lacking a center of symmetry or macroscopically ordered dipolar molecules exhibit the Pockels effect. On the other hand, all materials, including amorphous materials and liquids, exhibit a quadratic (Kerr) electro-optic effect. The changes in the impermeability tensor elements are proportional to the square of the applied field. When the linear effect is present, it generally dominates over the quadratic effect.

Application of the electric field induces changes in the index ellipsoid and the impermeability tensor of Eq. (3*b*) according to

$$\mathbf{X}^T\left[\frac{1}{n^2}+\Delta\frac{1}{n^2}\right]\mathbf{X}=1 \tag{5}$$

where the perturbation is

$$\Delta\left[\frac{1}{n^2}\right]=\left[\frac{1}{n^2}\right]\Bigg\|_{E\neq 0}-\left[\frac{1}{n^2}\right]\Bigg\|_{E=0}=\sum_{k=1}^{3}r_{ijk}E_k+\sum_{k=1}^{3}\sum_{l=1}^{3}s_{ijkl}E_kE_l \tag{6}$$

Since n is dimensionless, and the applied electric field components are in units of V/m, the units of the linear r_{ijk} coefficients are in m/V and the quadratic coefficients s_{ijkl} are in m^2/V^2.

The linear electro-optic effect is represented by a third rank tensor r_{ijk} with $3^3 = 27$ independent elements, that if written out in full form, will form the shape of a cube. The permutation symmetry of this tensor is $r_{ijk} = r_{ikj}$, $i, j, k = 1, 2, 3$ and this symmetry reduces the number of independent elements to 18.[22] Therefore, the tensor can be represented in contracted notation by a 6×3 matrix; that is, $r_{ijk} \Rightarrow r_{ij}$, $i = 1, \ldots, 6$ and $j = 1, 2, 3$. The first suffix is the same in both the tensor and the contracted matrix notation, but the second two tensor suffixes are replaced by a single suffix according to the following relation.

Tensor notation	11	22	33	23,32	31,13	12,21
Matrix notation	1	2	3	4	5	6

Generally, the r_{ij} coefficients have very little dispersion in the optical transparent region of a crystal.[23] The electro-optic coefficient matrices for all crystal classes are given in Table 1. References 16, 23, 24, and 25, among others, contain extensive tables of numerical values for indices and electro-optic coefficients for different materials.

The quadratic electro-optic effect is represented by a fourth rank tensor s_{ijkl}. The permutation symmetry of this tensor is $s_{ijkl} = s_{jikl} = s_{ijlk}$, $i, j, k, l = 1, 2, 3$. The tensor can be represented by a 6×6 matrix; that is, $s_{ijkl} \Rightarrow s_{kl}$, $k, l = 1, \ldots, 6$. The quadratic electro-optic coefficient matrices for all crystal classes are given in Table 2. Reference 16 contains a table of quadratic electro-optic coefficients for several materials.

The Linear Electro-Optic Effect

An electric field applied in a general direction to a noncentrosymmetric crystal produces a linear change in the constants $(1/n^2)_i$ due to the linear electro-optic effect according to

$$\Delta(1/n^2)_i=\sum_j r_{ij}E_j \qquad \begin{matrix} i=1,\ldots,6 \\ j=x,y,z=1,2,3 \end{matrix} \tag{7}$$

where r_{ij} is the ijth element of the linear electro-optic tensor in contracted notation. In matrix form Eq. (7) is

$$\begin{pmatrix}\Delta(1/n^2)_1\\ \Delta(1/n^2)_2\\ \Delta(1/n^2)_3\\ \Delta(1/n^2)_4\\ \Delta(1/n^2)_5\\ \Delta(1/n^2)_6\end{pmatrix}=\begin{pmatrix}r_{11}&r_{12}&r_{13}\\ r_{21}&r_{22}&r_{23}\\ r_{31}&r_{32}&r_{33}\\ r_{41}&r_{42}&r_{43}\\ r_{51}&r_{52}&r_{53}\\ r_{61}&r_{62}&r_{63}\end{pmatrix}\begin{pmatrix}E_x\\ E_y\\ E_z\end{pmatrix} \tag{8}$$

$$\begin{pmatrix} s_{11} & s_{12} & s_{12} & 0 & 0 & 0 \\ s_{12} & s_{11} & s_{12} & 0 & 0 & 0 \\ s_{12} & s_{12} & s_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & s_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & s_{44} \end{pmatrix}$$

Isotropic:

$$\begin{pmatrix} s_{11} & s_{12} & s_{12} & 0 & 0 & 0 \\ s_{12} & s_{11} & s_{12} & 0 & 0 & 0 \\ s_{12} & s_{12} & s_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{2}(s_{11}-s_{12}) & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{2}(s_{11}-s_{12}) & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{2}(s_{11}-s_{12}) \end{pmatrix}$$

E_x, E_y, and E_z are the components of the applied electric field in principal coordinates. The magnitude of $\Delta(1/n^2)$ is typically on the order of less than 10^{-5}. Therefore, these changes are mathematically referred to as perturbations. The new impermeability tensor $[1/n^2]'$ in the presence of an applied electric field is no longer diagonal in the reference principal dielectric axes system. It is given by

$$[1/n^2]' = \begin{pmatrix} 1/n_x^2 + \Delta(1/n^2)_1 & \Delta(1/n^2)_6 & \Delta(1/n^2)_5 \\ \Delta(1/n^2)_6 & 1/n_y^2 + \Delta(1/n^2)_2 & \Delta(1/n^2)_4 \\ \Delta(1/n^2)_5 & \Delta(1/n^2)_4 & 1/n_z^2 + \Delta(1/n^2)_3 \end{pmatrix} \tag{9}$$

and is determined by the unperturbed principal refractive indices, the electro-optic coefficients, and the direction of the applied field relative to the principal coordinate system. However, the field-induced perturbations are symmetric, so the symmetry of the tensor is not disturbed. The new index ellipsoid is now represented by

$$(1/n^2)'_1 x^2 + (1/n^2)'_2 y^2 + (1/n^2)'_3 z^2 + 2(1/n^2)'_4 yz + 2(1/n^2)'_5 xz + 2(1/n^2)'_6 xy = 1 \tag{10}$$

or equivalently, $\mathbf{X}^T[1/n^2]'\mathbf{X} = 1$, where $\mathbf{X} = [x\ y\ z]^T$.[19,26] The presence of cross terms indicates that the ellipsoid is rotated and the lengths of the principal dielectric axes are changed. Determining the new orientation and shape of the ellipsoid requires that $[1/n^2]'$ be diagonalized, thus determining its eigenvalues and eigenvectors. After diagonalization, in a suitably rotated new coordinate system $\mathbf{X}' = [x'\ y'\ z']$ the perturbed ellipsoid will then be represented by a square sum:

$$\frac{x'^2}{n_{x'}^2} + \frac{y'^2}{n_{y'}^2} + \frac{z'^2}{n_{z'}^2} = 1 \tag{11}$$

The eigenvalues of $[1/n^2]'$ are $1/n_{x'}^2$, $1/n_{y'}^2$, $1/n_{z'}^2$. The corresponding eigenvectors are $\mathbf{x}' = [x_{x'}\, y_{x'}\, z_{x'}]^T$, and $\mathbf{y}' = [x_{z'}\, y_{z'}\, z_{z'}]^T$, respectively.

The Quadratic or Kerr Electro-Optic Effect

An electric field applied in a general direction to any crystal, centrosymmetric or noncentrosymmetric, produces a quadratic change in the constants $(1/n^2)_i$ due to the quadratic electro-optic effect according to

$$\begin{pmatrix} \Delta(1/n^2)_1 \\ \Delta(1/n^2)_2 \\ \Delta(1/n^2)_3 \\ \Delta(1/n^2)_4 \\ \Delta(1/n^2)_5 \\ \Delta(1/n^2)_6 \end{pmatrix} = \begin{pmatrix} s_{11} & s_{12} & s_{13} & s_{14} & s_{15} & s_{16} \\ s_{21} & s_{22} & s_{23} & s_{24} & s_{25} & s_{26} \\ s_{31} & s_{32} & s_{33} & s_{34} & s_{35} & s_{36} \\ s_{41} & s_{42} & s_{43} & s_{44} & s_{45} & s_{46} \\ s_{51} & s_{52} & s_{53} & s_{54} & s_{55} & s_{56} \\ s_{61} & s_{62} & s_{63} & s_{64} & s_{65} & s_{66} \end{pmatrix} \begin{pmatrix} E_x^2 \\ E_y^2 \\ E_z^2 \\ E_y E_z \\ E_x E_z \\ E_x E_y \end{pmatrix} \tag{12}$$

E_x, E_y, and E_z are the components of the applied electric field in principal coordinates. The perturbed impermeability tensor and the new index ellipsoid have the same form as Eqs. (9) and (10).

Normally, there are two distinctions made when considering the Kerr effect: the ac Kerr effect and the dc Kerr effect. The induced changes in the optical properties of the material can occur as the result of a slowly varying applied electric field, or it can result from the electric field of the light itself. The former is the dc Kerr effect and the latter is the ac or optical Kerr effect. The dc Kerr effect is given by

$$\Delta n = \lambda \mathrm{K} \mathrm{E}^2 \tag{13}$$

where K is the Kerr constant in units of m/V^2 and λ is the freespace wavelength. Some polar liquids such as nitrobenzene ($C_6H_5NO_2$), which is poisonous, exhibit very large Kerr constants which are much greater than those of transparent crystals.[27] In contrast to the linear Pockels electro-optic effect, larger voltages are required for any significant Kerr modulation.

The ac or optical Kerr effect occurs when a very intense beam of light modulates the optical material. The optical Kerr effect is given by

$$n = n_o + n_2 I \tag{14}$$

which describes the intensity dependent refractive index n, where n_o is the unmodulated refractive index, n_2 is the second order nonlinear refractive index (m^2/W), and I is the intensity of the wave (W). Equation 14 is derived from the expression for the electric field induced polarization in a material as a function of the linear and nonlinear susceptibilities. This intensity dependent refractive index is used as the basis for Kerr-lens mode-locking of ultrashort lasers. It is also responsible for nonlinear effects of self-focusing and self-phase modulation.[28]

A Mathematical Approach: The Jacobi Method

The analytical design and study of electro-optic modulators require robust mathematical techniques due to the small, anisotropic perturbations to the refractive index profile of a material. Especially with the newer organic crystals, polymers, and tailored nanostructured materials, the properties are often biaxial before and after applied voltages. The optimum modulator configuration may not be along principal axes. In addition, sensitivities in modulation characteristics of biaxial materials (natural and/or induced) can negatively impact something as simple as focusing a beam onto the material. Studying the electro-optic effect is basically an eigenvalue problem.

Although the eigenvalue problem is a familiar one, obtaining accurate solutions has been the subject of extensive study.[29–32] A number of formalisms are suggested in the literature to address the specific problem of finding the new set of principal dielectric axes relative to the zero-field principal

dielectric axes. Most approaches, however, do not provide a consistent means of labeling the new axes. Also, some methods are highly susceptible to numerical instabilities when dealing with very small off-diagonal elements as in the case of the electro-optic effect. In contrast to other methods,[15,22,26,30,33,34] a similarity transformation is an attractive approach for diagonalizing a symmetric matrix for the purpose of determining its eigenvalues and eigenvectors.[21,29,30,32,35]

The Jacobi method utilizes the concepts of rigid-body rotation and the properties of ellipsoids to determine the principal axes and indices of a crystal by constructing a series of similarity transformations that consist of elementary plane rotations. The method produces accurate eigenvalues and orthogonal eigenvectors for matrices with very small off-diagonal elements, and it is a systematic procedure for ordering the solutions to provide consistent labeling of the principal axes.[21,31] The sequence of transformations are applied to the perturbed index ellipsoid and convert from one set of orthogonal axes $\mathbf{X} = [x, y, z]$ to another set $[x', y', z']$, until a set of axes coincides with the new principal dielectric directions and the impermeability matrix is diagonalized. Since similarity is a transitive property, several transformation matrices can be multiplied to generate the desired cumulative matrix.[21,29] Thus, the problem of determining the new principal axes and indices of refraction of the index ellipsoid in the presence of an external electric field is analogous to the problem of finding the cumulative transformation matrix $[a] = [a_m] \cdots [a_2][a_1]$ that will diagonalize the perturbed impermeability tensor. The transformation required matrix, $[a]$, is simply the product of the elementary plane rotation matrices multiplied in the order in which they are applied.

When plane rotations are applied to the matrix representation of tensors, the magnitude of a physical property can be evaluated in any arbitrary direction. When the matrix is transformed to diagonal form, the eigenvalues lie on the diagonal and the eigenvectors are found in the rows or columns of the corresponding transformation matrices. Specifically, a symmetric matrix $[\mathbf{A}]$ can be reduced to diagonal form by the transformation $[a][\mathbf{A}][a]^T = [\lambda]$, where $[\lambda]$ is a 3×3 diagonal matrix and $[a]$ is the orthogonal transformation matrix. Since the eigenvalues of $[\mathbf{A}]$ are preserved under similarity transformation, they lie on the diagonal of $[\lambda]$, as in Eq. (1).

In terms of the index ellipsoid, first recall that the perturbed index ellipsoid in the original (zero field) coordinate system is $\mathbf{X}^T[1/n^2]'\mathbf{X} = 1$, where $[1/n^2]'$ is given by Eq. (9). A suitable matrix, $[a]$, will relate the "new" principal axes $\mathbf{X}'$ of the perturbed ellipsoid to the "old" coordinate system; that is, $\mathbf{X}' = [a]\mathbf{X}$, or $\mathbf{X} = [a]^T\mathbf{X}'$. Substituting these relationships into the index ellipsoid results in

$$\begin{aligned} ([a]^T\mathbf{X}')^T[1/n^2]'[a]^T\mathbf{X}' &= 1 \\ \mathbf{X}'^T[a][1/n^2]'[a]^T\mathbf{X}' &= 1 \\ \mathbf{X}'^T[1/n^2]''\mathbf{X}' &= 1 \end{aligned} \tag{15}$$

where $[a][1/n^2]'[a]^T = [1/n^2]''$ is the diagonalized impermeability matrix in the new coordinate system and $[a]$ is the cumulative transformation matrix.

Using the Jacobi method, each simple elementary plane rotation that is applied at each step will zero an off-diagonal element of the impermeability tensor. The goal is to produce a diagonal matrix by minimizing the norm of the off-diagonal elements to within a desired level of accuracy. If m transformations are required, each step is represented by

$$[1/n^2]_m = [a_m][1/n^2]_{m-1}[a_m]^T \tag{16}$$

To determine the form of each elementary plane rotation, the Jacobi method begins by first selecting the largest off-diagonal element $(1/n^2)_{ij}$ and executing a rotation in the (i, j) plane, $i < j$, so as to zero that element. The required rotation angle Ω is given by

$$\tan(2\Omega) = \left(\frac{2(1/n^2)_{ij}}{(1/n^2)_{ii} - (1/n^2)_{jj}} \right) \qquad i, j = 1, 2, 3 \tag{17}$$

For example, if the largest off-diagonal element is $(1/n_{12}^2) = (1/n_{21}^2)$, then the plane rotation is represented by

$$[a] = \begin{pmatrix} \cos\Omega & \sin\Omega & 0 \\ -\sin\Omega & \cos\Omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{18}$$

which is a counter clockwise rotation about the three-axis. If $(1/n^2)_{ii} = (1/n^2)_{jj}$, which can occur in isotropic and uniaxial crystals, then $|\Omega|$ is taken to be 45°, and its sign is taken to be the same as the sign of $(1/n^2)_{ij}$. The impermeability matrix elements are updated with the following equations, which are calculated from the transformation of Eq. (15):

$$\begin{pmatrix} (1/n_{11}^2)' & 0 & (1/n_{13}^2)' \\ 0 & (1/n_{22}^2)' & (1/n_{23}^2)' \\ (1/n_{13}^2)' & (1/n_{23}^2)' & (1/n_{33}^2)' \end{pmatrix} = \begin{pmatrix} \cos\Omega & \sin\Omega & 0 \\ -\sin\Omega & \cos\Omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1/n_{11}^2 & 1/n_{12}^2 & 1/n_{13}^2 \\ 1/n_{12}^2 & 1/n_{22}^2 & 1/n_{23}^2 \\ 1/n_{13}^2 & 1/n_{23}^2 & 1/n_{33}^2 \end{pmatrix} \begin{pmatrix} \cos\Omega & -\sin\Omega & 0 \\ \sin\Omega & \cos\Omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{19}$$

Once the new elements are determined, the next iteration step is performed, selecting the new largest off-diagonal element and repeating the procedure with another suitable rotation matrix. The process is terminated when all of the off-diagonal elements are reduced below the desired level (typically 10^{-10}). The next step is to determine the cumulative transformation matrix $[a]$. One way is to multiply the plane rotation matrices in order, either as $[a] = [a_m] \cdots [a_2][a_1]$ or equivalently for the transpose of [a] as

$$[a]^T = [a_1]^T [a_2]^T \cdots [a_m]^T \tag{20}$$

The set of Euler angles, which also defines the orientation of a rigid body, can be obtained from the cumulative transformation matrix $[a]$.[36,37] These angles are given in the Appendix. Several examples for using the Jacobi method are given in Ref. 21.

Determining the Eigenpolarizations and Phase Velocity Indices of Refraction

After the perturbed impermeability matrix is diagonalized, the polarization directions of the two allowed linear orthogonal waves $\mathbf{D}_1$ and $\mathbf{D}_2$ that propagate independently for a given wavevector direction $\mathbf{k}$ can be determined along with their respective phase velocity refractive indices $n_{x'''}$ and $n_{y'''}$. These waves are the only two that can propagate with unchanging orientation for the given wavevector direction. Figure 4*a* depicts these axes for a crystal in the absence of an applied field. Figure 4*b* depicts the x''' and y''' axes, which define the fast and slow axes, when an electric field is applied in a direction so as to reorient the index ellipsoid. The applied field, in general, rotates the allowed polarization directions in the plane perpendicular to the direction of phase propagation as shown in Fig. 4*b*. Determining these "eigenpolarizations," that is, $\mathbf{D}_1$, $\mathbf{D}_2$, n_1, and n_2, is also an eigenvalue problem.

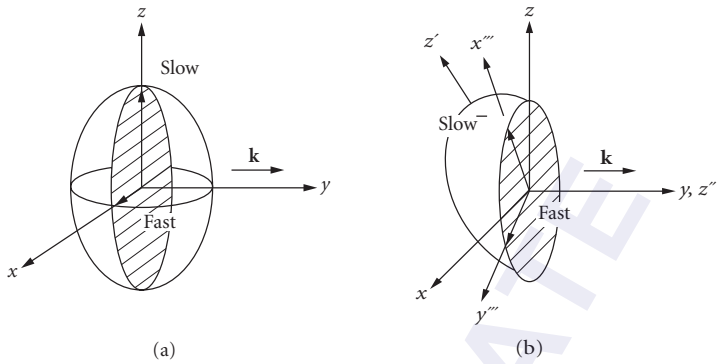

FIGURE 4 (*a*) The cross-section ellipse for a wave propagating along the *y* principal axis is shown with no field applied to the crystal; (*b*) with an applied electric field the index ellipsoid is reoriented, and the eigenpolarizations in the plane transverse to **k** are rotated, indicated by x''' and y'''.

The perturbed index ellipsoid resulting from an external field was given by Eq. (10) in the original principal-axis coordinate system. For simplicity, the coefficients may be relabeled as

$$Ax^2 + By^2 + Cz^2 + 2Fyz + 2Gxz + 2Hxy = 1$$

or

$$\mathbf{X}^T \begin{pmatrix} A & H & G \\ H & B & F \\ G & F & C \end{pmatrix} \mathbf{X} = 1 \tag{21}$$

where *x, y,* and *z* represent the original dielectric axes with no applied field and $\mathbf{X}^T = [x\ y\ z]$. However, before the eigenpolarizations can be determined, the direction of light propagation, **k**, through the material whose index ellipsoid has been perturbed, must be defined. The problem is then to determine the allowed eigenpolarizations and phase velocity refractive indices associated with this direction of propagation. The optical wavevector direction **k** is conveniently specified by the spherical coordinates angles θ_k and ϕ_k in the (*x, y, z*) coordinate system as shown in Fig. 5. Given **k**, the cross

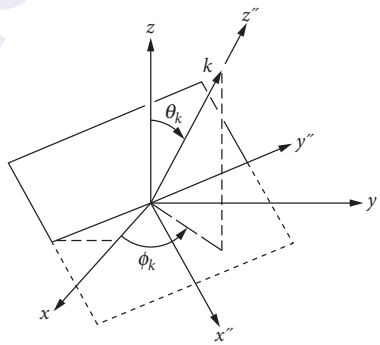

FIGURE 5 The coordinate system (x'', y'', z'') of the wavevector **k** is defined with its angular relationship (ϕ_k, θ_k) with respect to the unperturbed principal dielectric axes coordinate system (*x, y, z*).[21]

section ellipse through the center of the perturbed ellipsoid of Eq. (21) may be drawn. The directions of the semiaxes of this ellipse represent the fast and slow polarization directions of the two waves $\mathbf{D}_1$ and $\mathbf{D}_2$ that propagate independently. The lengths of the semiaxes are the phase velocity indices of refraction. The problem is to determine the new polarization directions x''' of $\mathbf{D}_1$ and y''' of $\mathbf{D}_2$ relative to the (x, y, z) axes and the corresponding new indices of refraction $n_{x'''}$ and $n_{y'''}$.

The first step is to do a transformation from the (x, y, z) (lab or principal axis) coordinate system to a coordinate system (x'', y'', z'') aligned with the direction of phase propagation. In this example, (x'', y'', z'') is chosen such that $z'' \| \mathbf{k}$, and x'' is lying in the (z, z'') plane. The (x'', y'', z'') system is, of course, different from the (x', y', z') perturbed principal axes system. Using the spherical coordinate angles of $\mathbf{k}$, the (x'', y'', z'') system may be produced first by a counterclockwise rotation ϕ_k about the z axis followed by a counterclockwise rotation θ_k about y'' as shown in Fig. 5. This transformation is described by $\mathbf{X}'' = [a]\mathbf{X}$, or $[a]^T\mathbf{X}'' = \mathbf{X}$ and is explicitly,

$$X = \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \begin{pmatrix} \cos\phi_k & -\sin\phi_k & 0 \\ \sin\phi_k & \cos\phi_k & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \cos\theta_k & 0 & -\sin\theta_k \\ 0 & 1 & 0 \\ \sin\theta_k & 0 & \cos\theta_k \end{pmatrix} \begin{pmatrix} x'' \\ y'' \\ z'' \end{pmatrix} \tag{22}$$

The equation for the cross section ellipse normal to $\mathbf{k}$ is determined by substituting Eq. (22) into Eq. (21) and setting $z'' = 0$ or by matrix substitution as follows:

$$\begin{aligned} ([a]^T\mathbf{X}'')^T[1/n^2]'([a]^T\mathbf{X}'') &= 1 \\ \mathbf{X}''^T \underbrace{[a][1/n^2]'[a]^T}_{[1/n^2]''}\mathbf{X}'' &= 1 \end{aligned} \tag{23}$$

which results in

$$\mathbf{X}''^T[1/n^2]''\mathbf{X}'' = 1$$

or

$$(x'' \quad y'' \quad z'')\begin{pmatrix} A'' & H'' & G'' \\ H'' & B'' & F'' \\ G'' & F'' & C'' \end{pmatrix}\begin{pmatrix} x'' \\ y'' \\ z'' \end{pmatrix} = 1 \tag{24}$$

The coefficients of the cross section ellipse equation described by Eq. (24), with z'' set to zero, are used to determine the eigenpolarization directions and the associated phase velocity refractive indices for the chosen direction of propagation. The cross section ellipse normal to the wavevector direction $\mathbf{k} \| z''$ is represented by the 2×2 submatrix of $[1/n^2]''$:

$$(x'' \; y'')\begin{pmatrix} A'' & H'' \\ H'' & B'' \end{pmatrix}\begin{pmatrix} x'' \\ y'' \end{pmatrix} = A''x''^2 + B''y''^2 + 2H''x''y'' = 1 \tag{25}$$

The polarization angle β_1 of x''' ($\mathbf{D}_1$) with respect to x'', as shown in Fig. 6, is given by

$$\beta_1 = \frac{1}{2}\tan^{-1}\left[\frac{2H''}{(A''-B'')}\right] \tag{26}$$

The polarization angle β_2 of y''' ($\mathbf{D}_2$) with respect to x'' is $\beta_1 + \pi/2$. The axes are related by a plane rotation $\mathbf{X}''' = [a_{\beta 1}]\mathbf{X}''$ or

$$\begin{pmatrix} x'' \\ y'' \end{pmatrix} = \begin{pmatrix} \cos\beta_1 & -\sin\beta_1 \\ \sin\beta_1 & \cos\beta_1 \end{pmatrix}\begin{pmatrix} x''' \\ y''' \end{pmatrix} \tag{27}$$

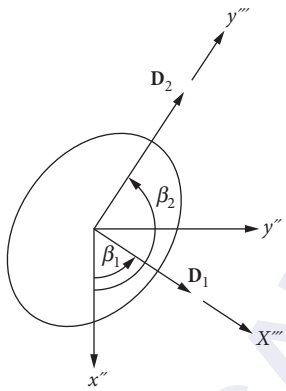

FIGURE 6 The polarization axes (x''', y''') are the *fast* and *slow* axes and are shown relative to the (x'', y'') axes of the wavevector coordinate system. The wavevector **k** and the axes z'' and z''' are normal to the plane of the figure.[21]

The refractive indices, $n_{x'''}$ and $n_{y'''}$ may be found by performing one more rotation in the plane of the ellipse normal to **k**, using the angle β_1 or β_2 and the rotation of Eq. (27). The result is a new matrix that is diagonalized,

$$[1/n_2]''' = \begin{pmatrix} 1/n_{x'''} & 0 \\ 0 & 1/n_{y'''} \end{pmatrix} = [a_{\beta 1}]^T [1/n_2]'' [a_{\beta 1}] \tag{28}$$

The larger index corresponds to the slow axis and the smaller index to the fast axis.

7.5 MODULATOR DEVICES

An electro-optic modulator is a device with operation based on an electrically induced change in index of refraction or change in natural birefringence. Depending on the device configuration, the following properties of the light wave can be varied in a controlled way: phase, polarization, amplitude, frequency, or direction of propagation. The device is typically designed for optimum performance at a single wavelength, with some degradation in performance with wideband or multimode lasers.[16,38,39]

Electro-optic devices can be used in analog or digital modulation formats. The choice is dictated by the system requirements and the characteristics of available components (optical fibers, sources/detectors, etc.). Analog modulation requires large signal-to-noise ratios (SNR), thereby limiting its use to narrow-bandwidth, short-distance applications. Digital modulation, on the other hand, is more applicable to large-bandwidth, medium to long distance systems.[38,39]

Device Geometries

A bulk electro-optic modulator can be classified as one of two types, *longitudinal* or *transverse*, depending on how the voltage is applied relative to the direction of light propagation in the device. Basically a bulk modulator consists of an electro-optic crystal sandwiched between a pair of electrodes and, therefore, can be modeled as a capacitor. In general, the input and output faces are parallel for the beam to undergo a uniform phase shift over the beam cross section.[16] Waveguide modulators are discussed later in the section "Waveguide or Integrated-Optic Modulators" and have a variety of electrode configurations that are analogous to longitudinal and transverse orientations, although the distinction is not as well defined.

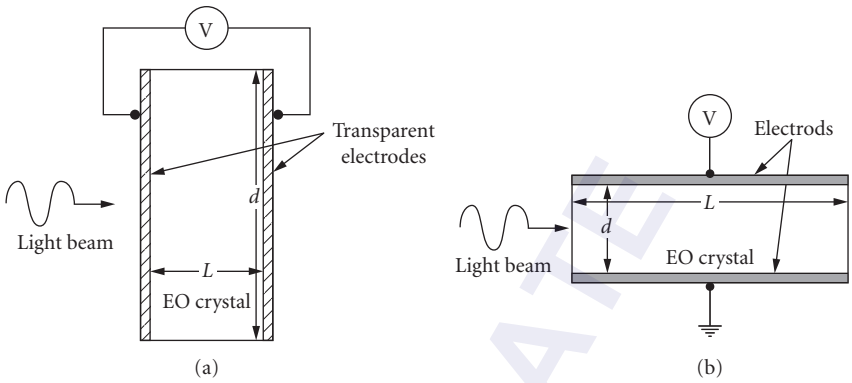

FIGURE 7 (*a*) A longitudinal electro-optic modulator has the voltage applied parallel to the direction of light propagation and (*b*) a transverse modulator has the voltage applied perpendicular to the direction of light propagation.[16]

In the bulk longitudinal configuration, the voltage is applied parallel to the wavevector direction as shown in Fig. 7*a*.[16,25,40–43] The electrodes must be transparent to the light either by the choice of material used for them (metal-oxide coatings of SnO, InO, or CdO) or by leaving a small aperture at their center at each end of the electro-optic crystal.[25,41–43] The ratio of the crystal length L to the electrode separation b is defined as the *aspect ratio.* For this configuration $b = L$, and, therefore, the aspect ratio is always unity. The magnitude of the applied electric field inside the crystal is $E = V/L$. The induced phase shift is proportional to V and the wavelength λ of the light but not the physical dimensions of the device. Therefore, for longitudinal modulators, the required magnitude of the applied electric field for a desired degree of modulation cannot be reduced by changing the aspect ratio, and it increases with wavelength. However, these modulators can have a large acceptance area and are useful if the light beam has a large cross-sectional area.

In the transverse configuration, the voltage is applied perpendicular to the direction of light propagation as shown in Fig. 7*b*.[16,40–43] The electrodes do not obstruct the light as it passes through the crystal. For this case, the aspect ratio can be very large. The magnitude of the applied electric field is $E = V/d$, ($b = d$), and d can be reduced to increase E for a given applied voltage, thereby increasing the aspect ratio L/b. The induced phase shift is inversely proportional to the aspect ratio; therefore, the voltage necessary to achieve a desired degree of modulation can be greatly reduced. Furthermore,

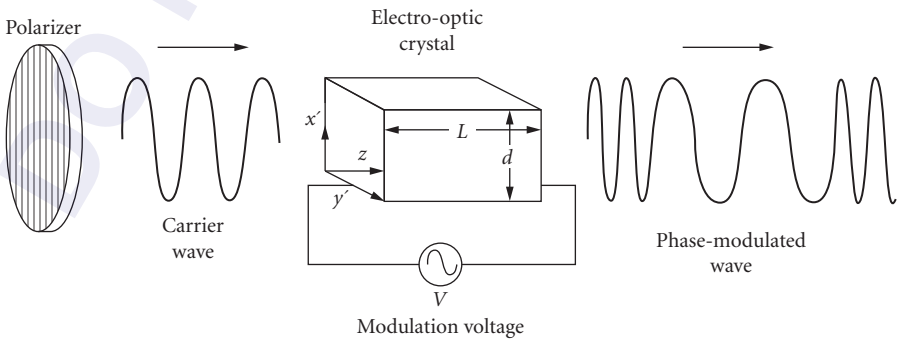

FIGURE 8 A longitudinal phase modulator is shown with the light polarized along the new x' principal axis when the modulation voltage V is applied.[16]

the interaction length can be long for a given field strength. However, the transverse dimension d is limited by the increase in capacitance, which affects the modulation bandwidth or speed of the device, and by diffraction for a given length L, since a beam with finite cross section diverges as it propagates.[16,41,44]

Bulk Modulators

The modulation of phase, polarization, amplitude, frequency, and position of light can be implemented using an electro-optic bulk modulator with polarizers and passive birefringent elements. Three assumptions are made in this section. First, the modulating field is *uniform* throughout the length of the crystal; the change in index or birefringence is uniform unless otherwise stated. Second, the modulation voltage is dc or very low radian frequency ω_m ($\omega_m \ll 2\pi/\tau$); the light experiences the same induced Δn during its transit time τ through the crystal of length L, and the capacitance is negligible. Finally, light propagation is taken to be along a principal axis, before and after the voltage is applied; therefore, the equations for the eigenpolarizations are presented in terms of the *optical electric field* **E**, rather than the *displacement vector* **D**, which is a common practice in various optical references. For other general configurations, the equations should be expressed in terms of the eigenpolarizations $\mathbf{D}_1$ and $\mathbf{D}_2$. However, the electric field will determine the direction of energy flow, which is generally not in the same direction as the wavevector. References 16 and 41, among others, provide examples of modulator devices using potassium dihydrogen phosphate (KDP), lithium niobate ($LiNbO_3$), lithium tantalate ($LiTaO_3$), gallium arsenide (GaAs), and barium titanate ($BaTiO_3$).

Phase Modulator A light wave can be phase modulated, without change in polarization or intensity, using an electro-optic crystal and an input polarizer in the proper configuration. This is the simplest electro-optic modulator. As an example, consider a longitudinal device that is made of a $LiNbO_3$ crystal as shown in Fig. 8, with the voltage applied in the z direction. In general, an applied voltage V will rotate the principal axes in the crystal cross section. However, for phase modulation, the input polarizer must be aligned parallel to one of the principal axes that will have a preserved orientation when the voltage is on or off. The $LiNbO_3$ crystal is uniaxial with symmetry 3m, and it is a common material for electro-optic modulators. Substituting into Eq. (7) results in

$$\begin{pmatrix} 0 & -r_{22} & r_{13} \\ 0 & r_{22} & r_{13} \\ 0 & 0 & r_{33} \\ 0 & r_{51} & 0 \\ r_{51} & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 \\ 0 \\ E_z \end{pmatrix} = \begin{pmatrix} r_{13}E_z \\ r_{13}E_z \\ r_{33}E_z \\ 0 \\ 0 \\ 0 \end{pmatrix} \tag{29}$$

Figure 8 indicates the polarizer along x' provides an input optical electric field $E_{\text{in}}(t) = E_x \cos\omega t$. The voltage is applied in the z direction and thus, has only one component, E_z. In this case, the perturbed index ellipsoid will be

$$x^2(1/n_o^2 + r_{13}E_z) + y^2(1/n_o^2 + r_{13}E_z) + z^2(1/n_e^2 + r_{33}E_z) = 1 \tag{30}$$

where $n_x = n_y = n_o$ is the ordinary refractive index and $n_z = n_e$ is the extraordinary refractive index of this uniaxial crystal. The orientation of the principal axes remains unchanged, but the lengths of the axes, and hence the phase velocity refractive indices, have been modified by the applied electric field. The optical wave at the output of the crystal at $z = L$ is

$$E_{\text{out}}(t) = E_x \cos(\omega t - \phi) \tag{31}$$

where

$$\phi = \frac{2\pi}{\lambda}(n_{X'} + \Delta n_{x'})L = \phi_{o'} + \Delta\phi_{x'} \tag{32}$$

is the total phase shift consisting of a natural phase term $\phi_o = (2\pi/\lambda)Ln_{x'}$, with $n_{x'}$ being the unperturbed index in the x' (= x, in this example) direction, and an electrically induced phase term $\Delta\phi_{x'} = (2\pi/\lambda)L\Delta n_{x'}$ for a polarization along x', The new x' axis has length $2n_{x'}$, where

$$(1/n_{x'})^2 = (1/n_o^2) + r_{13}E_z \tag{33}$$

Using the derivative $\Delta(1/n^2)' = -2n^{-3}\Delta n$ results in

$$\Delta n_x' \approx (-1/2)n_o^3 r_{13}E_z \tag{34}$$

an approximation often seen in literature.

For a longitudinal modulator the applied electric field is $E_z = V/L$, and the induced phase shift is $\Delta\phi_{x'} = \pi/\lambda\, n_x^3 rV$, which is independent of L and is linearly related to V. For a transverse modulator $E = V/d$ and the induced phase shift is $\Delta\phi_{x'} = \pi/\lambda\, n_{x'}^3 rV(L/d)$, which is a function of the aspect ratio L/d and V. The voltage that would produce an induced phase shift of $\Delta\phi_{x'} = \pi$ is the *half-wave voltage*. The half-wave voltage is $V_\pi = \lambda/n_x^3 r$ for a longitudinal modulator and $V_\pi = (\lambda/n_x^3 r)(d/L)$ for a transverse modulator.

Whenever possible, it is desired to take advantage of the largest electro-optic coefficient. In $LiNbO_3$, $r_{13} = 10$ and $r_{33} = 32$. To use r_{33}, the optical input signal should be polarized in the z direction.

If a dc applied voltage is used, one of two possibilities is required for a crystal and its orientation. The first possibility is a crystal having principal axes which will not rotate with applied voltage V; an example is $LiNbO_3$ with V applied in the z direction and an input polarization along the $x' = x$ axis propagating along $z' = z$. The second possibility is a crystal having a characteristic plane, that is, a plane exhibiting a constant refractive index perpendicular to the direction of propagation. If a field is applied such that the axes rotate in this plane, the input wave must be polarized along one of the new principal axes. Therefore, it will always be polarized along a principal axis, whether the voltage is on or off. An example is KDP with V along the z axis and an input wave polarized along the new principal axis x' and propagating along $z' = z$. Phase modulation is then achieved by turning the voltage on and off.

If the applied modulation voltage is sinusoidal in time ($V = V_m \sin\omega_m t$), the corresponding electric field can be represented by $E = E_m \sin\omega_m t$.

The magnitude of the field varies only with time, not space; it is a stationary wave applied in the same direction for all the time. In other words, this time-varying voltage signal is to be distinguished from a traveling wave voltage which will be discussed in the next section. In this case,

$$\begin{aligned}\phi &= \left(\frac{2\pi}{\lambda}\right)\left(n_{x'} - \frac{1}{2}n_x^3 rE_m \sin\omega_m t\right)L \\ &= \left(\frac{2\pi}{\lambda}\right)n_{x'}L - \delta\sin\omega_m t\end{aligned} \tag{35}$$

The parameter $\delta = (\pi/\lambda)n_x^3 rE_m L = \pi V_m/V_\pi$, where V_π is the half-wave voltage for a given configuration, is the *phase modulation index* or *depth-of-phase modulation*. By neglecting the constant phase term ϕ_o, applying the identity $\cos(\delta\sin\omega_m t) + j\sin(\delta\sin\omega_m t) = \exp[j\delta\sin\omega_m t] = \sum_{l=-\infty}^{\infty} J_l(\delta)\exp[jl\omega t]$, and equating the real and imaginary parts, the output light wave becomes

$$\begin{aligned}E_o(t) = E_i[&j_o(\delta)\cos\omega t + J_l(\delta)\cos(\omega+\omega_m)t - J_1(\delta)\cos(\omega-\omega_m)t \\ &+ J_2(\delta)\cos(\omega+2\omega_m)t + J_2(\delta)\cos(\omega-2\omega_m)t + \cdots]\end{aligned} \tag{36}$$

The output consists of components at frequencies ω and $(\omega + n\omega_m)$, $n = \pm 1, \pm 2, \ldots$. For no modulation, $\delta = 0$ and $J_o(0) = 1$, $J_n(0) = 0$ for $n \neq 0$ and $E_o(t) = E_i \cos\omega t = E_{i_{x'}}(t)$.[16] For $\delta \approx 2.4048$, $J_0(\delta) = 0$ all the power is transferred to harmonic frequencies.[41] For the case of small modulation index, $\delta \ll 1$, most of the power resides in the carrier frequency at ω and a small amount resides in the first two sidebands at frequencies $\omega \pm \omega_m$. This condition makes phase modulators useful in laser mode-locking. Increasing δ results in the presence of more sidebands.

Polarization Modulator (***Dynamic Retardation***) Polarization modulation involves the coherent addition of two orthogonal waves, resulting in a change of the input polarization state at the output. As with a phase modulator, the basic components for an electro-optic polarization modulator (or dynamic retardation plate or polarization state converter) is an electro-optic crystal and an input polarizer. The crystal and applied voltage V (dc assumed) are configured to produce dynamically the fast and slow axes in the crystal cross section. In this case, however, the polarizer is positioned such that the input light wave is decomposed equally into the two orthogonal linear eigenpolarizations along these axes as shown in Fig. 9. If the light is polarized along the x axis and propagates along the z principal axis, for example, the propagating fields are

$$E_{x'} = E_o \cos[\omega t - (2\pi/\lambda) n_x z]$$
$$E_{y'} = E_o \cos[\omega t - (2\pi/\lambda) n_y z] \tag{37}$$

where the fast and slow axes are x' and y'. The corresponding refractive indices are

$$n_{x'} \approx n_x - \frac{1}{2} r_x n_x^3 E = n_x - \Delta n_x$$
$$n_{y'} \approx n_y - \frac{1}{2} r_y n_y^3 E = n_y - \Delta n_y \tag{38}$$

where n_x and n_y are the indices in the absence of an applied field and r_x, r_y are the appropriate electro-optic coefficients for the material being used and the orientation of the applied voltage. As the two polarizations propagate at different speeds through the crystal, a phase difference (relative phase) or *retardation* Γ evolves between them as a function of length:

$$\Gamma = \frac{2\pi}{\lambda}(n_{x'} - n_{y'})L$$
$$= \frac{2\pi}{\lambda}(n_x - n_y)L - \frac{\pi}{\lambda}\left(r_x n_x^3 - r_y n_y^3\right)EL = \Gamma_o + \Gamma_i \tag{39}$$

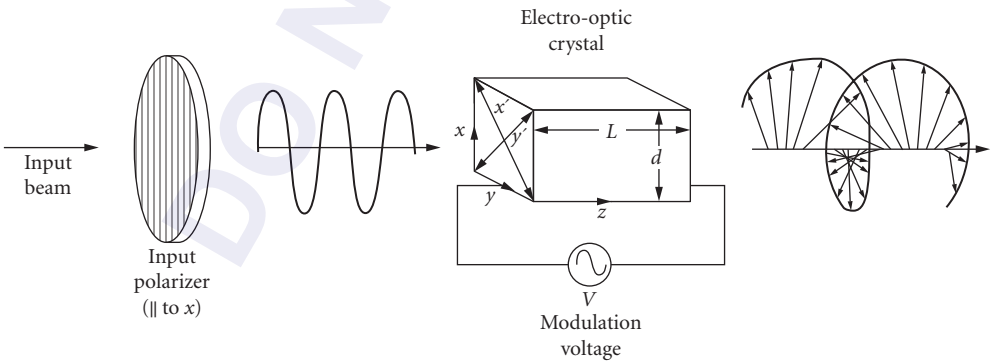

FIGURE 9 A longitudinal polarization modulator is shown with the input polarizer oriented along the x principal axis at 45° with respect to the perturbed x' and y' axes.

where Γ_o is the natural phase retardation in the absence of an applied voltage and Γ_i is the induced retardation linearly related to V.

For a longitudinal modulator the applied electric field is $E = V/L$, and the induced retardation is $\Gamma_i = (\pi/\lambda)(r_x n_y^3 = r_x n_x^3)V$, which is independent of L and linearly related to V.

For a transverse modulator $E = V/d$, and the induced retardation is $\Gamma_i = (\pi/\lambda)(r_y n_y^3 - r_x n_x^3)V(L/d)$, which is dependent on the aspect ratio L/d and V.

The optical fields at the output can be expressed in terms of Γ:

$$E_{x'} = \cos \omega t$$
$$E_{y'} = \cos(\omega t - \Gamma) \tag{40}$$

Therefore, the desired output polarization is obtained by applying the appropriate voltage magnitude. Figure 10 illustrates the evolution of the polarization state as a function of propagation distance z. In terms of an active device, Fig. 10 also can be interpreted as a change in polarization state as a function of applied voltage for fixed length. The eigenpolarizations $E_{x'}$ and $E_{y'}$ are in phase at $z = 0$. They have the same frequency but different wavelengths. Light from one polarization gradually couples into the other. In the absence of natural birefringence, $n_x - n_y = 0$, the voltage that would produce a retardation of $\Gamma = \Gamma_i = \pi$, such that a vertical polarization input becomes a horizontal polarization

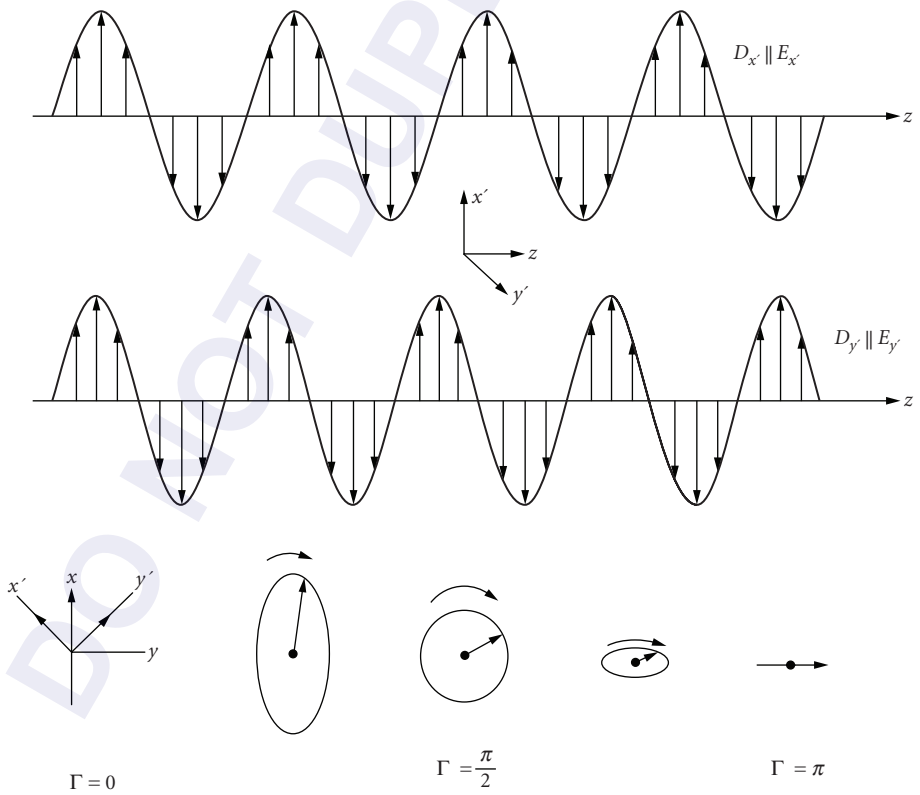

FIGURE 10 The polarization state of an input vertical linear polarization is shown as a function of crystal length L or applied voltage V. The retardation $\Gamma = \pi$ for a given length L_π in a passive $\lambda/2$ wave plate or applied voltage V_π in an electro-optic polarization modulator.[16]

output, is the *half-wave voltage* V_π. For a longitudinal modulator $V_\pi = \lambda/(r_x n_x^3 - r_y n_y^3)$, which is independent of L. For a transverse modulator $V_\pi = \lambda/(r_x n_x^3 - r_y n_y^3)(d/L)$, which is dependent on the aspect ratio L/d. The total retardation in terms of V_π (calculated assuming no birefringence) is

$$\Gamma = \Gamma_o + \pi\left(\frac{v}{v_\pi}\right) \tag{41}$$

To cancel the effect of natural birefringence, the phase retardation Γ_o can be made a multiple of 2π by slightly polishing the crystal to adjust the length or by applying a bias voltage. If birefringence is present, an effective V_π can be calculated that would give a total retardation of $\Gamma = \pi$.

To achieve polarization modulation, a birefringence must exist in the crystal cross section. If the cross section is a characteristic plane, then the input polarization propagates through the crystal unchanged when $V = 0$. If an applied voltage causes the axes to rotate 45° in this cross section with respect to the input polarization, as in Fig. 9, then the input will decompose into two equal components and change polarization state at the output. If the cross section has natural birefringence, then the input polarization state will change with $V = 0$ as well as with an applied voltage.

Amplitude Modulator The intensity (optical energy) of a light wave can be modulated in several ways. Some possibilities include using (1) a dynamic retarder configuration with a crossed polarizer at the output, (2) a dynamic retarder configuration with a parallel polarizer at the output, (3) a phase modulator configuration in a branch of a Mach-Zehnder interferometer, or (4) a dynamic retarder with push-pull electrodes. The intensity modulator parameter of interest is the *transmission* $T = I_o/I_i$, the ratio of output to input intensity.

An intensity modulator constructed using a dynamic retarder with crossed polarizers is shown in Fig. 11. The transmission for this modulator is

$$T(V) = \sin^2\left(\frac{\Gamma}{2}\right) = \sin^2\left(\frac{\Gamma_o}{2} + \frac{\pi V}{2V_\pi}\right) \tag{42}$$

For linear modulation, where the output is a replica of the modulating voltage signal, a fixed bias of $\Gamma_o = \pi/2$ must be introduced either by placing an additional phase retarder, a $\lambda/4$ wave plate (Fig. 11), at the output of the electro-optic crystal or by applying an additional dc voltage of $V_\pi/2$. This bias produces a transmission of $T = 0.5$ in the absence of a modulating voltage. If the crystal cross section has natural birefringence, then a variable compensator (Babinet-Soleil) or a voltage less than $V_\pi/2$ must be used to tune the birefringence to give a fixed retardation of $\pi/2$.

For a sinusoidal modulation voltage $V = V_m \sin \omega_m t$, the retardation at the output of the crystal, including the bias, is

$$\Gamma = \Gamma_o + \Gamma_i = \frac{\pi}{2} + \Gamma_m \sin \omega_m t \tag{43}$$

where $\Gamma_m = \pi V_m/V_\pi$ is the *amplitude modulation index* or *depth-of-amplitude modulation* and V_π is the half-wave voltage. The transmission becomes

$$\begin{aligned} T(V) &= \sin^2\left(\frac{\pi}{4} + \frac{\Gamma_m}{2}\sin \omega_m t\right) \\ &= \frac{1}{2}\left[1 - \cos\left(\frac{\pi}{2} + \Gamma_m \sin \omega_m t\right)\right] \end{aligned} \tag{44}$$

If the modulation voltage is small ($V_m \ll 1$), then the modulation depth is small ($\Gamma_m << 1$) and

$$T(V) = \frac{1}{2}[1 + \Gamma_m \sin \omega_m t] \tag{45}$$

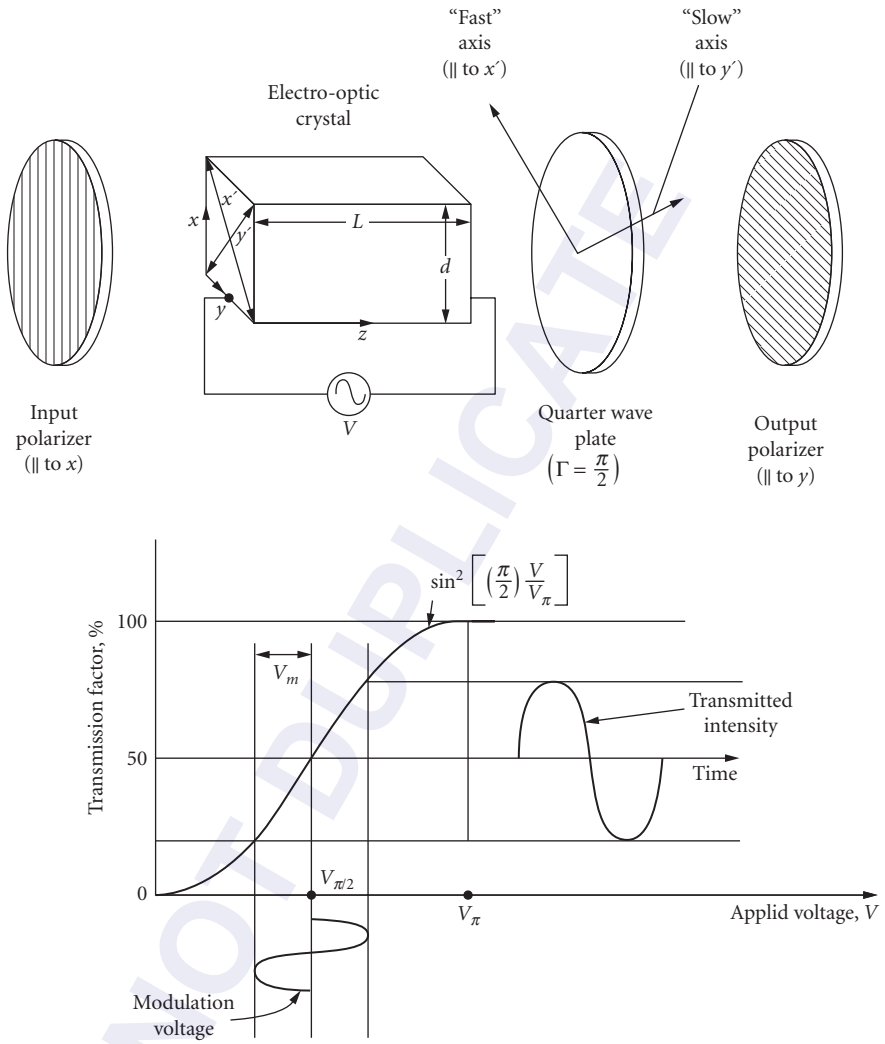

FIGURE 11 A longitudinal intensity modulator is shown using crossed polarizers with the input polarization along the x principal axis. A $\lambda/4$ wave plate is used as a bias to produce linear modulation.[16]

Therefore, the transmission or output intensity is linearly related to the modulating voltage. If the signal is large, then the output intensity becomes distorted and higher-order odd harmonics appear.[16]

The dynamic retarder with parallel polarizers has a transmission of[16]

$$t = \cos^2\left(\frac{\Gamma}{2}\right) = \cos^2\left(\frac{\pi}{4} + \frac{\Gamma_m}{2}\sin\omega_m t\right)$$

$$= \frac{1}{2}\left[1 + \cos\left(\frac{\pi}{2} + \Gamma_m \sin\omega_m t\right)\right] \tag{46}$$

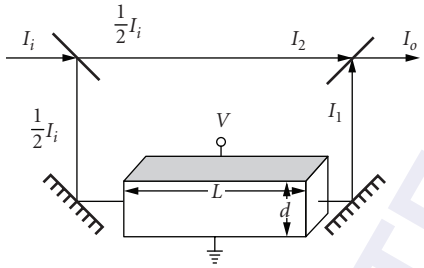

FIGURE 12 An intensity modulator is shown implementing a Mach-Zehnder interferometer configuration with a phase modulator in one branch.[42]

For small modulation, $T(V) = 1/2[-\Gamma_m \sin \omega_m t]$ and again, the output is a replica of the modulating voltage.

Similarly, the output of a Mach-Zehnder interferometer is given by

$$I_o = I_1 + I_2 + \frac{1}{2}[I_i \cos \Gamma_o + I_i] = I_i \cos\left(\frac{\Gamma_o}{2}\right) \tag{47}$$

where Γ_o is the relative phase shift between the two branches. An intensity modulator is produced by placing a phase modulator in one branch as shown in Fig. 12. The total retardation is $\Gamma = \Gamma_o + \Gamma_i$, as before. The transmission is

$$T = \frac{I_o}{I_i} = \cos^2\left(\frac{\Gamma}{2}\right) \tag{48}$$

The push-pull modulator is based on the Mach-Zehnder interferometer. In this case, a phase modulator is placed in each branch with opposite polarity voltages applied to the arms; the phase modulators are driven 180° out of phase. This configuration requires lower drive voltages and provides a shorter transit time for the light for a defined degree of modulation.[45]

Frequency Modulator In frequency modulation a shift or deviation in the frequency by ω_d from the optical carrier instantaneous frequency ω is desired. One approach to achieve a shift in frequency is to use an intensity modulator configuration of an electro-optic crystal between left- and right-hand circular polarizers. The electrodes on the modulator must be designed to produce an applied circular electric field.[46]

A crystal and its orientation are selected such that there is no birefringence in the crystal cross section at zero voltage. When a circular electric field with frequency ω_m, is applied; however, a birefringence is induced in the crystal cross section, and the induced principal axes rotate with angular velocity $\omega_m/2$ in the opposite sense with respect to the modulating field. The relative rotation between the axes and the modulating field creates a frequency shift in the optical electric field as it propagates through the crystal.

An example of such a device[46] is shown in Fig. 13. There are two sets of electrodes in the transverse configuration. The applied voltages are 90° out of phase to produce a left circular modulating field:

$$E_x = E_m \cos \omega_m t$$
$$E_y = E_m \sin \omega_m t \tag{49}$$

The principal axes in the crystal cross section rotate through an angle

$$\beta_1(t) = -\frac{1}{2}(\omega_m t + \Phi) \tag{50}$$

where Φ is a fixed angle that depends on the electro-optic coefficients r_{ij} of the crystal and not on the electric field magnitude.

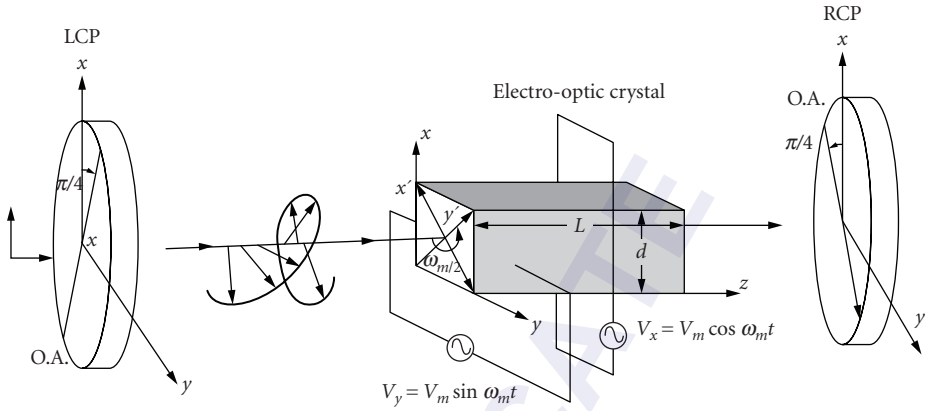

FIGURE 13 A frequency modulator using a phase modulator with two pairs of transverse electrodes set 90° out of phase to produce a circular applied electric field. The phase modulator is placed between left and right circular polarizers to create a frequency deviation in the output optical field.

The input optical wave (after the left circular polarizer) has field components

$$E_{i_x} = E_i \cos \omega t$$
$$E_{i_y} = E_i \sin \omega t \tag{51}$$

The induced retardation $\Gamma_i = \Gamma = (2\pi/\lambda)\Delta nL$ is independent of time, since Δn is constant although the principal axes are rotating at constant angular velocity. The optical field components along the induced principal axes at the output of the crystal are

$$E_{o_{x'}} = E_i \cos\left(\omega t - \beta_1 + \frac{\Gamma}{2}\right)$$
$$E_{o_{y'}} = E_i \sin\left(\omega t - \beta_1 + \frac{\Gamma}{2}\right) \tag{52}$$

In terms of the original stationary *x*, *y* axes, the optical field components at the output are

$$E_{o_x} = E_i \cos(\Gamma/2)\cos \omega t - E_i \sin(\Gamma/2)\sin[(\omega + \omega_m)t + \Phi]$$
$$E_{o_y} = E_i \cos(\Gamma/2)\sin \omega t - E_i \sin(\Gamma/2)\cos[(\omega + \omega_m)t + \Phi] \tag{53}$$

The first terms in E_{o_x} and E_{o_y} represent left circular polarization at the original optical frequency ω with constant amplitude $E_i \cos(\Gamma/2)$ and phase independent of the rotating principal axes (that is, of β_1). The second terms represent right circular polarization at frequency $(\omega + \omega_m)$ with constant amplitude $E_i \sin(\Gamma/2)$ and phase proportional to $2\beta_1 = \omega_m t$. Therefore, the frequency shift ω_d is the modulation frequency ω_m. If the retardation $\Gamma = \pi$, the frequency of the light has complete deviation to $(\omega + \omega_m)$. If Γ is very small, the component optical fields at frequency $(\omega + \omega_m)$ are linearly related to Γ and therefore, to the applied voltage.

A shift in frequency to $(\omega - \omega_m)$ is obtained if the optical and the applied modulating electric fields rotate in the opposite sense.

Scanners The position of an optical beam can be changed dynamically by using an electro-optic deflecting device or scanner. Analog scanners are based on refraction phenomena: (1) refraction at a dielectric interface (prism) and (2) refraction by an index gradient that exists perpendicular to the direction of light propagation. Digital scanners or switches are based on birefringence.

One of the most important parameters characterizing the performance of a scanner is its resolution, the number of independent resolvable spots it can scan, which is limited by the diffraction occurring at the aperture of the device. The Rayleigh criterion states that two spots are just resolved when the angular displacement of the beam $\Delta\varphi$ is equal to the half-angle divergence θ due to diffraction.[15] Therefore, the total number of resolvable spots is given by the ratio of the total deflection angle φ to the half-angle divergence θ

$$N = \frac{\varphi}{\theta} \tag{54}$$

The half-angle divergence is $\theta = \varpi/w$, where w is the beamwidth, $\varpi = 1$ for a rectangular beam of uniform intensity, $\varpi = 1.22$ for a circular beam of uniform intensity, and $\varpi = 1.27$ for a beam of Gaussian intensity distribution.[47]

An analog scanner can be constructed by a prism of electro-optic material with electrodes on the crystal faces as shown in Fig. 14. The resolution is maximum in this isosceles-shaped prism when the beam is transmitted through at the minimum deviation angle and is[47,48]

$$N = \Delta n\left(\frac{l}{\varpi\lambda}\right)\left(\frac{w}{W}\right) \tag{55}$$

where l is the base length of the prism and w/W is the ratio of the beamwidth to input aperture of the prism. This type of device typically requires a voltage much higher than the half-wave voltage V_π to resolve N spots.[42]

An analog scanner based on a gradient index of refraction[49] is shown in Fig. 15. The voltage is applied to a crystal such that the change in index is linear with distance perpendicular to the direction of light propagation; that is, $n(x) = n_o + (2\Delta n/W)x$, where W is the width of the crystal. For linear gradient and small refraction angles, the wavefront remains planar. The (small) deflection angle of the ray after propagating a distance L in the crystal is approximated to be[47]

$$\varphi = L\frac{dn}{dx} \tag{56}$$

and the resolution is

$$N = \frac{\varphi}{\theta} = 2\Delta n\left(\frac{L}{\varpi\lambda}\right)\left(\frac{w}{W}\right) \tag{57}$$

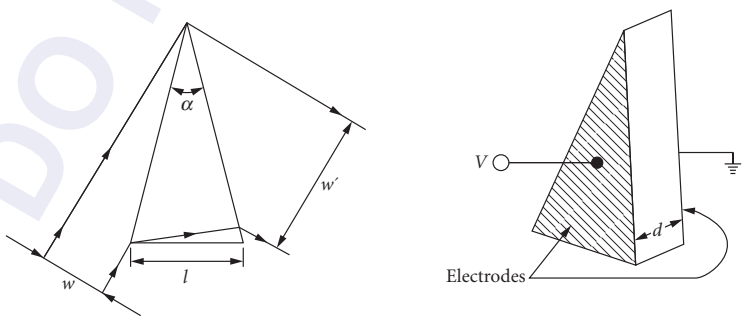

FIGURE 14 An analog scanner can be constructed using an isosceles-shaped prism with the beam transmitted at the minimum deviation angle.[48]

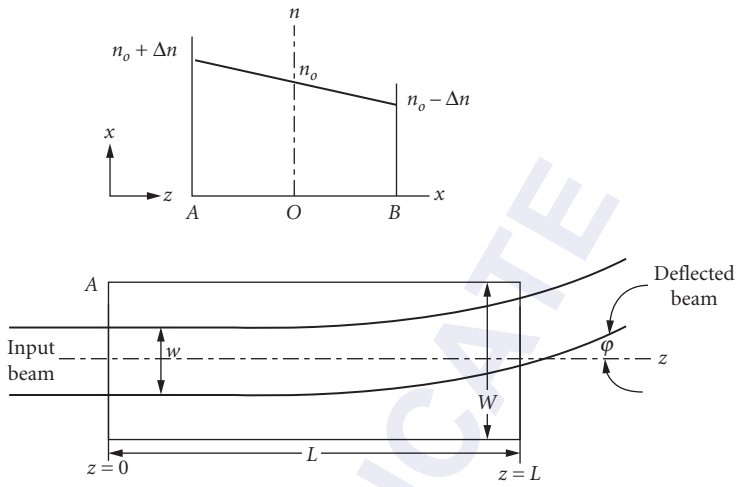

FIGURE 15 An analog scanner based on an index gradient is shown.[49]

A large crystal length L is needed to obtain appreciable deflection, since Δn is very small ($\sim 10^{-4}$). Laser beams, however, are very narrow to make such a device practical.

Digital light deflection can be implemented with a number of *binary units*,[42,50] each of which consists of a polarization modulator followed by a birefringent crystal (or discriminator) as shown in Fig. 16. The polarizer is oriented to give a horizontal polarization input to the birefringent crystal, such as calcite, and passes through undeflected. With an applied voltage, the principal axes rotate 45° and the input is then decomposed into orthogonal components of equal amplitude. The voltage

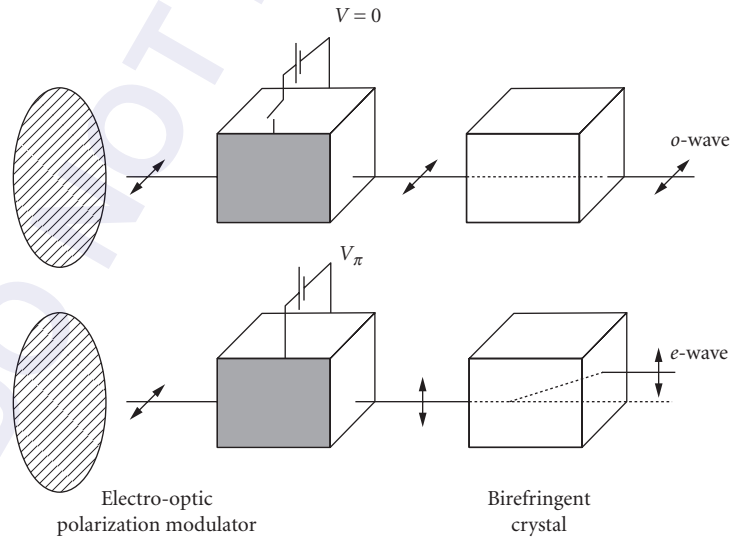

FIGURE 16 The component of a digital scanner is a binary unit. It consists of a polarization modulator followed by a birefringent crystal which serves as a discriminator.[42]

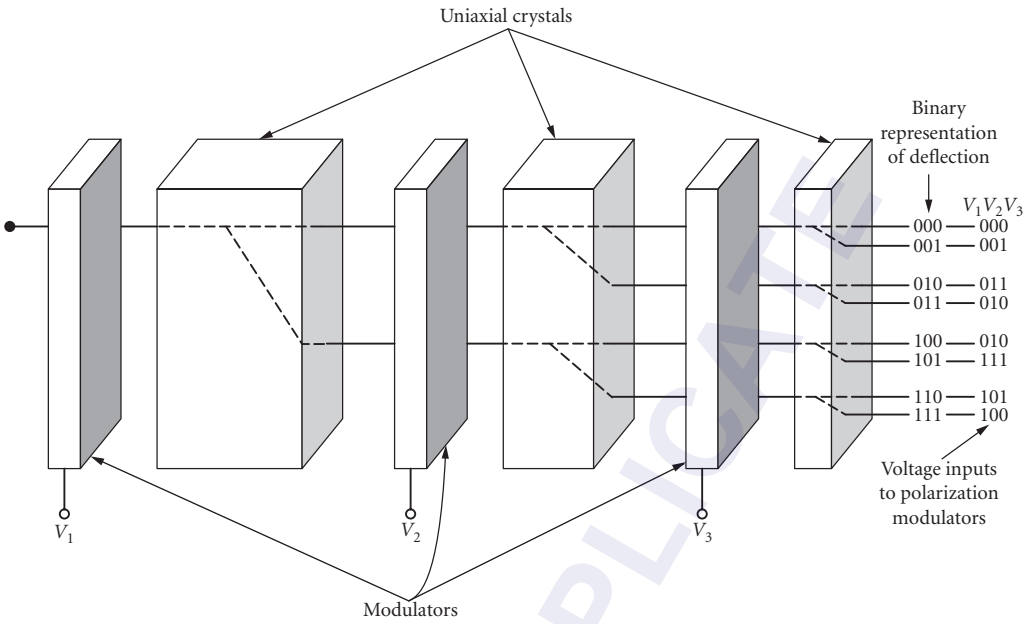

FIGURE 17 A three-stage digital scanner produces 2^3 possible deflected positions at the output.[50]

magnitude is set to produce a retardation of π, thereby rotating the polarization by 90°. The vertical polarization then enters the birefringent crystal which deflects it.[47,51]

The number of binary units n would produce a deflector of 2^n possible deflected positions at the output. An example of a three-stage deflector is shown in Fig. 17.[50–52] The on-off states of the three voltages determine at what position the output beam would be deflected. For example, if all three voltages are off, the input polarization remains horizontal through the system and is undeflected at the output. However, if all three voltages are on, the horizontal input is rotated 90°, becoming vertical after the first polarization modulator, and is deflected. The polarization is rotated 90° after the second modulator, becoming horizontal, and therefore, propagates straight through the birefringent crystal. Finally, the polarization is rotated 90° after the third modulator, becoming vertical, and is deflected. The corresponding output represents a binary five, that is, 101.

Traveling Wave Modulators The bandwidth of bulk modulators is limited by the transit time of the light through the crystal compared to the modulation frequency. The transit time of the light is the time for it to pass through the crystal

$$\tau = \frac{nL}{c} \tag{58}$$

where n is the index seen by the light. This parameter has no relevance for modulation frequencies $\omega_m << 2\pi/\tau$; the modulation field appears uniform in the crystal at very low frequencies. A rule of thumb for defining the limiting frequency such that τ can be neglected is that the length of the crystal be less than one-tenth the wavelength of the modulating field[53] or $L << 2\pi c/\omega_m\sqrt{\varepsilon}$.[41] The electro-optic crystal is modeled as a lumped capacitor at low frequencies.

As the modulating frequency becomes larger, the transit time must be taken into account in evaluating modulator performance. The modulation electric field has the form $E = E_m \sin \omega_m t$, and the optical phase can no longer follow the time-varying index of refraction adiabatically. The result is a

reduction in the modulation index parameters, δ for phase modulation and Γ_m for amplitude modulation, by a factor[16,41,44]

$$\rho = \frac{\sin\left(\frac{1}{2}\omega_m \tau\right)}{\frac{1}{2}\omega_m \tau} \tag{59}$$

Therefore, the phase modulation index at high frequencies becomes

$$\delta_{\mathrm{RF}} = \delta \cdot \rho = \delta \cdot \left[\frac{\sin\left(\frac{1}{2}\omega_m \tau\right)}{\frac{1}{2}\omega_m \tau}\right] \tag{60}$$

and the amplitude modulation index at high frequencies becomes

$$\Gamma_{m_{\mathrm{RF}}} = \Gamma_m \cdot \rho = \Gamma_m \cdot \left[\frac{\sin\left(\frac{1}{2}\omega_m \tau\right)}{\frac{1}{2}\omega_m \tau}\right] \tag{61}$$

If $\tau = 2\pi/\omega_m$ such that the transit time of the light is equal to the time period of the modulation signal, then there is no retardation; the retardation produced in the first half of the crystal is exactly canceled by the retardation produced in the second half.[41] The maximum modulation frequency for a given crystal length L is determined by the allowable ρ parameter set by the designer.

The limitation of the transit time on the bandwidth of the modulator can be overcome by applying the voltage as a traveling wave, propagating collinearly with the optical wave. Figure 18 illustrates a transverse traveling wave configuration. The electrode is designed to be an extension of the driving transmission line to eliminate electrode charging time effects on the bandwidth. Therefore, the transit time problem is addressed by adjusting the phase velocity of the modulation signal to be equal to the phase velocity of the optical signal.[16,41,44]

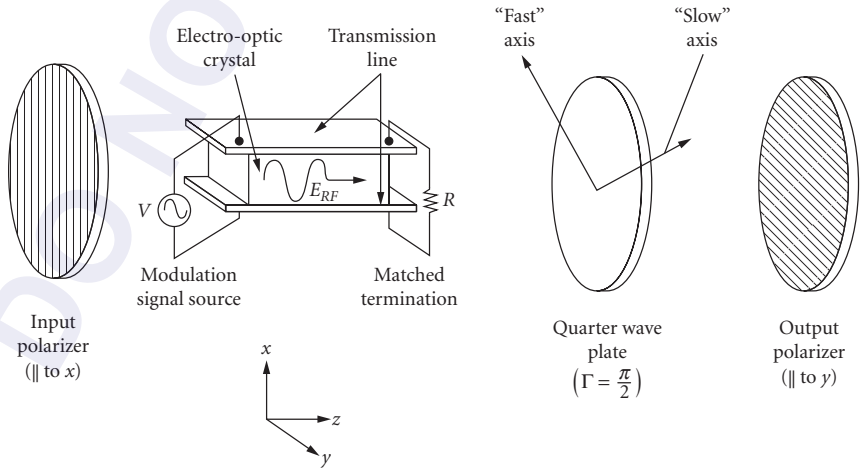

FIGURE 18 A transverse traveling wave modulator has a modulating voltage polarized in the same orientation as the input light and propagating collinearly.[16]

The applied modulation electric field has the form

$$E_{\mathrm{RF}}(t,z) = E_m \sin(\omega_m t - k_m z) \tag{62}$$

for propagation along the z axis of a crystal. The direction of field vibration is the direction of the applied field, not the direction it is traveling, and is along x in Fig. 18. The parameter k_m is the wavevector magnitude of the modulation field and is

$$k_m = \frac{\omega_m}{v_m} = \frac{\omega_m n_m}{c} \tag{63}$$

where v_m and $n_m = \sqrt{\varepsilon}$ are the phase velocity and index of refraction of the modulating signal. A mismatch in the phase velocities of the modulating signal and optical wave will produce a reduction in the modulation index δ or Γ_m, by a factor

$$\rho_{tw} = \frac{\sin\left[\dfrac{\omega_m}{2c}(n - n_m)L\right]}{\dfrac{\omega_m}{2c}(n - n_m)L} = \frac{\sin(\Delta L)}{\Delta L} \tag{64}$$

In the case of amplitude modulation, Eq. (64) holds only if there is no natural birefringence in the cross section of the crystal. The eigenpolarization magnitudes are functions of time and space. Therefore, they satisfy the coupled wave equations, which are more complicated when birefringence is present.[16]

With no phase velocity mismatch, the phase modulation index is $\delta_{\mathrm{RF}} = \delta$ and is linearly proportional to the crystal length L. Likewise, $\Gamma_{\mathrm{RF}} = \Gamma_m$ for amplitude modulation. With a mismatch, the maximum possible phase modulation index is $\delta_{\mathrm{RF}_{\max}} = \delta/(\Delta L)$ likewise for the amplitude modulation index $\Gamma_{\mathrm{RF}_{\max}}$. The modulation index becomes a sinusoidal function of L. This maximum index can be achieved for crystal lengths $L = \pi/2\Delta, 3\pi/2\Delta$, and so on. The ratio n/n_m is approximately 1/2 for $LiNbO_3$, producing a walk-off between the optical and modulation waves.[44] Therefore, for a given length L the modulation frequency is greatly affected by the velocity mismatch.

Waveguide or Integrated-Optic Modulators Electro-optic modulators are often fabricated as integrated optical devices. Because of the small dimensions of the waveguides, these modulators require lower drive voltages and operate at higher frequencies than bulk modulators. However, the disadvantages of integrated-optic modulators are that they have lower optical power handling capabilities; they present coupling difficulties when interfaced with free-space beams; and they are designed to operate at a specific wavelength or narrow spectral window rather than working with broad optical spectra. On the other hand, because of their size, they are compatible with single mode optical fibers, and as a result, they have globally transformed communications with optical data rates up to 40 Gbps. Integrated-optic modulators can also find usage as sensors; such as gyroscopes, voltage sensors, or other phase-sensitive applications.

Most integrated optic waveguide modulators are formed on crystalline wafer surfaces, such as $LiNbO_3$, using standard photolithography techniques. The waveguides are formed by changing the refractive index in the guiding region using methods such as annealed proton exchange (APE) or titanium in-diffusion, and then depositing electrodes on the wafer surface. Integrated optic modulators have also been made by applying organic electro-optic material over glass waveguides, such that the application of the RF signal voltage modulates the waveguide cladding, thereby changing the effective propagation constant of the guided mode.[54]

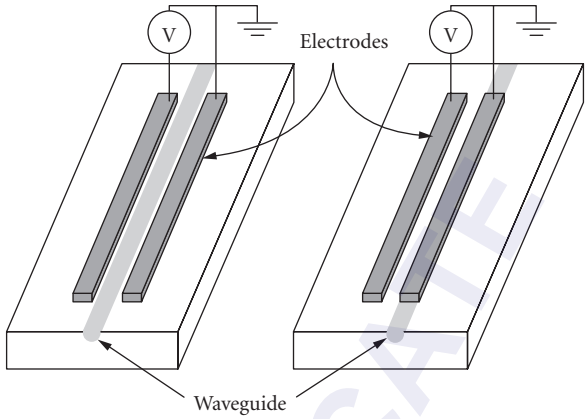

FIGURE 19 Schematic cross sections of two typical configurations of imbedded optical waveguides.

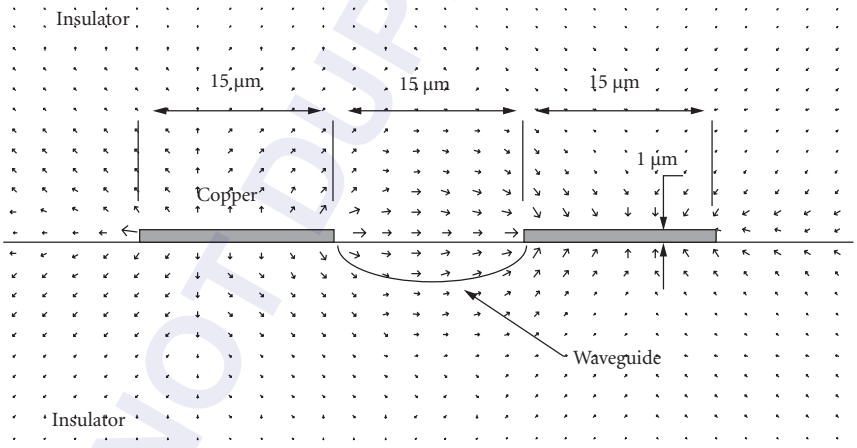

FIGURE 20 Electric field lines from electrodes across the embedded electro-optic waveguide. The electric field distribution can not be assumed to be uniform, as in bulk modulators.

The basic operation principles of waveguide modulators are the same as for bulk modulators; except that the spatial electrical and optical fields may not overlap completely. Figure 19 illustrates schematic cross sections of two typical configurations of embedded optical waveguides, and Fig. 20 shows that the field lines can not be assumed uniform as in the case of bulk modulators. Thus, the equation describing the electro-optically induced change in refractive index for a given configuration must include an overlap correction factor, Γ_{wg}.[55] For example, with a waveguide modulator, Eq. (34) would become

$$\Delta n'_x = \Delta\beta/k = -n_o^3 r_{13} \Gamma_{wg} E_z/2 \tag{65}$$

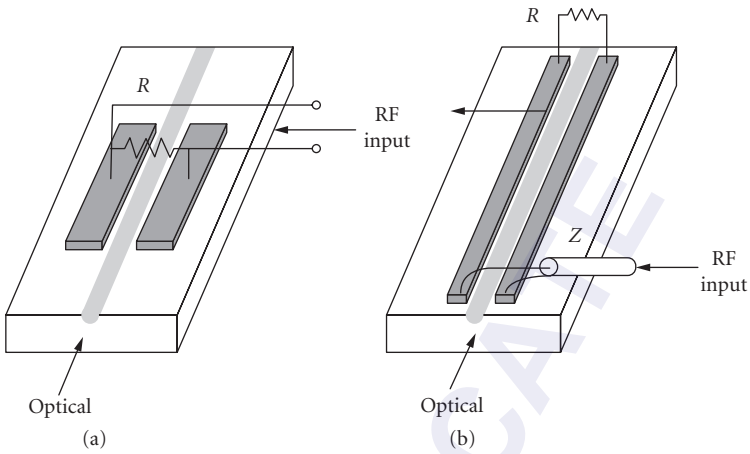

FIGURE 21 Electrode configurations on waveguides create either (*a*) lumped circuit element modulators or (*b*) traveling wave modulators.

where β is the propagation constant of the guided optical wave for a particular waveguide geometry. The overlap correction factor must be derived numerically. The total phase shift resulting from Δn over the propagation length L is again the sum of the natural phase shift and an electrically induced phase shift, but now includes a correction factor according to

$$\phi = \beta L + \Delta\beta L = \frac{2\pi}{\lambda}(n_x' + \Delta n_x')L = \frac{2\pi}{\lambda}(n_x' - n_o^3 r_{13}\Gamma_{\text{wg}} E_z/2)L \tag{66}$$

Waveguide modulators can be either lumped circuit element modulators or traveling wave modulators, based on their electrode configurations, which are illustrated by the phase modulators shown in Fig. 21. Similar to low frequency bulk modulators, lumped circuit element modulators have a modulation bandwidth that is limited by the parallel load resistance and electrode capacitance, which is proportional to the electrode length and gap. Decreasing the electrode length or increasing the electrode gap will decrease capacitance, and hence the RC time constant, but at the expense of requiring a higher drive voltage for a given voltage-L product. Traveling wave modulators, on the other hand, are bandwidth limited by the velocity mismatch between the propagating optical wave and the traveling RF or microwave signal.

Figure 21 illustrates phase modulators; however, amplitude (intensity) modulators are prevalent in communications applications, where they have found widespread use in fiber optical telecommunications and optical transmission of cable TV over fiber. Figure 22 shows a variety of electrode and waveguide configurations that implement intensity modulators. The Mach-Zehnder interferometer in Fig. 22*a* consists of traveling wave electrodes that modulate one or both arms and incur a phase difference between them. The phase-modulated optical signal recombines at the output *Y*-junction either constructively or destructively, so that intensity modulation results. There is an inherent 3 dB loss at the recombining *Y*-junction, due to an antisymmetric radiation mode that can not remain guided, which is a characteristic that does not exist for the bulk interferometric modulator. The directional coupler in Fig. 22*b* is designed to bring the two arms close to each other such that coupling occurs between the respective guided modes. Application of modulation controls the amount of cross coupling between the two guides and intensity modulation again results. In Fig. 22*c*, a device is shown that consists of a silicon substrate, a silica undercladding, and a doped-silica waveguide covered with an electro-optic polymer that has a refractive index slightly less than that of the core. When a voltage is applied to the electrodes, an electric field is produced through the electro-optic polymer and the passive optical waveguide, thus affecting the phase of the propagating light.

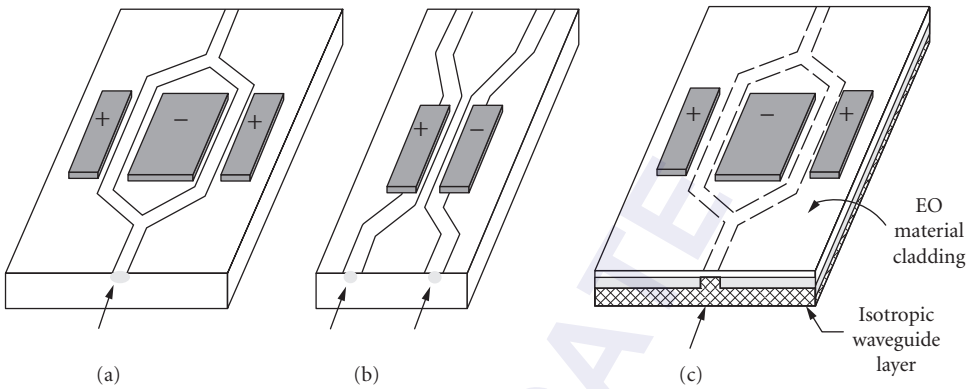

FIGURE 22 (*a*) Mach-Zehnder interferometer, (*b*) directional coupler, and (*c*) electro-optic cladding modulator.

Materials and Design Considerations

Two fundamental considerations to design an electro-optic modulator are signal voltage (and V_π) and frequency response. The goal is to achieve a desired depth of modulation with the smallest amount of drive power and at the same time obtain the largest possible bandwidth. In general, when designing bulk modulators, the field of the modulation signal and optical wave are assumed to have 100 percent overlap, whereas for waveguide modulators the overlap is not complete or uniform and a correction factor is needed. Bulk modulators are also capable of handling higher optical powers than waveguides, but at the expense of higher drive voltages and generally less modulation bandwidth. These are the trades that must be considered in choosing an electro-optic modulator.

This section discusses the various materials used to make electro-optic modulators and how the properties of electro-optic materials can affect the device performance. The various criteria and parameters that describe device performance are summarized.

Choice of Material An electro-optic material must be selected that would perform ideally at a given wavelength or a broad spectral range, and in a given environment. The material should have a large electro-optic coefficient, good homogeneity, low absorption, low dispersion, high resistivity; and thermal, mechanical, and photochemical stability. The fabricated modulator should have good ohmic contacts, and the fabrication techniques should be economically and technically feasible.

From a practical point of view, there are several limits on the performance of electro-optic modulators that must be considered. For example, some materials with natural birefringence, such as KDP and ferroelectric $LiTaO_3$ and $LiNbO_3$, are sensitive to temperature variations and would induce a temperature-dependent phase shift in the light, called thermal drift. Some of these materials also have acoustic resonances due to the piezo-electric effect that cause undesirable peaks in the frequency response.[24,45,52,56] The optical power handling capability, which is wavelength dependent, should be known so as not to induce photorefractive damage to the material.

Electro-optic materials include inorganic crystals, organic crystals, semiconductors, macroscopically oriented amorphous organics (dye-doped polymers), and liquids. Each of these materials are suited to particular applications based on their material properties and are briefly summarized as follows:

1. *Inorganic crystals* have high optical power handling ability and superior optical quality. Lithium niobate, $LiNbO_3$, continues to be the "workhorse" of electro-optic modulators, both as a bulk modulator and especially as a waveguide. For laser applications, such as Pockels cells, crystals with high optical power handling capabilities are used. KDP and BBO are typical Pockels cell crystals for visible to near infrared applications, while CdTe is used for longer wavelengths.
2. *Organic crystals* have been explored for their large electro-optic coefficients that exceed those of inorganic crystals and their fast response time. The organic crystal 4-dimethylamino-4-stilbazolium tosylate

(DAST) presently has the highest known electro-optic coefficient and is commercially grown. While the electro-optic coefficients are large, organic crystals cannot be grown into large single crystals like inorganics, and they generally have lower power handling capabilities.

3. *Semiconductors* have been investigated as electro-optic materials because of the potential for these materials to be integrated with electronic integrated circuits and because of their transparency in the infrared; however, the effect is typically weak. Materials that have been studied include GaAs, ZnSe, ZnTe, CdS, CdTe:InP, CuCl, InSb, InGaAsP, and CdHgTe.[57]
4. *Ordered dye-doped polymers* are a class of amorphous organic materials whose individual molecules display extremely large electro-optic properties. The electronic properties are based on field-induced delocalized π-electrons and additional donor and acceptor groups on opposite sides of the molecules. A mixture of these molecules does not exhibit a macroscopic electro-optic effect until the molecules have generally been oriented in the same direction. This is accomplished by several means: an electric field is applied to the assembly of molecules while above the glass transition temperature, then the material and orientation is solidified; or the orientation may be obtained by self-assembly techniques such as Langmuir-Blodgett. While the electro-optic effect can be large in these materials, over time the ordering of assembly of molecules can degrade, causing the effect to weaken. Nevertheless, research in this area remains active.
5. *Liquids* can exhibit the Pockels effect under applied electric field if the molecules are dipolar with donor acceptor groups, similar to dye-doped polymers. Some liquids also have very large Kerr coefficients and are the basis of Kerr cells.

Performance Criteria

The following parameters are indicators of modulator performance. Basically, the tradeoffs occur between the aspect ratio L/b, the drive voltage, and the electrode configuration (lumped or traveling wave) to achieve a desired depth of modulation with the smallest amount of power and at the same time obtain the largest possible bandwidth.

Modulation Bandwidth The bandwidth is the difference between the two closest frequencies at which the modulation index, δ or Γ, falls to 50 percent of the maximum value.[55,58] Therefore, the 3 dB optical bandwidth is determined by setting the modulation reduction factor ρ or ρ_{tw} to 0.5.[44,55,58] Modulation speed depends on the electrode type, lumped or traveling wave, and the modulator capacitance per length, which depends on the RF dielectric constant ε and the geometry of the electrodes. For a lumped modulator the bandwidth is limited by the optical (c/Ln) or electrical ($c/L\sqrt{\varepsilon}$) transit time, whichever is smaller, or the time constant of the lumped-circuit parameters ($1/RC$), where R is the resistance in the circuit and C is the capacitance of the modulator. For a traveling wave modulator the bandwidth ν_{tw} is limited by the velocity mismatch between the optical and modulation waves, $\nu_{tw} = c/Ln(1 - \sqrt{3}/\eta)$.[16]

Power per Unit Bandwidth (Specific Energy) and Resonant Circuits To apply the modulating signal efficiently to a *lumped* electro-optic modulator, a resonant *RLC* circuit can be created by adding an inductance and resistance in parallel to the modulator, which is modeled by a capacitor C.[16,41] The terminating resistance R ensures that more of the voltage drop occurs over the modulator rather than the internal resistance of the source R_s.

The impedance of the resonant circuit is high over a bandwidth (determined by the RC time constant) of $\Delta\nu = \Delta\omega_m/2\pi \simeq 1/2\pi RC$ centered at the resonant frequency of $\omega_o = 1/\sqrt{LC}$, where the impedance of the parallel *RLC* circuit is exactly equal to R. A peak voltage V_m must be applied to achieve a desired peak retardation $\Gamma_m = \pi V_m/V_\pi$. Therefore, $V_m = \Gamma_m(V_\pi/\pi)$. The power required to achieve Γ_m is $P = V_m^2/2R$, where $1/2R = \pi C\Delta\nu$, giving

$$P/\Delta\nu = \frac{1}{\pi}\Gamma_m^2 V_\pi^2 C \tag{67}$$

The power per unit bandwidth (mW/MHz) depends on the modulator capacitance C and the peak modulation voltage V_m to give the desired depth of modulation Γ_m. The required drive power increases with modulation frequency.[41,55] Since the capacitance is a function of the modulator active area dimensions, the required power is also a function of the modulator dimensions.[55] Furthermore, since V_π is directly proportional to the wavelength λ, a higher input power (voltage) is required at longer wavelengths for a given peak retardation.

Extinction Ratio The extinction ratio is the maximum depth of intensity modulation for a time-varying voltage at the output when the optical bias is adjusted properly.[56,58] If for no voltage the output intensity is I_o and for maximum applied voltage the output intensity is I_m, then the extinction ratio is defined as[58]

$$\eta_m = \frac{|I_m - I_o|}{I_o} \qquad I_m \le I_o$$

$$\eta_m = \frac{|I_m - I_o|}{I_m} \qquad I_m \ge I_o \tag{68}$$

Material effects, such as crystal imperfections, temperature sensitivities, and birefringence, can degrade the extinction ratio,[16,38,45] thereby affecting the signal-to-noise ratio at the detector.[58] Another definition is in terms of the transmission T, $\eta_m = T_{\max}/T_{\min}$.[42,59] In general, $T_{\max} < 1$ due to absorption, reflection, and scattering losses, and $T_{\min} > 0$ due to beam-divergence angle, residual crystal birefringence, crystal inhomogeneity, electric field uniformity, background scattered light, and polarizer-analyzer alignment.[40] Extinction ratio also can be applied to phase modulation, since phase changes can be related to equivalent changes in intensity.[58]

Maximum Frequency Deviation A similar figure of merit as exists for intensity modulators likewise exists for frequency modulators. The maximum deviation of a frequency modulator is defined as[55]

$$D_{\max} = \frac{|\omega_d - \omega|}{\omega} \tag{69}$$

where ω_d is the frequency shift when the maximum voltage is applied.

Percent Modulation Percent modulation is an intensity modulation parameter. Basically, it is the transmission $T = I_o/I_i$ times 100 percent at a specific wavelength. For a device with total retardation of $\Gamma = \pi/2$ radians at no voltage, the transmission $T = 0.5$. Then 70 percent modulation is achieved with an analog signal if a voltage is applied such that $\Gamma = 2$ radians; that is, $\sin^2(1) = 0.70$.[58] Hundred percent intensity modulation is the output intensity varying between the input intensity and zero intensity.[41] A peak voltage of $V = V_\pi/2$ is required to achieve this level of performance for a linear modulator.

Another definition of percent modulation is the ratio of the peak output intensity at the modulation frequency to the maximum output intensity at dc voltage.[56] Reference 45 defines percent modulation as the peak modulation voltage output per dc voltage output, assuming no temperature variations.

Degree of Modulation For a sinusoidal reference of an optical electric field, $E(t) = E_i \sin \omega t$, an amplitude-modulated signal is typically expressed as

$$E(t) = E_i(1 + m \sin \omega_m t)\sin \omega t \tag{70}$$

where m is the degree of modulation at a specific wavelength.[17] For $m << 1$ the intensity is

$$I = \frac{1}{2}E_i^2(1 + 2m \sin \omega_m t) \tag{71}$$

The amplitude modulation index is then $\Gamma_m = 2m$, a function of the degree of modulation. The degree of modulation is often referred to as percent modulation for intensity modulation (70 to 100 percent nominal) and as modulation index for phase modulation (1 radian nominal).[38]

Modulation Efficiency Modulation efficiency is defined as the percentage of total power which conveys information.[60,61] The total power of an amplitude-modulated optical carrier is a function of the modulation frequency and is proportional to $1 + m^2\langle \sin^2 \omega_m t\rangle = 1 + (1/2)m^2$. Therefore, the modulation efficiency is[60]

$$\xi = \frac{\frac{1}{2}m^2}{1 + \frac{1}{2}m^2} \tag{72}$$

The maximum efficiency is achieved when m is maximum; that is, $m = (1/2)\Gamma_m = \pi V/2V_\pi$. In terms of the input power P the modulation efficiency is[61]

$$\xi = \frac{\Gamma^2}{P} \tag{73}$$

where $\Gamma = \pi V/V_\pi$ for maximum efficiency.

Optical Insertion Loss For an external modulator, in particular, the optical insertion loss must be minimized when coupling light into and out of the device. For an input light intensity I_{in} the insertion loss IL is[58]

$$IL = 1 - \frac{I_m}{I_{\text{in}}} \qquad I_m \geq I_o$$

$$IL = 1 - \frac{I_o}{I_{\text{in}}} \qquad I_m \leq I_o \tag{74}$$

where I_o and I_m are the output intensities at no voltage and maximum voltage, respectively. If a beam has a large cross-sectional area, the modulator must have a large acceptance area to couple all or most of the light into the device. A longitudinal modulator typically has a large acceptance area. Minimizing insertion loss in a transverse modulator is more of a challenge due to its narrow width, particularly for wide beams. However, a transverse modulator requires less voltage for a desired degree of modulation.

7.6 APPLICATIONS

Section 7.5 have discussed various device geometries and how the geometries translate into phase, amplitude, frequency, or displacement modulators. In this section, several applications of these modulators are discussed and examples are given. Waveguide modulators are discussed in another chapter of this *Handbook* and will not be further discussed here. Instead, high-speed electro-optic sampling, sensors applications, and laser mode-locking are discussed as classical application of both Pockels and Kerr electro-optic modulation.

Electro-Optic Sampling

Electro-optic sampling is a technique that can be used to sample ultrashort temporal phenomena that cannot be otherwise measured by conventional means. The sensing of terahertz radiation to

perform spectroscopy or to measure other short electrical phenomena in electrical circuits are two examples. The technique has been enabled by the advent of pulsed laser systems, creating picosecond to femtosecond optical pulses of duration shorter than the electrical pulse to be measured. It consists of a "probe" pulsed optical light beam that is modulated by the temporary short electric field, both of which are coincident within an electro-optic crystal or material. Because the probe duration is less than the modulating electrical pulse (which may be a terahertz pulse or other electrical transient), the probe polarization is modified through the electro-optic effect, the degree to which is based on the strength of the electric field at that instant of time. A polarizer is placed after the electro-optic crystal, so that the change in intensity of one particular polarization can be measured. The temporal position of the probe relative to the electrical signal is slowly varied. However, at a particular instant of time, many optical pulses are perturbed, thus permitting the use of slower speed detectors to measure the variation of the optical power.

Figure 23*a* illustrates a typical terahertz time-domain spectroscopy (TDS) system that utilizes a pump-probe method of electro-sampling to measure terahertz pulses. A ZnTe crystal or an organic DAST crystal is used as the electric field sampling sensor. However, since these both are noncentrosymmetric crystals, they can also be used to generate the terahertz pulse by the second-order process of optical rectification. Figure 23*b* shows the reconstructed terahertz pulse.

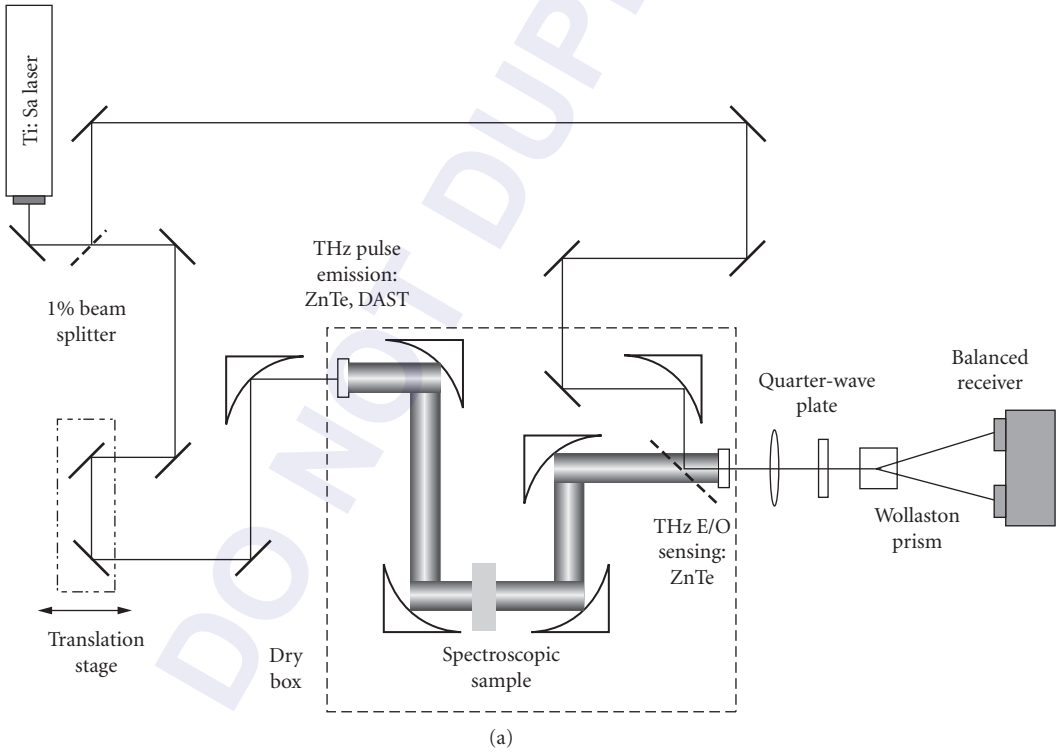

FIGURE 23 (*a*) A terahertz TDS system uses a Ti:Sapphire laser to emit ultrashort optical pulses, which are split into a pump beam to generate terahertz pulses, and a probe beam used to sample the terahertz pulses. An electro-optic crystal is used as a sensor. (*b*) The terahertz pulse reconstructed by sampling the electric field strength at different points in time.

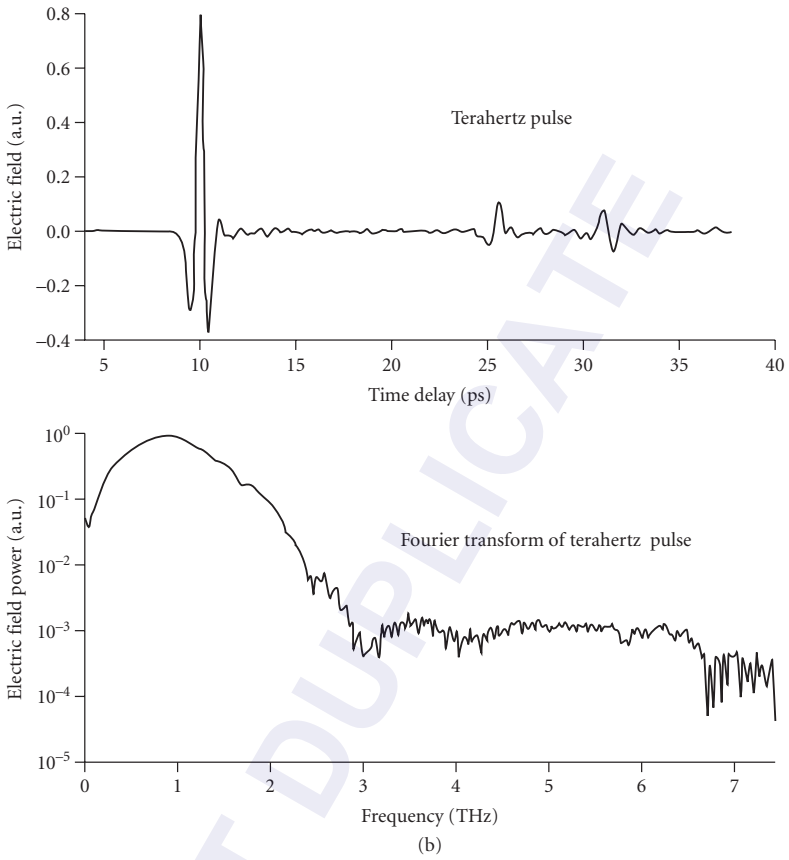

FIGURE 23 (*Continued*)

Sensors

A practical commercial sensor based on the electro-optic effect is a high-voltage sensor. This sensor uses the Pockels effect to sense high voltages without contact with a conductor or a voltage source. It finds application in improving reliability of electric utility systems. In contrast to other modulators discussed in this chapter, wherein a low-drive voltage was desired, high-voltage sensors accurately measure voltages as high as 765 kV. The electro-optic material for the sensor is being used as a bulk modulator, and the excitation voltage is of low frequency.

In contrast to the low-frequency high-voltage sensor just discussed, an integrated optic Mach Zehnder interferometer (MZI) can be used as a high-power microwave sensor or RF sensor. This device has been shown to operate over a wide frequency range of 200 MHz to 12 GHz.[63]

Laser Mode-Locking

Mode-locking is a resonant phenomenon that results in ultrashort laser pulses. Mode-locking occurs by a relatively weak modulation of the radiation passing through the resonator, which results in initiating a pulse that becomes shorter with each pass through the resonator. The pulse compression technique uses the Kerr nonlinearity of an optical medium. The pulses propagating

through the medium experience nonlinear phase shifts that lead to spectral broadening, resulting in a spread of frequencies, or chirp. The different frequency components are superimposed by propagation in a dispersive medium, or by reflection from a dispersive element. The effects of a fast saturable absorber to produce mode-locking can be simulated by Kerr focusing. The Kerr effect within the resonator causes the high-intensity part of the optical beam to be focused, whereas the low-intensity components remain unfocused. If an aperture is placed in the beam path, the low-intensity parts are attenuated, and the pulse is shortened. This effect is now calld Kerr-lens mode-locking (KLM).[28] The KLM technique is commonly used for mode-locking of Ti:Sapphire lasers.

7.7 APPENDIX: EULER ANGLES

Euler angles represent a set of three independent parameters which specify the orientation of a rigid body, in this case the index ellipsoid. Orthogonal transformations are used to convert from one set of axes (x, y, z) to another set (x', y', z'). The two sets of axes are related to each other by nine direction cosines. An orthogonal transformation matrix consisting of direction cosines and having a determinant of + 1 corresponds to defining the orientation of a rigid body.

The transformation matrix is developed by a specific sequence of three plane rotations (not in principal planes) in a defined order. There are 12 possible conventions for defining a set of Euler angles in a right-handed coordinate system.[36] One convention that has been proposed as a standard is the y convention.[64] The transformation evolves by an initial counterclockwise rotation ζ about the z axis, followed by a counterclockwise rotation η about the intermediate y' axis, and finally a counterclockwise rotation ω about z''. The resulting transformation matrix is

$$\bar{a} = \begin{pmatrix} \cos\omega & \sin\omega & 0 \\ -\sin\omega & \cos\omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \cos\eta & 0 & -\sin\eta \\ 0 & 1 & 0 \\ \sin\eta & 0 & \cos\eta \end{pmatrix} \begin{pmatrix} \cos\zeta & \sin\zeta & 0 \\ -\sin\zeta & \cos\xi & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{A.1}$$

To find the Euler angles (ζ, η, ω), Eq. (A.l) is rearranged as[37]

$$\begin{pmatrix} \cos\omega & -\sin\omega & 0 \\ \sin\omega & \cos\omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix} = \begin{pmatrix} \cos\eta & 0 & -\sin\eta \\ 0 & 1 & 0 \\ \sin\eta & 0 & \cos\eta \end{pmatrix} \begin{pmatrix} \cos\zeta & \sin\zeta & 0 \\ -\sin\xi & \cos\zeta & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{A.2}$$

where $\bar{a}$ is the cumulative transformation matrix of the normalized eigenvectors. Multiplying the matrices, the Euler angles are related to the elements of $\bar{a}$:

$$a_{11}\cos\omega - a_{21}\sin\omega = \cos\eta\cos\zeta \tag{A.3a}$$

$$a_{12}\cos\omega - a_{22}\sin\omega = \cos\eta\sin\zeta \tag{A.3b}$$

$$a_{13}\cos\omega - a_{23}\sin\omega = -\sin\eta \tag{A.3c}$$

$$a_{11}\sin\omega + a_{21}\cos\omega = -\sin\zeta \tag{A.3d}$$

$$a_{12}\sin\omega + a_{22}\cos\omega = \cos\zeta \tag{A.3e}$$

$$a_{13}\sin\omega + a_{23}\cos\omega = 0 \tag{A.3f}$$

$$a_{31} = \sin\eta\cos\zeta \tag{A.3g}$$

$$a_{32} = \sin\eta\sin\zeta \tag{A.3h}$$

$$a_{33} = \cos\eta \tag{A.3i}$$

From Eq. (A.3f), the angle ω is $\omega = \tan^{-1}(-a_{23}/a_{13})$. From Eq. (A.3$c$), the angle η is $\eta = \sin^{-1}(a_{23}\sin\omega - a_{13}\cos\omega)$. From Eq. (A.3$d$), the angle ζ is $\zeta = \sin^{-1}(-a_{11}\sin\omega - a_{21}\cos\omega)$.[37]

LIQUID CRYSTALS

Sebastian Gauza and Shin-Tson Wu

CREOL, The College of Optics and Photonics
University of Central Florida
Orlando, Florida

ABSTRACT

This chapter introduces the basic properties of liquid crystal materials, electro-optic properties of liquid crystal cells, and operation principles of liquid crystal display (LCD) devices, including the large screen thin-film-transistor LCD TVs and transflective LCDs for mobile displays.

8.1 GLOSSARY

C_{ii}	reduced elastic constants
d	liquid crystal thickness
d_R	reflective region cell gap
d_T	transmissive region cell gap
E	activation energy
F	Onsager reaction field
f_i	oscillator strength
f_c	crossover frequency
G	isotropic intermolecular attraction energy
H_{fi}	heat fusion enthalpy
h	cavity field factor
I	moment of inertia
J	mean-field coupling constant
K_{ii}	elastic constants
k	Boltzmann constant
L	length of the molecule
l	aspect ratio

n	liquid crystal director
$n_{e,o}$	refractive indices
N	molecular packing density
P_4	order parameter of the fourth rank
P_s	spontaneous polarization
R	gas constant
p	molecular length-to-width ratio
S	order parameter of the second rank ($= P_2$)
T_c	clearing temperature
V_n	mole volume
V_b	bias voltage
V_{th}	threshold voltage
Z	number of electrons
$\alpha_{l,t}$	molecular polarizability
α_i	Leslie viscosity coefficients
β	angle between dipole and molecular axis
γ_1	rotational viscosity
δ	phase retardation
ε	dielectric constant
ε_0	vacuum permittivity
$\Delta\varepsilon$	dielectric anisotropy
Δn	birefringence
μ	dipole moment
η_i	Miesowicz viscosity coefficient
θ	twist angle
Λ	friction coefficient
Φ	volume fraction of the molecules
λ	wavelength
ϕ	tilt angle
ϕ_s	pretilt angle
τ	response time
ω	frequency

8.2 INTRODUCTION TO LIQUID CRYSTALS

Liquid crystal (LC) was discovered in 1888 when an Austrian botanist named Friedrich Reinitzer observed that a material known as cholesteryl benzoate exhibiting two distinct melting points.[1] In his experiments, Reinitzer increased the temperature of a solid sample and observed that the crystal changes into a hazy liquid. As he continued to increase the temperature further, the hazy liquid turned into a clear state. Because of this early work, Reinitzer is often credited as the discoverer of a new phase of matter—the LC phase which is also known as liquid crystalline or mesophase. Most people are familiar with the fact that matter can exist in three different states: solid, liquid, and gas (vapor). However, this is a simplification, and under extreme conditions other forms of matter can exist, for example, plasma at very high temperatures or superfluid helium at very low temperatures. The difference between these states of matter is the degree of order in the material, which is directly related to the surrounding temperature and pressure. If the temperature is raised,

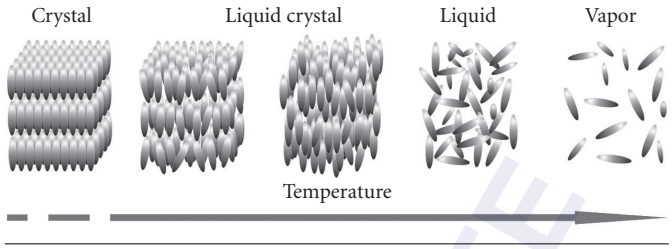

FIGURE 1 Schematic arrangement of the molecules in different phases.

more energy is transferred into the system, leading to increasingly stronger vibrations. Finally, at the transition temperatures between the solid and liquid states, the long range positional order is broken and the constituents may move in a random fashion (Fig. 1), constantly bumping into one another and abruptly changing the direction of motion. However, the thermal energy is not high enough to completely overcome the attractive forces between the constituents, so there is still some positional order at short range. Because of the remaining cohesion, the density of the liquid is constant even though the liquid takes the shape of its container, as opposed to a solid. The liquid and solid phases are called condensed phases. If we keep on raising the temperature until the next phase change, as shown in Fig. 1, the substance enters its gas (or vapor) state and its constituents are no longer bounded to each other.

The molecular order of an LC lies between those of the isotropic liquid and the crystal. The classification of LC materials is based on the degree of orientational and positional order. When the LC molecules are sandwiched between two glass substrates with their inner surfaces coated by an alignment agent, such as rubbed polyimide, the LC molecules tend to form a statistically preferred direction called the director, denoted by the vector **n**. To specify the amount of orientational order in an LC phase, an order parameter is defined as

$$S = \langle P_2(\cos\theta)\rangle = \frac{2}{3}\langle \cos^2\theta - 1\rangle \tag{1}$$

where < > denotes a thermal averaging and θ is the angle between each molecule and the director **n**. If the molecules are perfectly oriented (crystal state), that is, if $\theta = 0$ with the director, then $S = 1$. On the contrary, if the molecules are randomly oriented about **n**, that is, an isotropic state, then $S = 0$ because there is no orientational order. So the higher the order parameter, the more ordered the liquid crystal phase is. In a typical LC system, order parameter decreases as the temperature increases. Temperature dependence of the order parameter S is shown in Fig. 2. Most common values

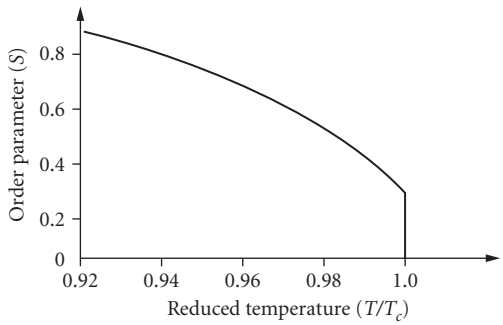

FIGURE 2 Temperature dependent order parameter of the liquid crystal phase.

of S are between 0.3 and 0.8. The order parameter is typically determined by the measured macroscopic properties like optical birefringence or diamagnetism. At certain temperatures, the LC material may gain a certain amount of positional order. When it happens, the center of mass of the LC molecules, although still forming a fluid, prefers to lie, on average, in layers as Fig. 1 depicts. This positional ordering may be described in terms of the density of the center of the mass of the molecules as

$$\rho(z) = \rho_0\left[1 + \Psi\cos\left(\frac{2\pi z}{d}\right)\right] \tag{2}$$

where z is the coordinate parallel to the layer normal, the average density of the fluid is ρ_0, d is the distance between layers, and ψ is the order parameter. The modulus of ψ, $|\psi|$, represents the amplitude of the oscillation of the density. When $|\psi| = 0$, there is no layering, but if $|\psi| > 0$ then some amount of sinusoidal layering exists. Different LC phases are formed as a consequence, which has been described later in this chapter.

From a basic physics point of view, LC materials are of great interest and have contributed to the modern understanding of phase transitions and order phenomena in one, two, and three dimensions. To most of the people today, LC is almost synonymous to flat panel displays (LCDs) for computers, mobile phones, and other electronic equipments. However, there is a rapid development of the other types of applications. For example, there have been developments in telecommunications, pattern recognition, real time holography, light shutters, nonmechanical beam steering, and so on.[2] Liquid crystals constitute a unique form of soft matter and are becoming increasingly more important in pure material science in the development of polymer materials and biomaterials.

8.3 TYPES OF LIQUID CRYSTALS

Considering the geometrical structure of the mesogenic molecules, the liquid crystals can be classified into several types. The widespread LCDs are using rod-shaped nematic molecules, as shown in Fig. 3, where one molecular axis is much longer than the other two. These molecules are called calamitic liquid crystals. Molecules have to be rigid in one part (rigid core) and flexible in another (terminal flexible hydrocarbon chain). Different physical properties may be affected by exchanging one of the terminal chains with a group having different polarities. Liquid crystals formed by disc-shaped molecules with one molecular axis much shorter than the other two are called discotic liquid crystals, as shown in Fig. 3. In this case, the rigid part of the molecule is disc-shaped, typically having multiple aromatic rings. There are some possible intermediates between rod-shaped and disc-shaped molecules known as lath-like LC molecules. Transition to the mesophase (liquid crystalline phase) may be caused by either temperature or influence of solvents. The LCs obtained from the former method are called thermotropic. If the influence of solvents induces the transition, the LCs are called lyotropic. The LC materials capable of forming thermotropic as well as lyotropic mesophases are called amphotropic liquid crystals, as Fig. 4 shows. The lyotropic liquid crystal phases are formed by dissolving amphiphilic molecules in a suitable solvent. Amphiphilic molecules consist of

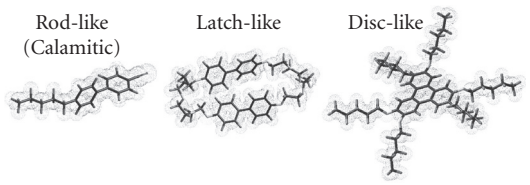

FIGURE 3 Molecular geometry of different types of LC.

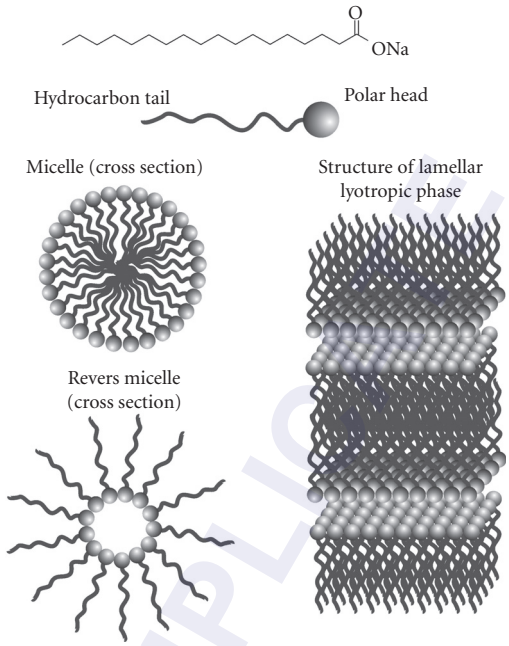

FIGURE 4 Examples of the lyotropic LCs.

hydrophobic group at one end and hydrophilic group at another. Such molecules form self-organized structures in solvents with different polarities. A very good example is soap. When dissolved in water (polar solvent), hydrophobic tails face each other and hydrophilic parts face solvent, forming a micelle. Another type, which is biologically important, is phospholipids which form bilayers. Such aggregations are the building units of biological membranes. Another important structure is liquid crystal polymers. As thermotropic mesogenes, these structures consist of mesogenic subunits (rod-like or disc-like) which are linked together with flexible linkage units, as shown in Fig. 5. If rigid mesogenic units are linked directly by flexible links, the main-chain polymer LC is formed. Mesogenic subunits can also be attached to the polymer chain as a side group which are known as side-chain polymer liquid crystals. Merged structure, called combined polymer liquid crystal has build-in main-chain as well as side-chain mesogenic units. Since the discovery of the first LC substances, there have been many research activities to determine what kind of structure forms desired liquid crystalline phase. Theory suggests that mesophases can be achieved when the molecules have elongated shape and some flexibility. Typically mesogenic molecules consist of several building blocks. If we concentrate on the most common calamitic LC block systems, it will contain elements shown in Fig. 6. As shown in Fig. 6, calamitic structures consist of a rigid rod formed by two (or more) ring systems (R1 and R2). These are connected together by a single bond or a linking group known as central bridge group. Molecular constituents at the ends of the rigid core (*para* position to the central group) are called terminal groups or chains. Usually at least one of the terminal groups must be a flexible carbon chain. Tables 1 to 3 show the most popular choices for the central bridge, ring systems, and terminal substituents.

The introduction of a linking group into a mesogenic molecule often determines linearity, increases overall molecular length, and changes polarizability anisotropy, thus influences mesomorphic and physical properties in general. The presence of a central linking bridge often widens the temperature range of the mesophase by reducing the melting point. However, sometimes, this may also affect the thermal and photochemical stability by increasing π-electron conjugation of the molecules. In some cases, linking groups may induce coloration.

TABLE 3 Terminal Units

Terminal Unit A	Terminal Unit B
C_nH_{2n+1} Alkyl	-F, -Cl, -Br, -I Single elements
OC_nH_{2n+1} Alkoxy	-CN, $-NO_2$, -NCS Highly polar moieties

Most calamitic liquid crystals possess aromatic and alicyclic rings in the molecular structures. These include single benzene ring (commonly 1,4-phenyl), alicyclic ring (commonly cyclohexane), heterocyclic ring (e.g., 1,3-pyrimidine), and a wide variety of the combinations. Individual benzene rings do not yield good mesogens. At least two rings are needed to create a rod-like LC. The exception is the 4-alkyl-benzoic acid, which forms a dimer by hydrogen bond, as depicted in Fig. 7. Beside the heterocyclic rings, ring systems of the rigid core could be laterally substituted by elements other than hydrogen (most popular are F and Cl) or groups of elements such as CH_3, NH_2, CN, and so on. This

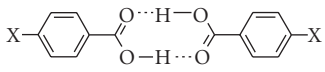

FIGURE 7 Dimeric structure formed by 4-alkyl-benzoic acid.

will reduce the melting point of a mesogen, however, increase its viscosity. Additionally, optical and dielectric anisotropies will be affected. In general, the core of the mesogen determines the mesogenic properties by establishing the primary shape of the molecule and its rigidity. Many terminal units (A, B) have been employed in the creation of mesogenic molecules. The most successful route is to use either small polar substituents or a fairly long, straight, hydrocarbon chain. The role of these groups is to act as either a flexible extension to the rigid core or as a dipolar moiety to introduce anisotropy in physical properties. Molecules can obtain chirality from the flexible chain if it is branched and chiral. Further, the terminal moieties are believed to be responsible for stabilizing the molecular order essential for the mesophase generation. All physical properties strongly depend on the terminal units employed in the molecular system of mesogenic molecules. Some of the typical calamitic LC single compounds are listed in Table 4.[3]

8.4 LIQUID CRYSTALS PHASES

In this section, we focus on the calamitic liquid crystals which have been widely used in display industries. Other LC materials, such as discotic LCs, polymeric LCs, and lyotropic LCs which have great scientific values will not be discussed further. By doing so, we do not intend to minimize the importance of these materials. For example, Kevlar reveals the importance of lyotropic LC polymer material, while others are important in the biological sciences. The readers can find more precise information about these groups of LCs in Ref. 4.

Calamitic Liquid Crystals

When classifying LC phases after G. Friedel,[5] we first distinguish between two main types: one with nematic order and the other with smectic order (Fig. 8). In the nematic phase (of which tilted nematic is known as the cholesteric phase and is a special case) the molecules are free to move in all directions (e.g., there is no positional order of the center of mass). But on average, they keep their long axes locally parallel. In a smectic state, a number of structural variations exist and there is a positional order along one dimension (some smectic phases have positional order in more than one dimensions). A smectic LC is a layered structure with the molecules oriented parallel or tilted relative to the layer normal. Two smectic phases, called smectic *A* and smectic *C*, have acquired a special importance and are now relatively well understood. They are characterized by an absence of positional order within the layers. The molecules have some freedom to move within the layers, as in all smectic phases, but are much less free to move between the layers. These smectics can therefore be described as stacks of two-dimensional fluids, but behave as crystalline across the layers. The absence of in-layer order contributes to their high potential for future electro-optic applications. There are several smectic phases different from one another in areas such as the tilt angle of the director with regard to the layer normal, and the arrangement of molecules within each layer. The simplest is the smectic *A* phase (Fig. 8) characterized by a director parallel to the layer normal and a random positional order within the plane. Substances featuring the *A* phase often exhibit the smectic *C* phase at a lower temperature (Fig. 8). In this phase, the molecules have the same random order within the layer but tilt relative to the layer normal. The tilt angle normally increases with decreasing temperature. The other smectic phases are even more crystalline as they also feature some positional order within the layers. They may, for instance, exhibit hexagonal packing of the molecules.

Chiral Liquid Crystals

Molecules which are not identical to their mirror image are said to be chiral. A depiction of the simple concept of a chiral molecule is shown in Fig. 9. Another example is the human hand. Chiral molecules are able to form liquid crystals with structures related to those of nonchiral materials but with

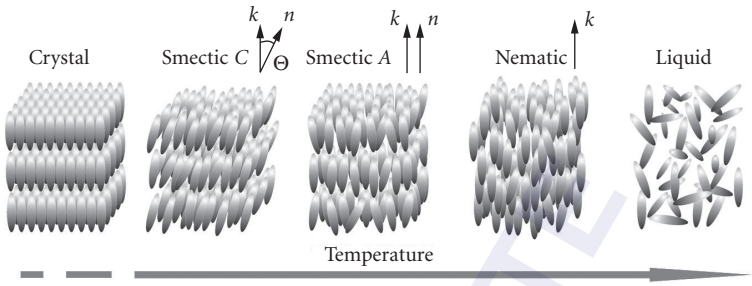

FIGURE 8 Schematic arrangement of the molecules in basic nematic and smectic phases.

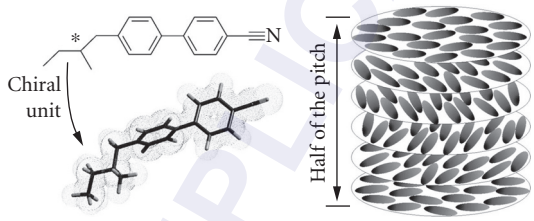

FIGURE 9 Chirality of the calamitic molecule and chiral nematic structure.

different properties. The cholesteric (or chiral nematic) liquid crystal phase is typically composed of nematic mesogenic molecules containing a chiral center which produces intermolecular forces that favor alignment between molecules at a slight angle to one another. When the molecules that make up a nematic liquid crystal are chiral, the chiral nematic phase will exist instead of the normal nematic. In this phase, the molecules prefer to lie next to each other in a slightly skewed orientation. This leads to the formation of a structure which can be visualized as a stack of very thin 2-D nematic-like layers with the director in each layer twisted with respect to those above and below, as Fig. 9 depicts. In this structure, the directors actually form a continuous helical pattern around the layer normal. The molecules shown here are merely representations of the many chiral nematic mesogens lying in the slabs of infinitesimal thickness with a distribution of orientation around the director. This is not to be confused with the planar arrangement found in smectic mesophases.

An important characteristic of the cholesteric mesophase is the pitch. The pitch, p, is defined as the distance it takes for the director to rotate one full turn in the helix as illustrated in Fig. 9. A by-product of the helical structure of the chiral nematic phase is its ability to selectively reflect light with central wavelength located $\lambda_0 = p \cdot \langle n \rangle$ and bandwidth $\Delta\lambda = p \cdot \Delta n$, where $\langle n \rangle$ represents the average refractive index and Δn, the birefringence of the LC. The cholesteric display reflects color without using color filters. Thus, its brightness is about 3× higher than those using color filters. This Bragg reflection is established by the helical pitch of the cholesteric layers. The angle the LC director changes can be made larger by increasing the temperature of the sample, and thus tighten the pitch. Hence, more thermal energy will result from the increased temperature. Similarly, decreasing the temperature of the chiral sample increases the pitch length of the chiral nematic liquid crystal. Similar pitch changes are possible by applying electromagnetic field to aligned cholesteric samples. An interesting phenomenon of chiral nematic phase is that chirality can be introduced to the nonchiral nematic material by adding a small amount of chiral nematic mesogens. Not necessarily all the molecules have to be chiral. Sometimes, slightly below phase transition to the isotropic state (clearing point), some anomalous phases appear. They are known as blue phases (BPs).[6,7] In many chiral compounds, with sufficiently

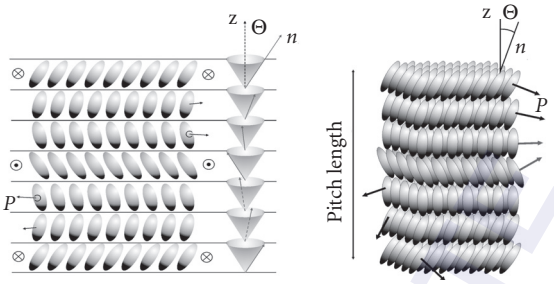

FIGURE 10 Structure of the ferroelectric smectic C^* phase.

high twist, up to three distinct blue phases appear. The two low-temperature phases, blue phase I (BP-I) and blue phase II (BP-II), have cubic symmetry. The highest temperature phase (closest to the clearing point), blue phase III (BP-III) appears to be amorphous.

Similar to chiral nematics, there are chiral forms of smectic phases. The only untilted chiral smectic phase is S_{A^*}. The most important feature of the chiral smectic phases with a tilted structure is ferroelectricity.[8,9] Due to their low symmetry, chiral smectic phases are able to exhibit spontaneous polarization (P_S) that is oriented perpendicular to the director n and parallel to the smectic layer plane. Ferroelectric smectic C^* phase (S_{C^*}) is the most known tilted chiral smectic phase. The structure of the S_{C^*} has layers of molecules which are tilted in each layer at a temperature-dependent angle (θ) to the layer normal. Additionally, there is a slight and continuous change in the direction of the molecular tilt between adjacent layers as described in Fig. 10. In a macroscopic sample, without surfaces or external electric field, tilt will follow the helix and result in zero total spontaneous polarization. However, if a strong electric field is applied, the helix is unwound and nonzero spontaneous polarization can be observed. Recently, more phases closely related to the ferroelectric S_{C^*} have been discovered. In these phases, the layer spacing and the polarization direction are related in a different manner than in S_{C^*} phase. In an antiferroelectric smectic C^* phase ($S_{C^*\text{anti}}$),[10] the spontaneous polarization and the molecular tilt in adjacent layers are pointing in alternating directions, as Fig. 11 shows. Thus, for the macroscopic sample, both average spontaneous polarization and ideally, average molecular tilts are zero. Sufficiently strong electric fields will switch the antiferroelectric order to ferroelectric order. An important difference between ferroelectric and antiferroelectric smectic C^* phase is that antiferrelectric repeats its helical structure every 180° of rotation about the layer normal, compared to 360° for the ferroelectric phase. Many existing ferroelectric phases are different in the proportion of number of the layers with opposite directions. Similar to blue phases in the chiral nematic, the twist grain boundary (TGB) phases appear in chiral smectics.[6,11] Just like in the blue

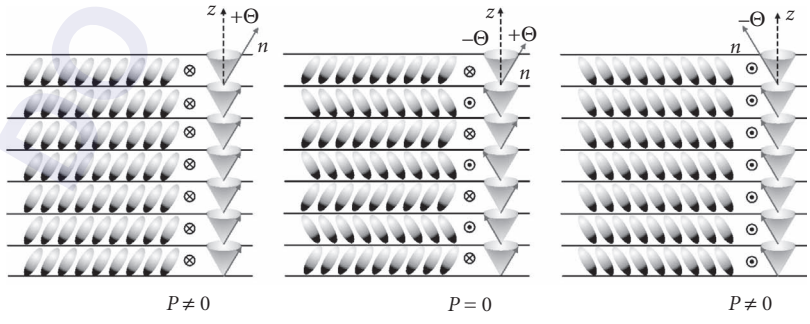

FIGURE 11 Structure of the antiferroelectric smectic C^* phase.

phases, high chirality subtly changes the energy of the system leading to a different type of structure. In this case, the free energy is minimized by introducing grain boundaries at periodic intervals. We may observe different TGB phases depending on the base of the phase from which they were developed. For example, Smectic C^* will generate a TGB_C phase.[6,12]

8.5 PHYSICAL PROPERTIES

The molecular order existing in the liquid crystalline phases induces anisotropy in the system. What it means is that all directions in the system are not equivalent to each other due to the shape of the molecules and the molecular distribution along the director **n**. The anisotropy of the physical property is the most useful feature of liquid crystals and enables electro-optical application of LC materials. The physical properties can be divided into scalar and nonscalar quantities. Typical scalar properties are the thermodynamic transition parameters such as transition temperatures, transition enthalpy, and entropy changes. The dielectric, diamagnetic, optical, elastic, and viscous properties are the most important nonscalar properties. We will concentrate on the physical properties of the nematic phase because we commonly employ this phase and its properties in electro-optical applications.

Phase Transitions

The difference in the transition temperatures between melting and clearing points give the range of stability of the mesophases. For polymorphous (more than one phase) substances, the higher ordered phase exhibits the lower transition temperatures. When a material melts, a change of state occurs from solid to liquid (mesophase) and this process requires energy (endothermic) from the surroundings. If several mesophases exist, then several transitions will occur. The melting transition has typically ~10× larger enthalpy change (30 to 40 kJ/mol) than a transition between different mesophases (3 to 5kJ/mol). The large enthalpy change is due to the drastic structural changes during the melting process; however, there is only a small difference between the different mesophases. One of the richest polymorphism of the single LC compound is shown by Terephthalylidene-bis-p-n-pentylaniline (TBPA) with six different mesophases, as shown in Fig. 12. A number of techniques (optical microscopy with hot stage, polarizing optical microscopy, differential thermal analysis, differential scanning calorimetry, etc.) may be used for determining the phase transition temperatures. Polarizing microscopy with hot stage and differential scanning calorimetry is particularly useful for the measurement of the phase transition temperatures. By using both methods, one can determine the number and type of mesophases and also the exact phase transitions, temperature, and enthalpy change associated with each transition. These are the crucial parameters to determine the components of eutectic mixture formulation for devices. A majority of the single liquid crystal components do not possess adequate range of required mesophase. Therefore, the

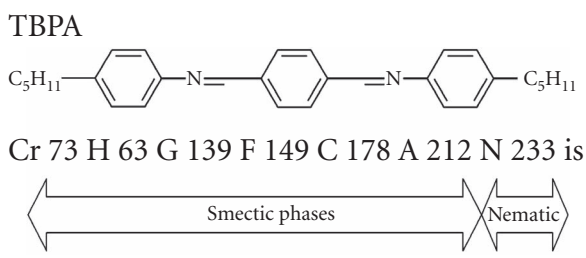

FIGURE 12 Molecular structure and mesomorphic properties of the TBPA.

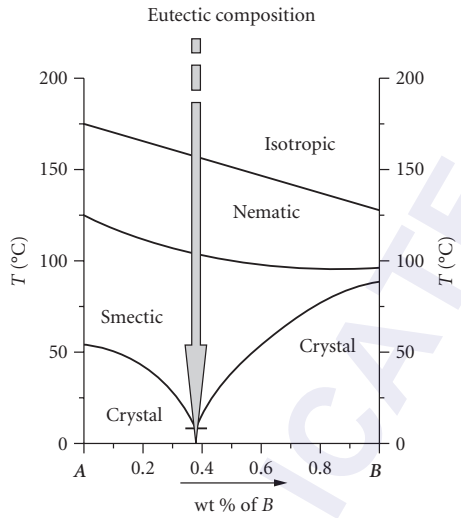

FIGURE 13 Simple phase diagram of the binary LC mixture.

eutectic compositions are required to lower the melting point of the material. It is known that the melting point of a binary (or higher number components) mixture is less than either of its constituent compounds. Figure 13 shows the phase diagram of a binary mixture. The mesogenic range for components 1 and 2 are shown in the two boundary vertical axes. The horizontal axis represents the molar concentration (X_2) of component 2. At a certain molar concentration, the melting point of the mixture will reach its minimum. Meanwhile, the clearing point of the mixture is linearly proportional to the molar concentration. The eutectic mixture calculation is based on the Schroder-Van Laar equation:[13,14]

$$T_i = \frac{\Delta H_{\text{fi}}}{\frac{\Delta H_{\text{fi}}}{T_{\text{fi}}} - R\ln(X_i)} \tag{3}$$

where T_i is the temperature at which the pure component melts in the mixture, ΔH_{fi} is the heat fusion enthalpy of the pure component i, T_{fi} is the melting point of the pure component i, R is the gas constant (1.98 cal/mol-K), and X_i is the mole fraction of the pure component i. The clearing point (T_c) of the eutectic mixture can be estimated from the clearing points (T_{ci}) of the individual components (X_i) as

$$T_c = \sum_i X_i T_{\text{ci}} \tag{4}$$

Dielectric Properties

It was already mentioned, that liquid crystals exhibit anisotropy in many of their physical properties. It is well known that liquid crystals as dielectric and diamagnetic materials are sensitive to the external electric and magnetic fields. Dielectric studies are in general concerned with the response

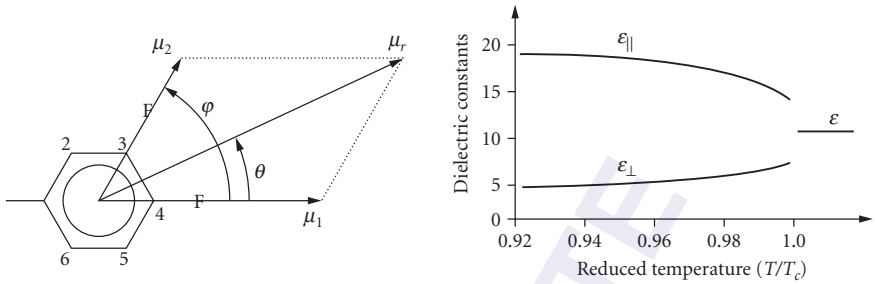

FIGURE 14 Dipole moment of the simple mesogenic structure.

of materials to the application of an electric field. Dielectric constants and their anisotropy affect the sharpness of the voltage-dependent optical transmission curve of a LC device and its threshold voltage.

The nematic liquid crystals are uniaxially symmetric to the axes of the director **n**, and the dielectric constants differ in value along the preferred axis ($\varepsilon_{\parallel}$) and perpendicular to this axis ($\varepsilon_{\perp}$). They are mainly determined by the dipole moment, μ, its angle, θ, with respect to the principal molecular axis, and order parameter, S. When the molecule has two (or more) polar groups with dipole moment μ_1 and μ_2, its effective dipole can be calculated by the vector addition method, see Fig. 14. In Fig. 14, the first dipole is along the principal molecular axis and the second dipole μ_2 is at an angle ϕ with respect to the principal molecular axis (and μ_1). The resultant dipole moment μ_r can be calculated from following equation:

$$\mu_r = \left(\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2\cos\phi\right)^{1/2} \tag{5}$$

Maier and Meier[15] have developed a mean field theory to correlate the microscopic molecular parameters with the macroscopic dielectric constants of anisotropic LCs:

$$\varepsilon_{\parallel} = NhF\{\langle\alpha_{\parallel}\rangle + (F\mu^2/3kT)[1-(1-3\cos^2\theta)S]\} \tag{6a}$$

$$\varepsilon_{\perp} = NhF\{\langle\alpha_{\perp}\rangle + (F\mu^2/3kT)[1+(1-3\cos^2\theta)S/2]\} \tag{6b}$$

$$\Delta\varepsilon = NhF\{(\langle\alpha_{\parallel}\rangle - \langle\alpha_{\perp}\rangle) - (F\mu^2/2kT)(1-3\cos^2\theta)S\} \tag{6c}$$

where N is the molecular packing density, $h = 3\varepsilon/(2\varepsilon + 1)$ is the cavity field factor, $\varepsilon = (\varepsilon_{\parallel} + 2\varepsilon_{\perp})/3$ is the averaged dielectric constant, F is the Onsager reaction field, $\langle\alpha_{\parallel}\rangle$ and $\langle\alpha_{\perp}\rangle$ are the principal elements of the molecular polarizability tensor, β is the angle between the dipole moment μ and the principal molecular axis, and S is the order parameter of the second rank. From Eq. (6), the dielectric constants of anisotropic liquid crystals are influenced by the molecular structure, temperature, and frequency. These individual effects are discussed separately.

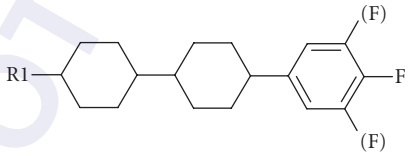
Structural Effect In general, $\Delta\varepsilon$ depends on the molecular constituents, temperature, and frequency. For a nonpolar liquid crystal compound, its dipole moment $\mu \sim 0$. Thus, its $\Delta\varepsilon$ is expected to be small and its magnitude is proportional to the differential molecular polarizability, similar to birefringence. On the other hand, for a LC molecule containing a polar group, such as cyano, isocyanate, fluoro, or chloro group, its $\Delta\varepsilon$ can be positive or negative depending on the position(s) of the polar group(s). If $\beta \sim 0$, that is, the dipole moment of the polar group is along the principal molecular axis, $\Delta\varepsilon$ is large and positive. Cyano-biphenyls are such examples. The $\Delta\varepsilon$ of 5CB is about 10 at $T = 20°C$ and $f = 1$ kHz. These positive $\Delta\varepsilon$ materials are useful for parallel or twist alignment. On the contrary, if $\beta > 55°$, $1 - 3\cos^2\beta > 0$ and $\Delta\varepsilon$ may become negative depending on the dipole moment as indicated in Eq. (6*c*).

From Eq. (6*c*), for a nonpolar compound, $\mu \sim 0$ and its dielectric anisotropy is very small ($\Delta\varepsilon < 0.5$). In this case, $\Delta\varepsilon$ is determined mainly by the differential molecular polarizability, that is, the first term in Eq. (6*c*). For a polar compound, the dielectric anisotropy depends on the dipole moment, angle θ, temperature (T) and applied frequency. If a LC has more than one dipole, then the resultant dipole moment is their vector summation. In a phenyl ring, the position of the dipole is defined as  . From Eq. (6*c*), if a polar compound has an effective dipole at $\theta < 55°$, then its $\Delta\varepsilon$ is positive. On the other hand, $\Delta\varepsilon$ becomes negative if $\theta > 55°$.

Fluoro (F)[16], cyano (CN)[17], and isothiocyanato (NCS)[18] are the three commonly employed polar groups. Among them, fluoro group possess a modest dipole moment ($\mu \sim 1.5$ Debye), high resistivity, and low viscosity. However, its strong negativity compresses the electron clouds and, subsequently, lowers the compound's birefringence. For direct-view LCDs, the required birefringence is around 0.1, depending on the LC alignment and cell gap (d) employed. On the other hand, the cyano and isothiocyanato groups not only exhibit a large dipole moment ($\mu \sim 3.9$ Debye for $C{\equiv}N$ and ~3.7 Debye for $N{=}C{=}S$) but also contribute to lengthen the π-electron conjugation. As a result, their birefringence is much higher than their fluorinated counterpart. High birefringence is favorable for long wavelength, such as infrared applications in order to use a thin cell gap to achieve the same phase change while keeping a fast response time. Under strong anchoring condition, the LC response time is proportional to d^2. However, the CN compounds are more viscous than the corresponding NCS and fluoro compounds. Therefore, their major applications are in low-end displays such as wrist watches and calculators where response time is not crucial.

Example 1: Positive $\Delta\varepsilon$ *LCs* Positive $\Delta\varepsilon$ LCs have been used in twisted nematic (TN)[19] and in-plane switching (IPS)[20,21] displays, although IPS can also use negative $\Delta\varepsilon$ LCs. For TFT LCD, the employed LC material must also possess a high resistivity ($>10^{13}$ Ω-cm) in order to steadily hold the charges and avoid image flickering.[22] The resistivity of a LC mixture depends heavily on the impurity contents, for example, ions. Purification process plays an important role in removing the ions for achieving high resistivity. Fluorinated compounds exhibit a high resistivity and are the natural choices for TFT LCDs.[23,24]

A typical fluorinated LC structure is shown below:



(I)

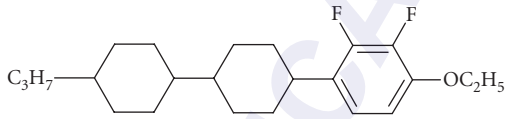
Most liquid crystal compounds discovered so far possess at least two rings, either cyclohexane-cyclohexane, cyclohexane-phenyl or phenyl-phenyl, and a flexible alkyl or alkoxy chain. The compound shown in structure (I) has two cyclohexane and one phenyl rings. The R_1 group represents a terminal alkyl chain, and a single or multiple fluoro substitutions take place in the phenyl ring. For multiple dipoles, the net dipole moment can be calculated from their vector sum. From Eq. (6*c*), to obtain the largest $\Delta\varepsilon$ for a given dipole, the best position for the fluoro substitution is along the principal molecular axis, that is, in the fourth position. The single fluoro compound should have $\Delta\varepsilon \sim 5$. To further increase $\Delta\varepsilon$, more fluoro groups can be added. For example, compound (I) has two more fluoro groups in the third and fifth positions.[24] Its $\Delta\varepsilon$ is about 10, but its birefringence would slightly decrease (because of the lower molecular packing density) and viscosity increases substantially (because of the higher moment of inertia). The birefringence of compound (I) is around 0.07. If a higher birefringence is needed, the middle cyclohexane ring can be replaced by a phenyl ring. The elongated electron cloud will enhance the birefringence to approximately 0.12 without increasing the viscosity noticeably.

The phase transition temperatures of a LC compound are difficult to predict before the compound is synthesized. In general, the lateral fluoro substitution lowers the melting temperature of the parent

compound because the increased intermolecular separation leads to a weaker molecular association. Thus, a smaller thermal energy is able to separate the molecules which implies to a lower melting point. A drawback of the lateral substitution is the increased viscosity.

Example 2: Negative $\Delta\varepsilon$ LCs From Eq. (6*c*), in order to obtain a negative dielectric anisotropy, the dipoles should be in the lateral (2,3) positions. For the interest of obtaining high resistivity, lateral difluoro group is a favorable choice. The negative $\Delta\varepsilon$ LCs are useful for vertical alignment.[25] The VA cell exhibits an unprecedented contrast ratio when viewed at normal direction between two crossed linear polarizers.[26,27] However, a single domain VA cell has a relatively narrow viewing angle and is only useful for projection displays. For wide-view LCDs, a multidomain (4 domains) vertical alignment (MVA) cell is required.[28]

The following structure is an example of the negative $\Delta\varepsilon$ LC:[29]



(II)

Compound (II) has two lateral fluoro groups in the (2,3) positions so that their dipoles in the horizontal components are perfectly cancelled whereas the vertical components add up. Thus, the net $\Delta\varepsilon$ is negative. A typical $\Delta\varepsilon$ of lateral difluoro compounds is −4. The neighboring alkoxy group also has a dipole in the vertical direction. Therefore, it contributes to enlarge the dielectric anisotropy ($\Delta\varepsilon \sim -6$). However, the alkoxy group has a higher viscosity than its alkyl counterpart and it also increases the melting point by ~20°.

Temperature Effect In general, as temperature rises $\varepsilon_{\parallel}$ decreases but $\varepsilon_{\perp}$ increases gradually resulting in a decreasing $\Delta\varepsilon$. From Eq. (6*c*) the temperature dependence of $\Delta\varepsilon$ is proportional to S for the nonpolar LCs and S/T for the polar LCs. At $T > T_c$, the isotropic phase is reached and dielectric anisotropy vanishes, as Fig. 14 shows.

Frequency Effect From Eq. (6), two types of polarizations contribute to the dielectric constant: (1) induced polarization (the first term), and (2) orientation polarization (the dipole moment term). The field-induced polarization has a very fast response time, and it follows the alternating external field. But the permanent dipole moment associated orientation polarization exhibits a longer decay time, τ. If the external electric field frequency is comparable to $1/\tau$, the time lag between the average orientation of the dipole moments and the alternating field becomes noticeable. At a frequency $\omega(=2\pi f)$ which is much higher than $1/\tau$, the orientation polarization cannot follow the variations of the external field any longer. Thus, the dielectric constant drops to $\varepsilon_{\parallel}$ which is contributed solely by the induced polarization:[30]

$$\varepsilon_{\parallel}(\omega) = \varepsilon_{\infty} + \frac{\varepsilon_{\parallel} - \varepsilon_{\infty}}{1 + \omega^2\tau^2} \tag{7}$$

where $\varepsilon_{\parallel} = \varepsilon_{\parallel}(\omega = 0)$ and $\varepsilon_{\infty} = \varepsilon_{\parallel}(\omega = \infty)$ are the parallel component of the dielectric constant at static and high frequencies, respectively.

In an aligned LC, the molecular rotation around their short axis is strongly hindered. Thus, the frequency dispersion occurs mainly at $\varepsilon_{\parallel}$, while $\varepsilon_{\perp}$ remains almost constant up to mega-Hertz region. Figure 15 shows the frequency dependent dielectric constants of the M1 LC mixture (from Roche) at various temperatures.[31] As the frequency increases $\varepsilon_{\parallel}$ decreases and beyond the crossover frequency f_c, $\Delta\varepsilon$ changes sign. The dielectric anisotropies of M1 are fairly symmetric at low and high frequencies. The crossover frequency is sensitive to the temperature. As temperature rises, the $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ of M1 both decrease slightly. However, the frequency-dependent $\varepsilon_{\parallel}$ is strongly dependent on the temperature, but $\varepsilon_{\perp}$ is inert. Thus, the crossover frequency increases exponentially with the temperature as: $f_c \sim \exp(-E/kT)$, where E is the activation energy. For M1 mixture, $E = 0.96$ eV.[31]

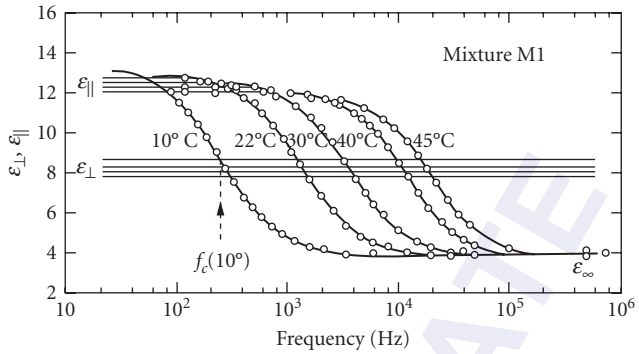


FIGURE 15 The frequency dependent dielectric constants of the M1 LC mixture (from Roche). (*Redrawn from Ref. 31.*)

Dual frequency effect is a useful technique for improving the response times of a LC device.[32] In the dual frequency effect, a low frequency ($f < f_c$, where $\Delta\varepsilon > 0$) an electric field is used to drive the device to its ON state, and during the decay period a high frequency ($f > f_c$, where $\Delta\varepsilon < 0$) electric field is applied to speed up the relaxation process. From material standpoint, a LC mixture with low f_c and large $|\Delta\varepsilon|$ at both low and high frequencies is beneficial. But for a single LC substance (such as cyanobiphenyls), its f_c is usually too high ($>10^6$ Hz) to be practically employed.

In such a high frequency regime, the imaginary part of dielectric constant (which is responsible for absorption) becomes so significant that the dielectric heating effect is amplified and heats up the LC. The electro-optic properties of the cell are then altered. The imaginary part of dielectric constant contributes to heat. Thus, if a LC device is operated at MHz frequency region, significant heating effect due to the applied voltage will take place. This heating effect may be large enough to change all the physical properties of the LC. Dielectric heating is more severe if the crossover frequency is high.[33–35]

Thus, liquid crystals are useful electro-optic media in the spectral range covering from UV, visible, IR to microwave. Of course, in each spectral region, an appropriate LC material has to be selected. For instance, the totally saturated LC compounds should be chosen for UV application because of photostability. For flat panel displays, LCs with a modest conjugation are appropriate. On the other hand, highly conjugated LCs are favorable for IR and microwave applications for the interest of keeping fast response time.

Optical Properties

Refractive indices and absorption are fundamentally and practically important parameters of a LC compound or mixture.[36] Almost all the light modulation mechanisms are involved with refractive index change. The absorption has a crucial impact on the photostability or lifetime of the liquid crystal devices. Both refractive indices and absorption are determined by the electronic structures of the liquid crystal studied.

The major absorption of a LC compound occurs in ultraviolet (UV) and infrared (IR) regions. The $\sigma \rightarrow \sigma^*$ electronic transitions take place in the vacuum UV (100 to 180 nm) region whereas the $\pi \rightarrow \pi^*$ electronic transitions occur in the UV (180 to 400 nm) region. Figure 16 shows the measured polarized UV absorption spectra of 5CB.[37] The λ_1 band which is centered at ~200 nm consists of two closely overlapped bands. The Λ_2 band shifts to ~282 nm. The λ_2 band should occur in the vacuum UV region (λ_0~120 nm) which is not shown in the figure.

Refractive Indices Refractive index has great impact on LC devices. Almost every electro-optic effect of LC modulators, no matter amplitude or phase modulation, involves refractive index

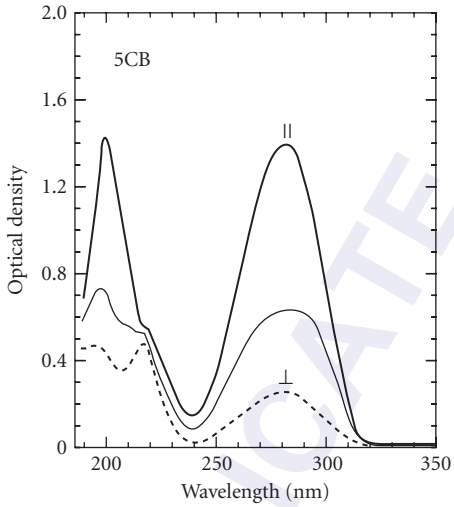

FIGURE 16 The measured polarized absorption spectra of 5CB. The middle trace is for unpolarized light. $\lambda_1 \sim 200$ nm and $\lambda_2 \sim 282$ nm.

change. An aligned LC exhibits anisotropic properties, including dielectric, elastic, and optical anisotropies. Let us take a homogeneous alignment as an example.[38] Assume a linearly polarized light is incident to the LC cell at normal direction. If the polarization axis is parallel to the LC alignment axis (i.e., LC director which represents an average molecular distribution axis), then the light experiences the extraordinary refractive index, n_e. If the polarization is perpendicular to the LC directors, then the light sees the ordinary refractive index n_o. The difference between n_e and n_o is called birefringence, defined as $\Delta n = n_e - n_o$. Refractive indices are dependent on the wavelength and temperature. For a full-color LCD, RGB color filters are employed. Thus, the refractive indices at these wavelengths need to be known in order to optimize the device performance. Moreover, about 50 percent of the backlight is absorbed by the polarizer. The absorbed light turns into heat and causes the LCD panel's temperature to increase. As the temperature increases, refractive indices decrease gradually. The following sections will describe how the wavelength and temperature affect the LC refractive indices.

Wavelength Effect Based on the electronic absorption, a three-band model which takes one $\sigma \rightarrow \sigma^*$ transition (the λ_0 -band) and two $\pi \rightarrow \pi^*$ transitions (the λ_1 - and λ_2 -bands) into consideration has been developed. In the three band model, the refractive indices (n_e and n_o) are expressed as follows:[39,40]

$$n_{e,o} \cong 1 + g_{0e,o}\frac{\lambda^2\lambda_0^2}{\lambda^2 - \lambda_0^2} + g_{1e,o}\frac{\lambda^2\lambda_1^2}{\lambda^2 - \lambda_1^2} + g_{2e,o}\frac{\lambda^2\lambda_2^2}{\lambda^2 - \lambda_2^2} \tag{8}$$

The three-band model clearly describes the origins of refractive indices of LC compounds. However, a commercial mixture usually consists of several compounds with different molecular structures in order to obtain a wide nematic range. The individual λ_i'*s* are therefore different. Under such a circumstance, Eq. (8) would have too many unknowns to quantitatively describe the refractive indices of a LC mixture.

In the off-resonance region, the right three terms in Eq. (8) can be expanded by a power series to the λ^{-4} terms to form the extended Cauchy equations for describing the wavelength-dependent refractive indices of *anisotropic* LCs:[40,41]

$$n_{e,o} \cong A_{e,o} + \frac{B_{e,o}}{\lambda^2} + \frac{C_{e,o}}{\lambda^4} \tag{9}$$

In Eq. (9), $A_{e,o}$, $B_{e,o}$, and $C_{e,o}$ are known as Cauchy coefficients. Although Eq. (9) is derived based on a LC compound, it can be extended easily to include eutectic mixtures by taking the superposition of each compound. From Eq. (9) if we measure the refractive indices at three wavelengths, the three Cauchy coefficients ($A_{e,o}$, $B_{e,o}$, and $C_{e,o}$) can be obtained by fitting the experimental results. Once these coefficients are determined, the refractive indices at any wavelength can be calculated. From Eq. (9) both refractive indices and birefringence decrease as the wavelength increases. In the long wavelength (IR and millimeter wave) region, n_e and n_o are reduced to A_e and A_o, respectively. The coefficients A_e and A_o are constants; they are independent of wavelength, but dependent on the temperature. That means, in the IR region the refractive indices are insensitive to wavelength, except for the resonance enhancement effect near the local molecular vibration bands. This prediction is consistent with many experimental evidences.[42]

Figure 17 depicts the wavelength-dependent refractive indices of E7 at $T = 25°C$. Open squares and circles represent the n_e and n_o of E7 in the visible region while the downward- and upward-triangles stand for the measured data at $\lambda = 1.55$ and 10.6 μm, respectively. Solid curves are fittings to the experimental n_e and n_o data in the visible spectrum by using the extended Cauchy equations [Eq. (9)]. The fitting parameters are listed as follows: ($A_e = 1.6933$, $B_e = 0.0078\ \mu m^2$, $C_e = 0.0028\ \mu m^4$) and ($A_o = 1.4994$, $B_o = 0.0070\ \mu m^2$, $C_o = 0.004\ \mu m^4$). In Fig. 17, the extended Cauchy model is extrapolated to the near- and far-infrared regions. The extrapolated lines almost strike through the center of the experimental data measured at $\lambda = 1.55$ and 10.6 μm. The largest difference between the extrapolated and experimental data is only 0.4 percent.

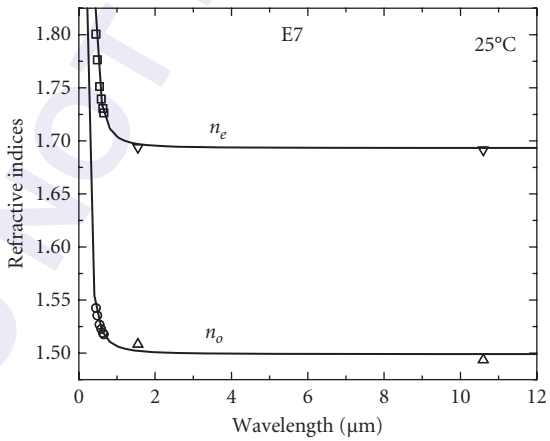

FIGURE 17 Wavelength-dependent refractive indices of E7 at $T = 25°C$. Open squares and circles are the n_e and n_o measured in the visible spectrum. Solid lines are fittings to the experimental data measured in the visible spectrum by using the extended Cauchy equation [Eq. (4.9)]. The downward- and upward-triangles are the n_e and n_o measured at $T = 25°C$ and $\lambda = 1.55$ and 10.6 μm, respectively.

Equation (9) applies equally well to both high and low birefringence LC materials in the off-resonance region. For low birefringence ($\Delta n < 0.12$) LC mixtures, the λ^{-4} terms are insignificant and can be omitted and the extended Cauchy equations are simplified as:[43]

$$n_{e,o} \cong A_{e,o} + \frac{B_{e,o}}{\lambda^2} \tag{10}$$

Thus, n_e and n_o each has only two fitting parameters. By measuring the refractive indices at two wavelengths, we can determine $A_{e,o}$ and $B_{e,o}$. Once these two parameters are determined, n_e and n_o can be calculated at any wavelength of interest. Because most of TFT LC mixtures have $\Delta n \sim 0.1$, the two-coefficient Cauchy model is adequate to describe the refractive index dispersions. Although the extended Cauchy equation fits experimental data well,[44] its physical origin is not clear. A better physical meaning can be obtained by the three-band model which takes three major electronic transition bands into consideration.

Temperature Effect The temperature effect is particularly important for projection displays.[45] Due to the thermal effect of the lamp, the temperature of the display panel could reach 50°C. It is important to know the LC properties at the anticipated operating temperature beforehand.

Birefringence Δn is defined as the difference between the extraordinary and ordinary refractive indices, $\Delta n = n_e - n_o$ and the average refractive indices $\langle n \rangle$ is defined as $<n> = (n_e + 2n_o)/3$. Based on these two definitions, n_e and n_o can be rewritten as

$$n_e = \langle n \rangle + \frac{2}{3}\Delta n \tag{11}$$

$$n_o = \langle n \rangle - \frac{1}{3}\Delta n \tag{12}$$

To describe the temperature dependent birefringence, the Haller approximation can be employed when the temperature is not too close to the clearing point:

$$\Delta n(T) = (\Delta n)_o (1 - T/T_c)^{\beta} \tag{13}$$

In Eq. (13), $(\Delta n)_o$ is the LC birefringence in the crystalline state (or $T = 0$ K), the exponent α is a material constant, and T_c is the clearing temperature of the LC material under investigation. On the other hand, the average refractive index decreases linearly with increasing temperature as[46]

$$<n> = A - BT \tag{14}$$

because the LC density decreases with increasing temperature. By substituting Eqs. (14) and (13) back to Eqs. (11) and (12), the 4-parameter model for describing the temperature dependence of the LC refractive indices is given as[47]

$$n_e(T) \approx A - BT + \frac{2(\Delta n)_o}{3}\left(1 - \frac{T}{T_c}\right)^{\beta} \tag{15}$$

$$n_o(T) \approx A - BT - \frac{(\Delta n)_o}{3}\left(1 - \frac{T}{T_c}\right)^{\beta} \tag{16}$$

The parameters $[A, B]$ and $[(\Delta n)_o, \beta]$ can be obtained separately by two-stage fittings. To obtain $[A, B]$, one can fit the average refractive index $\langle n \rangle = (n_e + 2n_o)/3$ as a function of temperature using Eq. (14). To find $[(\Delta n)_o, \beta]$, one can fit the birefringence data as a function of temperature using Eq. (13). Therefore, these two sets of parameters can be obtained separately from the same set of refractive indices but at different forms.

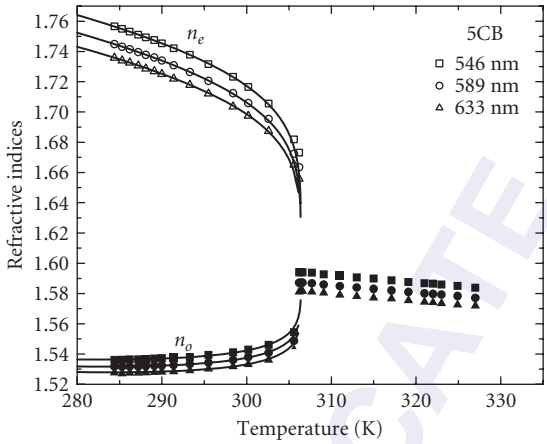

FIGURE 18 Temperature-dependent refractive indices of 5CB at $\lambda = 546$, 589, and 633 nm. Squares, circles, and triangles are experimental data for refractive indices measured at $\lambda =$ 546, 589, and 633 nm, respectively.

Figure 18 is a plot of the temperature dependent refractive indices of 5CB at $\lambda = 546$, 589, and 633 nm. As the temperature increases, n_e decreases, but n_o gradually increases. In the isotropic state, $n_e = n_o$ and the refractive index decreases linearly as the temperature increases. This correlates with the density effect.

Elastic Properties

The molecular order existing in liquid crystals has interesting consequences on the mechanical properties of these materials. They exhibit elastic behavior. Any attempt to deform the uniform alignments of the directors and the layered structures (in case of smectics) results in an elastic restoring force. The constants of proportionality between deformation and restoring stresses are known as elastic constants.

Elastic Constants Both threshold voltage and response time are related to the elastic constant of the LC used. There are three basic elastic constants involved in the electro-optics of liquid crystals depending on the molecular alignment of the LC cell: the splay (K_{11}), twist (K_{22}), and bend (K_{33}), as Fig. 19 shows. Elastic constants affect the liquid crystal's electro-optical cell in two aspects: the threshold voltage and the response time. The threshold voltage in the most common case of homogeneous electro-optical cell is expressed as follows:

$$V_{\text{th}} = \pi \sqrt{\frac{K_{11}}{\varepsilon_0 \Delta \varepsilon}} \tag{17}$$

Several molecular theories have been developed for correlating the Frank elastic constants with molecular constituents. Here we only introduce two theories: (1) the mean-field theory,[48,49] and (2) the generalized van der Waals theory.[50]

Mean-Field Theory In the mean-field theory, the three elastic constants are expressed as

$$K_{ii} = C_{ii} V_n^{-7/3} S^2 \tag{18a}$$

$$C_{ii} = (3A/2)(Lm^{-1}\chi_{ii}^{-2})^{1/3} \tag{18b}$$

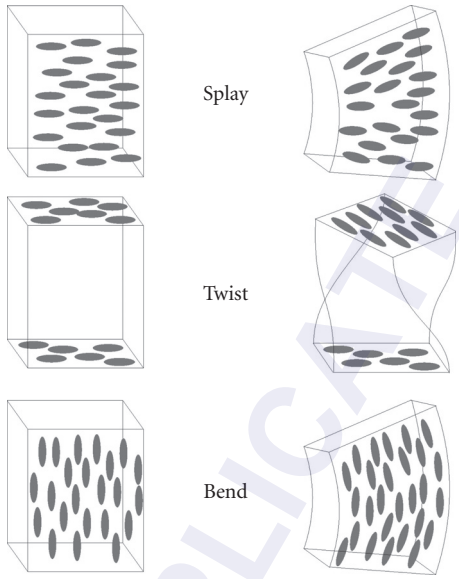

FIGURE 19 Elastic constants of the liquid crystals.

where C_{ii} is called the reduced elastic constant, V_n is the mole volume, L is the length of the molecule, m is the number of molecules in a steric unit in order to reduce the steric hindrance, $\chi_{11} = \chi_{22} = z/x$ and $\chi_{33} = (x/z)^2$, where x (y = x) and z are the molecular width and length, respectively, and $A = 1.3 \times 10^{-8}$ erg · cm^6.

From Eq. (18), the ratio of K_{11}: K_{22}: K_{33} is equal to 1: 1: $(z/x)^2$ and the temperature dependence of elastic constants is basically proportional to S^2. This S^2 dependence has been experimentally observed for many LCs. However, the prediction for the relative magnitude of K_{ii} is correct only to the first order. Experimental results indicate that K_{22} often has the lowest value, and the ratio of K_{33}/K_{11} can be either greater or less than unity.

Generalized van der Waals Theory Gelbart and Ben-Shaul[50] extended the generalized van der Waals theory for explaining the detailed relationship between elastic constants and molecular dimensions, polarizability, and temperature. They derived the following formula for nematic liquid crystals:

$$K_{ii} = a_i \langle P_2 \rangle \langle P_2 \rangle + b_i \langle P_2 \rangle \langle P_4 \rangle \tag{19}$$

where a_i and b_i represent sums of contributions of the energy and the entropy terms; they depend linearly on temperature, $\langle P_2 \rangle$ (=S) and $\langle P_4 \rangle$ are the order parameter of the second and the fourth rank, respectively. In general, the second term may not be negligible in comparison with the S^2 term depending on the value of $\langle P_4 \rangle$. As temperature increases, both S and $\langle P_4 \rangle$ decrease. If the $\langle P_4 \rangle$ of a LC is much smaller than S in its nematic range, Eq. (19) is reduced to the mean-field theory, or $K_{ii} \sim S^2$. The second term in Eq. (19) is responsible for the difference between K_{11} and K_{33}.

Viscosities

The resistance of fluid system to flow when subjected to a shear stress is known as viscosity. In liquid crystals several anisotropic viscosity coefficients may result, depending on the relative orientation

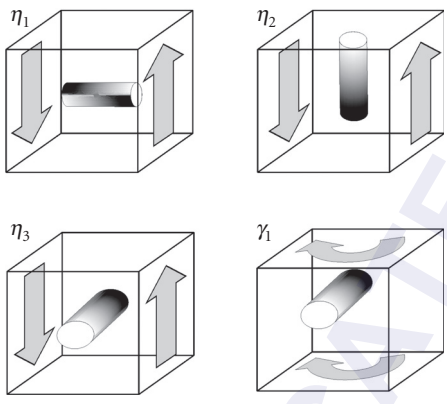

FIGURE 20 Anisotropic viscosity coefficients required to characterize a nematic.

of the director with respect to the flow of the LC material. When an oriented nematic liquid crystal is placed between two plates which are then sheared, four cases shown in Fig. 20 are to be studied. Three, are known as Miesowicz viscosity coefficients. They are $\eta 1$—when director of LC is perpendicular to the flow pattern and parallel to the velocity gradient, $\eta 2$—when director is parallel to the flow pattern and perpendicular to the velocity gradient and $\eta 3$—when director is perpendicular to the flow pattern and to the velocity gradient. Viscosity, especially rotational viscosity γ_1, plays a crucial role in the liquid crystals displays (LCD) response time. The response time of a nematic liquid crystals device is linearly proportional to γ_1.

The rotational viscosity of an aligned LC is a complicated function of molecular shape, moment of inertia, activation energy, and temperature. Several theories, including both rigorous and semiempirical, have been developed in an attempt to account for the origin of the LC viscosity. However, owing to the complicated anisotropic attractive and steric repulsive interactions among LC molecules, these theoretical results are not yet completely satisfactory. Some models fit certain LCs, but fail to fit others.[51] In the molecular theory developed by Osipov and Terentjev,[52] all six Leslie viscosity coefficients are expressed in terms of microscopic parameters:

$$\alpha_1 = -N\Lambda\frac{p^2-1}{p^2+1}P_4 \tag{20a}$$

$$\alpha_2 = -\frac{N\Lambda}{2}S - \frac{1}{2}\gamma_1 \cong -\frac{N\Lambda}{2}\left[S + \frac{1}{6}\sqrt{J/kT}\,e^{j/kT}\right] \tag{20b}$$

$$\alpha_3 = -\frac{N\Lambda}{2}S + \frac{1}{2}\gamma_1 \cong -\frac{N\Lambda}{2}\left[S - \frac{1}{6}\sqrt{J/kT}\,e^{j/kT}\right] \tag{20c}$$

$$\alpha_4 = \frac{N\Lambda}{35}\frac{p^2-1}{p^2+1}[7-5S-2P_4] \tag{20d}$$

$$\alpha_5 = \frac{N\Lambda}{2}\left[\frac{p^2-1}{p^2+1}\frac{3S+4P_4}{7} + S\right] \tag{20e}$$

$$\alpha_6 = \frac{N\Lambda}{2}\left[\frac{p^2-1}{p^2+1}\frac{3S+4P_4}{7} - S\right] \tag{20f}$$

where N represents molecular packing density, p is the molecular length-to-width (w) ratio, $J \cong J_o S$ is the Maier-Saupe mean-field coupling constant; k is the Boltzmann constant, T is the Kelvin temperature, S and P_4 are the nematic order parameters of the second and fourth order, respectively, and Λ is the friction coefficient of LC:

$$\Lambda \cong 100\ (1 - \Phi) N^2 w^6 p^{-2}\ [(kT)^5/G^3]\ (I_\perp/kT)^{1/2} \cdot \exp\ [3(G + I_o)/kT] \tag{21}$$

where Φ is the volume fraction of molecules ($\Phi = 0.5$ to 0.6 for dense molecular liquids), $G >> I_o$ is the isotropic intermolecular attraction energy, and $I_\perp$ and I_o are the inertia tensors.

From the above analysis, the parameters affecting the rotational viscosity of a LC are[53]

1. Activation energy ($E_a \sim 3G$): a LC molecule with low activation energy leads to a low viscosity.
2. Moment of inertia: a LC molecule with linear shape and low molecular weight would possess a small moment of inertia and exhibit a low viscosity.
3. Inter-molecular association: a LC with weak inter-molecular association, for example, not form dimer, would reduce the viscosity significantly.
4. Temperature: elevated temperature operation of a LC device may be the easiest way to lower viscosity. However, birefringence, elastic, and dielectric constants are all reduced as well.

8.6 LIQUID CRYSTAL CELLS

Three kinds of LC cells have been widely used for display applications. They are (1) twisted-nematic (TN) cell, (2) in-plane switching (IPS) cell, and multidomain vertical alignment (MVA) cell. For phase-only modulation, homogeneous cell is preferred. The TN cell dominates notebook market because of its high transmittance and low cost. However, its viewing angle is limited. For wide-view applications, for example, LCD TVs, optical film-compensated IPS and MVA are the two major camps. In this section, we will discuss the basic electro-optics of TN, IPS, and MVA cells.

Twisted-Nematic (TN) Cell

The first liquid crystal displays that became successful on the market were the small displays in digital watches. These were simple twisted nematic (TN) devices with characteristics satisfactory for such simple applications.[19] The basic operation principals are shown in Fig. 21. In the TN display, each LC cell consists of a LC material sandwiched between two glass plates separated by a gap of 5 to 8 μm.

The inner surfaces of the plates are deposited with transparent electrodes made of conducting coatings of indium tin oxide (ITO). These transparent electrodes are overcoated with a thin layer of polyimide with a thickness of about 80 angstroms. The polyimide films are unidirectional rubbed with the rubbing direction of the lower substrate perpendicular to the rubbing direction of the upper surface. Thus, in the inactivated state (voltage OFF), the local director undergoes a continuous twist of 90° in the region between the plates. Sheet polarizers are laminated on the outer surfaces of the plates. The transmission axes of the polarizers are aligned parallel to the rubbing directions of the adjacent polyimide films. When light enters the cell, the first polarizer lets through only the component oscillating parallel to the LC director next to the entrance substrate. During the passage through the cell, the polarization plane is turned along with the director helix, so that when the light wave arrives at the exit polarizer, it passes unobstructed. The cell is thus transparent in the OFF state; this mode is called normally white (NW).

Figure 22 depicts the normalized voltage-dependent light transmittance ($T_\perp$) of the 90° TN cell at three primary wavelengths: $R = 650$ nm, $G = 550$ nm, and $B = 450$ nm. Since human eye has the greatest

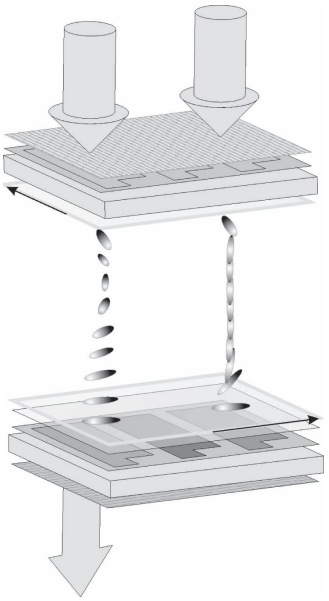

FIGURE 21 The basic operation principles of the TN cell.

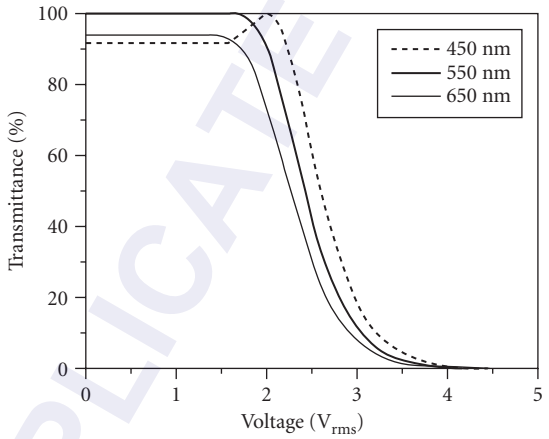

FIGURE 22 Voltage-dependent transmittance of a normally white 90° TN cell. $d\Delta n = 480$ nm.

sensitivity at green, we normally optimize the cell design at $\lambda \sim 550$ nm. To meet the Gooch-Tarry first minimum condition, for example, $d\Delta n = (\sqrt{3}/2)\lambda$, the employed cell gap is 5-μm and the LC birefringence is $\Delta n \sim 0.096$. From Fig. 22, the wavelength effect on the transmittance at V = 0 is within 8 percent. Therefore, the TN cell can be treated as an "achromatic" half-wave plate.

The response time of a TN LCD depends on the cell gap and the γ_1/K_{22} of the LC mixture employed. For a 5-μm cell gap, the optical response time is ~30 to 40 ms. At $V = 5\ V_{rms}$, the contrast ratio (CR) reaches ~500:1. These performances, although not perfect, are acceptable for notebook computers. A major drawback of the TN cell is its narrow viewing angle and grayscale inversion originated from the LC directors tilting out of the plane. Because of this molecular tilt, the viewing angle in the vertical direction is narrow and asymmetric, and has grayscale inversion.[54] Despite a relatively slow switching time and limited viewing angle, the TN cell is still widely used for many applications because of its simplicity and low cost. Recently, a fast-response (~2 ms gray-to-gray response time) TN notebook computer has been demonstrated by using a thin cell gap (2 μm), low viscosity LC mixture, and overdrive and undershoot voltage method.

In-Plane Switching (IPS) Cell

In an IPS cell, the transmission axis of the polarizer is parallel to the LC director at the input plane.[55] The optical wave traversing through the LC cell is an extraordinary wave whose polarization state remains unchanged. As a result, a good dark state is achieved since this linearly polarized light is completely absorbed by the crossed analyzer. When an electric field is applied to the LC cell, the LC directors are reoriented toward the electric field (along the y axis). This leads to a new director distribution with a twist $f(z)$ in the xy plane as Fig. 23 shows.

Figure 24 depicts the voltage-dependent light transmittance of an IPS cell. The LC employed is MLC-6686, whose $\Delta\varepsilon = 10$ and $\Delta n = 0.095$, the electrode width is 4 μm, electrode gap 8 μm, and cell

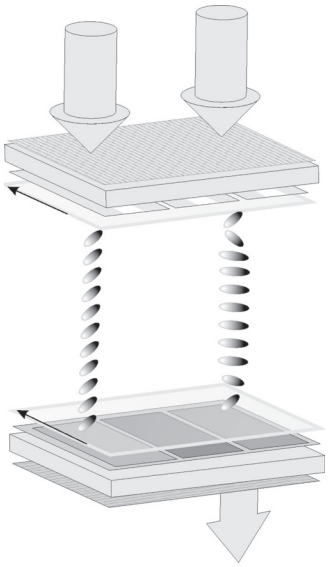

FIGURE 23 IPS mode LC display.

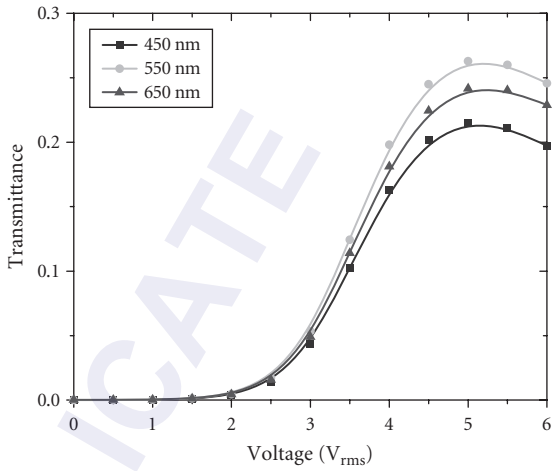

FIGURE 24 Voltage-dependent light transmittance of the IPS cell. LC: MLC-6686, $\Delta\varepsilon = 10$, electrode width = 4 μm, gap = 8 μm, and cell gap $d = 3.6$ μm.

gap $d = 3.6$ μm. The threshold voltage occurs at $V_{th} \sim 1.5\ V_{rms}$ and maximum transmittance at ~5 V_{rms} for both wavelengths. Due to absorption, the maximum transmittance of the two polarizers (without LC cell) is 35.4, 33.7, and 31.4 percent for RGB wavelengths, respectively.

Vertical Alignment (VA) Cell

The vertically aligned LC cell exhibits an unprecedentedly high contrast ratio among all the LC modes developed.[56] Moreover, its contrast ratio is insensitive to the incident light wavelength, cell thickness, and operating temperature. In principle, in voltage-OFF state the LC directors are perpendicular to the cell substrates, as Fig. 25 shows. Thus, its contrast ratio at normal angle is limited by the crossed polarizers. Application of a voltage to the ITO electrodes causes the directors to tilt away from the normal to the glass surfaces. This introduces birefringence and subsequently light transmittance because the refractive indices for the light polarized parallel and perpendicular to the directors are different.

Figure 26 shows the voltage-dependent transmittance of a VA cell with $d\Delta n = 350$ nm between two crossed polarizers. Here, a single domain VA cell employing Merck high resistivity MLC-6608 LC mixture is simulated. Some physical properties of MLC-6608 are listed as follows: $n_e = 1.562$, $n_o = 1.479$ (at $\lambda = 546$ nm and $T = 20°C$); clearing temperature $T_c = 90°C$; $\Delta\varepsilon = -4.2$, and rotational viscosity $\gamma_1 = 186$ mPas at 20°C.

From Fig. 26, an excellent dark state is obtained at normal incidence. As the applied voltage exceeds the Freederickz threshold voltage ($V_{th} \sim 2.1\ V_{rms}$), LC directors are reoriented by the applied electric field resulting in light transmission from the crossed analyzer. From the figure, RGB wavelengths reach their peak at different voltages, blue at ~4 V_{rms}, and green at ~6 V_{rms}. The on-state dispersion is more forgiven than the dark state. A small light leakage in the dark state would degrade the contrast ratio significantly, but less noticeable from the bright state.

It should be mentioned that in Figs. 25 and 26 only a single domain is considered, thus, its viewing angle is quite narrow. To achieve wide view, four domains with film compensation are required. Several approaches, such as Fujitsu's MVA (multidomain VA) and Samsung's PVA (Patterned VA),

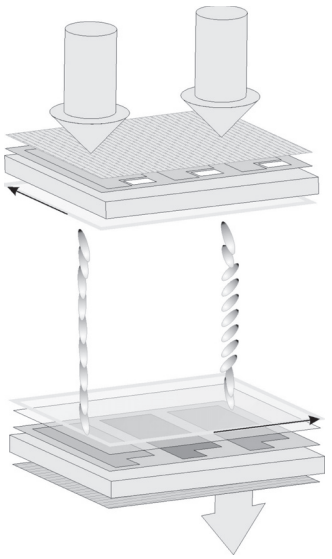

FIGURE 25 VA mode LC display.

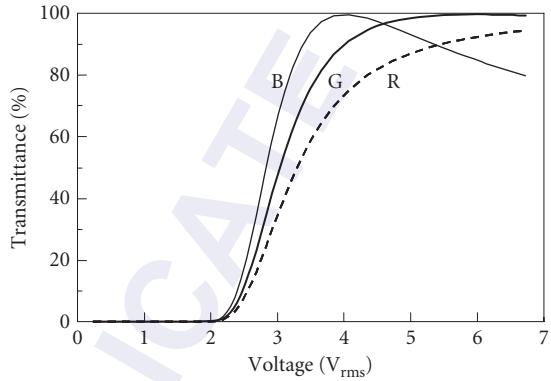

FIGURE 26 Voltage-dependent normalized transmittance of a VA cell. LC: MLC-6608. $d\Delta n$ = 350 nm. R = 650 nm, G = 550 nm, and B = 450 nm.

have been developed for obtaining four complementary domains. Figure 27 depicts the PVA structure developed by Samsung.

As shown in Fig. 27, PVA has no pretilt angle. The four domains are induced by the fringe electric fields. On the other hand, in Fujitsu's MVA, physical protrusions are used to provide initial pretilt direction for forming four domains. The protrusions not only reduce the aperture ratio but also cause light leakage in the dark state because the LCs on the edges of protrusions are tilted so that they exhibit birefringence. It would be desirable to eliminate protrusions for MVA and create a pretilt angle in each domain for both MVA and PVA to guide the LC reorientation direction. Based on this concept, surface polymer sustained alignment (PSA) technique has been developed.[57] A very small percentage (~0.2 wt %) of reactive mesogen monomer and photoinitiator are mixed in a negative $\Delta\varepsilon$ LC host and injected into a LCD panel. While a voltage is applied to generate four domains, a UV light is used to cure the monomers. As a result, the monomers are adsorbed onto the surfaces. These cured polymers, although in low density, will provide a pretilt angle within each domain to guide the LC reorientation. Thus, the rise time is reduced by nearly 2× while the decay time remains more or less unchanged.[58]

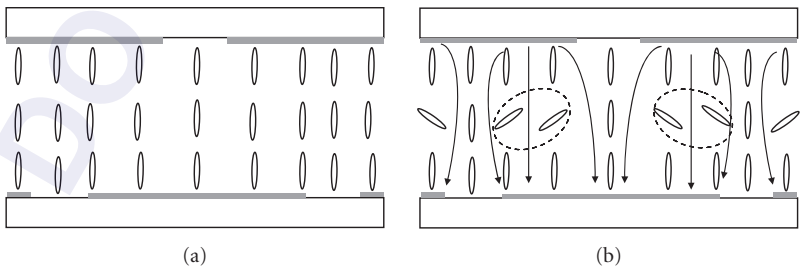

FIGURE 27 (*a*) LC directors of PVA at V = 0 and (*b*) LC directors of PVA at a voltage-on state. The fringe fields generated by the top and bottom slits create two opposite domains in this cross section. When the zigzag electrodes are used, four domains are generated.

8.7 LIQUID CRYSTALS DISPLAYS

The most common and well recognized applications of liquid crystals nowadays are displays. It is the most natural way to utilize extraordinary electro-optical properties of liquid crystals together with its liquid-like behavior. All the other applications are called as nondisplay applications of liquid crystals. Nondisplay applications are based on the liquid crystals molecular order sensitivity to the external incentive. This can be an external electric and magnetic field, temperature, chemical agents, mechanical stress, pressure, irradiation by different electromagnetic wave, or radioactive agents. Liquid crystals sensitivity for such wide spectrum of factors results in tremendous diversity of nondisplay applications. It starts from spatial light modulators for laser beam steering, adaptive optics through telecommunication area (light shutters, attenuators, and switches), cholesteric LC filters, LC thermometers, stress meters, dose meters to ends up with liquid crystals paints, and cosmetics. Another field of interest employing lyotropic liquid crystals is biomedicine where it plays an important role as a basic unit of the living organisms by means of plasma membranes of the living cells. More about existing nondisplays applications can be found in preferred reading materials.

Three types of liquid crystal displays (LCDs) have been developed: (1) transmissive, (2) reflective, and (3) transflective. Each one has its own unique properties. In the following sections, we will introduce the basic operation principles of these display devices.

Transmissive TFT LCDs

A transmissive LCD uses a backlight to illuminate the LCD panel to achieve high brightness (300 to 500 nits) and high contrast ratio (>2000:1). Some transmissive LCDs, such as twisted-nematic (TN), do not use phase compensation films or multidomain structures so that their viewing angle is limited and they are more suitable for single viewer applications, for example, mobile displays and notebook computers. With phase compensation films and multidomain structures, the direct-view transmissive LCDs exhibit a wide viewing angle and high contrast ratio, and have been widely used for desktop computers and televisions. However, the cost of direct-view large screen LCDs is still relatively expensive. To obtain a screen diagonal larger than 2.5 m, projection displays, such as data projector, using transmissive microdisplays are still a favorable choice. There, a high power arc lamp or light emitting diode (LED) arrays are used as light source. Using a projection lens, the displayed image is magnified by more than 50×. To reduce the size of optics and cost, the LCD panel is usually made small (<25 mm in diagonal) and each pixel size is ~20 to 40 μm. Thus, poly-silicon-based TFT LCD is the common choice.

Figure 28 shows the device structure of a transmissive thin-film-transistor (TFT) LCD using amorphous silicon (a-Si) transistors. LCD is a nonemissive display, that is, it does not emit light, instead, it functions as a two-dimensional spatial light modulator. Thus, a backlight is needed. A diffuser is used to homogenize the backlight in order to avoid hot spots. Some optical films are stacked to steer the Lambertian backlight to the central ±40° for improving display brightness. Since most LCDs require a linearly polarized light in order to obtain a high contrast ratio, two sheets of stretched dichroic polarizers are used for large size direct-view displays. The first glass substrate contains TFT arrays, which serve as independent light switches. Each display pixel is controlled by a TFT. Since TFT is sensitive and should be shielded from backlight illumination, the actual aperture ratio (the transparent ITO electrode area) is reduced to ~80 percent, depending on the pixel density. As the pixel density increases, the aperture ratio decreases. The LC layer is sandwiched between two ITO substrates whose inner surface is coated with a thin (80 to 100 nm) polyimide layer. Some LCDs (twisted-nematic, in-plane switching and fringe field switching) require rubbing but some (multidomain vertical alignment and patterned vertical alignment) do not. The cell gap is usually controlled at ~3.5 to 4.0 μm for a transmissive LCD. The performance of the display such as light throughput, response time, and viewing angle are all influenced by the LC configuration employed.

For direct-view LCDs, compact size, lightweight, and low power consumption are equally important as viewing angle, color, and contrast ratio. For direct-view LCDs, color filters are embedded in the inner side of the top (second) substrate. Three subpixels (red, green, and blue) form a color pixel. The size of

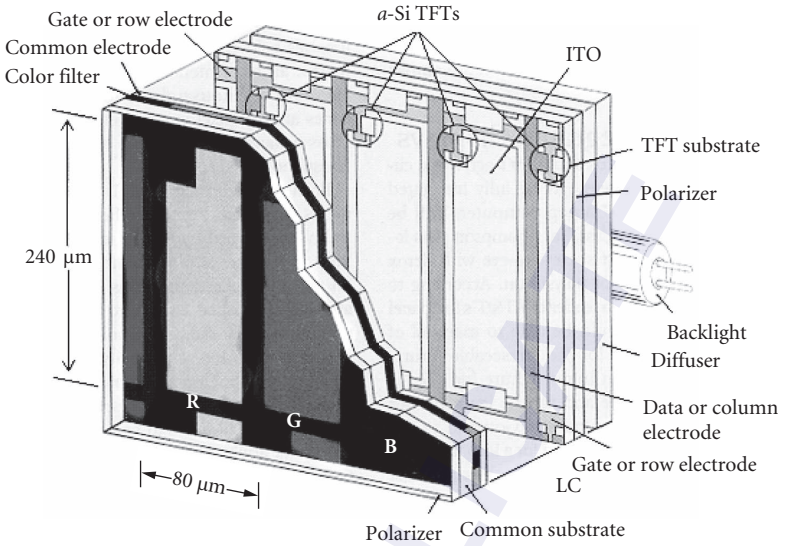

FIGURE 28 Device structure of a color pixel of a transmissive TFT LCD.

each subpixel is ~80 μm × 240 μm. Each subpixel transmits only one color; the other colors are absorbed. Figure 29 depicts the emission spectra of a backlight (cold cathode fluorescent lamp, CCFL) and RGB light emitting diodes (LEDs), and the transmission spectra of RGB color filters.

From Fig. 29, the transmission spectra of RGB color filters are relatively broad. The advantage is to transmit more light however its color purity is degraded. The peak transmission of the RGB color filters is ~70, 80, and 90 percent, respectively. Roughly speaking, each color filter only transmits ~25 percent of the incident white light. The rest ~75 percent is absorbed by the color pigments. Moreover, CCFL emits two unwanted lines: blue-green (~480 nm) and orange (~580 nm). The blue-green light will transmit through the blue and green color filters simultaneously. Similarly, the orange light will transmit through the green and red color filters simultaneously. These leaked lights will downgrade the color purity (or color saturation) of the display. Therefore, the color gamut of a typical transmissive TFT LCD is ~75 percent of NTSC (National Television System Committee) standard. With improved CCFL spectra, the color gamut can reach ~92 percent. LEDs have narrower emission spectra that also match

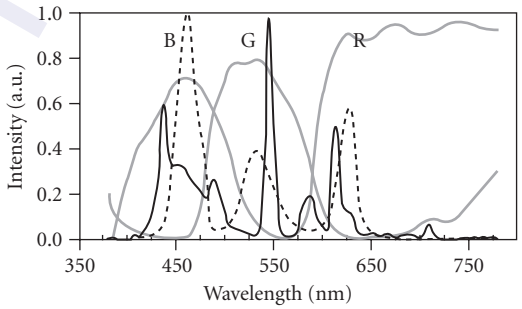

FIGURE 29 Transmission spectra of RGB color filters (thick gray lines), and emission spectra of CCFL backlight (thin black lines) and LEDs (dashed lines).

better with the transmission spectra of the color filters, thus the color gamut reaches ~120 percent.[59] For a display device, a wider color gamut is not necessarily better; natural colors are also important. After all, display is an art where perception plays an important role.

After taking into account the optical losses from polarizers, color filters, and TFT aperture ratio, the overall system optical efficiency is about 6 to 7 percent for a direct-view LCD. If wide view technology is included,[60] the total light efficiency is decreased to ~5 percent. Low optical efficiency implies high power consumption and more heat generation inside the display chasse. For a thin LCD, thermal dissipation is a critical issue. For portable displays, low power consumption is desirable because it lengthens the battery operating hours. Several approaches have been developed to reduce power consumption, for example, polarization conversion of backlight[61] and two-dimensional LED backlight with local dimming capability.[62–64] The use of LED backlight offers several additional advantages such as wide color gamut, high dynamic contrast ratio (>50,000:1), ~2× reduction in power consumption, and fast turn-on and off times (~10 ns) for reducing the motion picture image blurs.[65] Some technological concerns are color and power drifting as the junction temperature changes, and cost.

Reflective LCDs

Figure 30 shows a device structure of a TFT-based reflective LCD. The top linear polarizer and a broadband quarter-wave film forms an equivalent crossed polarizer for the incident and exit beams. This is because the LC modes work better under crossed-polarizer condition. The bumpy reflector not only reflects but also diffuses the ambient light to the observer in order to avoid specular reflection and widen the viewing angle. This is a critical part for reflective LCDs. The TFT is hidden beneath the bumpy reflector, thus the R-LCD can have a large aperture ratio (~90%). The light blocking layer (LBL) is used to absorb the scattered light from neighboring pixels. Two popular LCD modes have been widely used for R-LCDs: (1) VA cell, and (2) mixed-mode twisted nematic (MTN) cell. The VA cell utilizes the phase retardation effect while the MTN cell uses the combination of polarization rotation and birefringence effects.

In a reflective LCD, there is no built-in backlight unit; instead, it utilizes ambient light for reading out the displayed images. In comparison to transmissive LCDs, reflective LCDs have advantages in lower power consumption, lighter weight, and better sunlight readability. However, a reflective LCD is inapplicable under low or dark ambient conditions. Therefore, the TFT-based reflective LCD is gradually losing its ground.

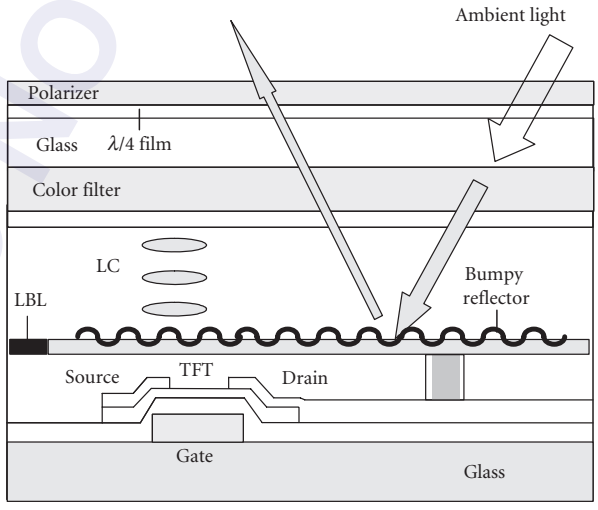

FIGURE 30 Device structure of a direct-view reflective LCD.

Flexible reflective LCDs using cholesteric liquid crystal display (Ch-LCD) and bistable nematic are gaining momentum because they can be used as electronic papers. These reflective LCDs use ambient light to readout the displayed images. Ch-LCD has helical structure which reflects color so that the display does not require color filters, neither polarizer. Thus, the reflectance for a given color band which depends on the pitch length and refractive index of the employed LC is relatively high (~30%). Moreover, it does not require a backlight so that its weight is light and the total device thickness can be thinner than 200 μm. Therefore, it is a strong contender for color flexible displays. Ch-LCD is a bistable device so that its power consumption is low, provided that the device is not refreshed too frequently. A major drawback of a reflective direct-view LCD is its poor readability under low ambient light.

Another reflective LCD developed for projection TVs is liquid-crystal-on-silicon (LCoS) microdisplay. Unlike a transmissive microdisplay, LCoS is a reflective device. Here the reflector employed is an aluminum metallic mirror. Crystalline silicon has high mobility so that the pixel size can be made small (<10 μm) and aperture ratio >90 percent. Therefore, the image not only has high resolution but also is seamless. By contrast, a transmissive microdisplay's aperture ratio is about 65 percent. The light blocked by the black matrices show up in the screen as dark patterns (also known as screen door effect). Viewing angle of a LCD is less critical in projection than direct-view displays because in a projection display the polarizing beam splitter has a narrower acceptance angle than the employed LCD.

Transflective LCDs

In a transflective liquid crystal display (TR-LCD), a pixel is divided into two parts: transmissive (T) and reflective (R). The T/R area ratio can vary from 80/20 to 20/80, depending on the applications. In dark ambient the backlight is on and the display works as a transmissive one, while at bright ambient the backlight is off and only the reflective mode is operational.

Dual-Cell-Gap Transflective LCDs In a TR-LCD, the backlight traverses the LC layer once, but the ambient light passes through twice. As a result, the optical path length is unequal. To balance the optical path difference between the T and R regions for a TR-LCD, dual-cell-gap device concept is introduced. The basic requirement for a TR-LCD is to find equal phase retardation between the T and R modes, which is

$$d_T(\Delta n)_T = 2d_R(\Delta n)_R \tag{22}$$

If T and R modes have the same effective birefringence, then the cell gap should be different. This is the so-called dual cell gap approach. On the other hand, if the cell gap is uniform (single cell gap approach), then we should find ways to make $(\Delta n)_T = 2(\Delta n)_R$. Let us discuss the dual cell gap approaches first.

Figure 31*a* shows the schematic device configuration of a dual-cell-gap TR-LCD. Each pixel is divided into a reflective region with cell gap d_R and a transmissive region with cell gap d_T. The LC employed could be homogeneous alignment (also known as ECB, electrically controlled birefringence) or vertical alignment, as long as it is a phase retardation type. To balance the phase retardation between the single and double pass of the T and R parts, we could set $d_T = 2d_R$. Moreover, to balance the color saturation due to single and double-pass discrepancy, we could use thinner or holed color filters in the R part. The top quarter wave plate is needed mainly for the reflective mode to obtain a high contrast ratio. Therefore, in the T region, the optic axis of the bottom quarter-wave plate should be aligned perpendicular to that of the top one so that their phase retardations are canceled.

A thin homogeneous cell is difficult to find a good common dark state for RGB wavelengths without a compensation film.[55] The compensation film can be designed into the top quarter-wave film shown in Fig. 31*a* to form a single film. Here, let us take a dual cell gap TR-LCD using VA (or MVA for wide-view) and MLC-6608 ($\Delta\varepsilon = -4.2$, $\Delta n = 0.083$) as an example. We set $d_R = 2.25$ μm in the R region and $d_T = 4.5$ μm in the T region. Figure 31*b* depicts the voltage-dependent transmittance (VT) and reflectance (VR) curves at normal incidence. As expected, both VT and VR curves perfectly overlap with each other. Here $d_R\Delta n = 186.8$ nm and $d_T\Delta n = 373.5$ nm are intentionally designed to be larger than $\lambda/4$ (137.5 nm) and $\lambda/2$ (275 nm), respectively, in order to reduce the on-state voltage to ~5 V_{rms}.

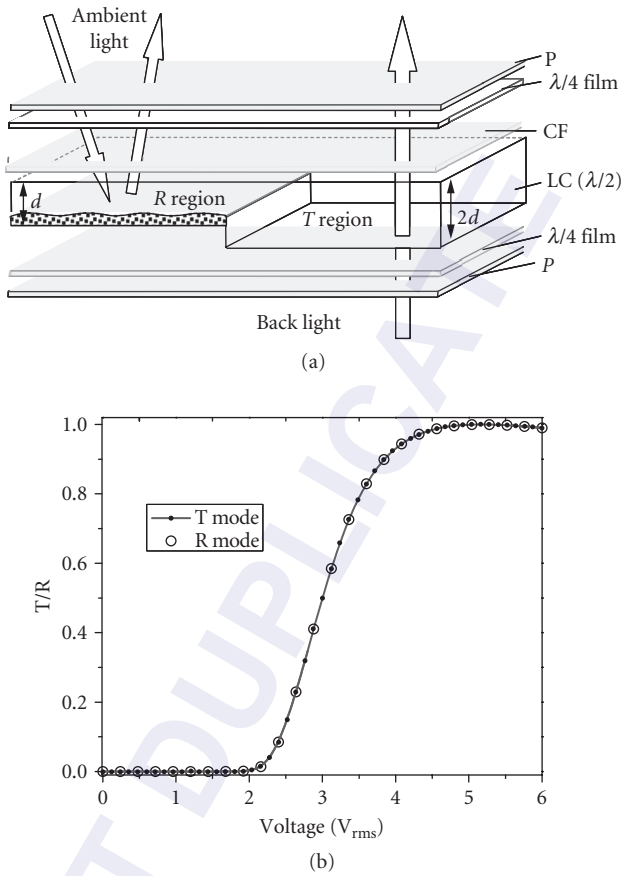

FIGURE 31 (*a*) Schematic device configuration of the dual-cell-gap TR-LCD. (*b*) Simulated VT and VR curves using VA (or MVA) cells. LC: MLC-6608, $dT = 4.5$ μm, $dR = 2.25$ μm, and $\lambda = 550$ nm.

Three problems of dual-cell-gap TR-LCDs are encountered: (1) Due to the cell gap difference the LC alignment is distorted near the T and R boundaries. The distorted LCs will cause light scattering and degrade the device contrast ratio. Therefore, these regions should be covered by black matrices in order to retain a good contrast ratio. (2) The thicker cell gap in the T region results in a slower response time than the R region. Fortunately, the dynamic response requirement in mobile displays is not as strict as those for video applications. This response time difference, although not perfect, is still tolerable. (3) The view angle of the single-domain homogeneous cell mode is relatively narrow because the LC directors are tilted out of the plane by the longitudinal electric field. To improve view angle, a biaxial film[66] or a hybrid aligned nematic polymeric film[67] is needed. Because the manufacturing process is compatible with the LCD fabrication lines, the dual-cell-gap TR-LCD is widely used in commercial products, such as iPhones.

Single-Cell-Gap Transflective LCDs As its name implies, the single-cell-gap TR-LCD has a uniform cell gap in the T and R regions. Therefore, we need to find device concepts to achieve $(\Delta n)_T = 2(\Delta n)_R$. Several approaches have been proposed to solve this problem. In this section, we will discuss two

examples: (1) dual-TFT method in which one TFT is used to drive the T mode and another TFT to drive the R mode at a lower voltage,[68] and (2) divided-voltage method:[69] to have multiple R parts and the superimposed VR curve matches the VT curve.

Example 3: Dual-TFT Method Figure 32*a* shows the device structure of a TR-LCD using two TFTs to separately control the gamma curves of the T and R parts. Here, TFT-1 is connected to the bumpy reflector and TFT-2 is connected to the ITO of the transmissive part. Because of the double passes, the VR curve has a sharper slope than the VT curve and it reaches the peak reflectance at a lower voltage, as shown in Fig. 32*b*. Let us use a 4.5-μm vertically aligned LC layer with 88° pretilt angle as an example. The LC mixture employed is Merck MLC-6608 and wavelength is $\lambda = 550$ nm. From Fig. 32*b*, the peak reflectance occurs at 3 V_{rms} and transmittance at 5.5 V_{rms}. Thus, the maximum voltage of TFT-1 should be set at 5.5 V and TFT-2 at 3 V. This driving scheme is also called double-gamma method.[70] The major advantage of this dual-TFT approach is its simplicity. However, each TFT takes up some real estate so that the aperture ratio for the T mode is reduced.

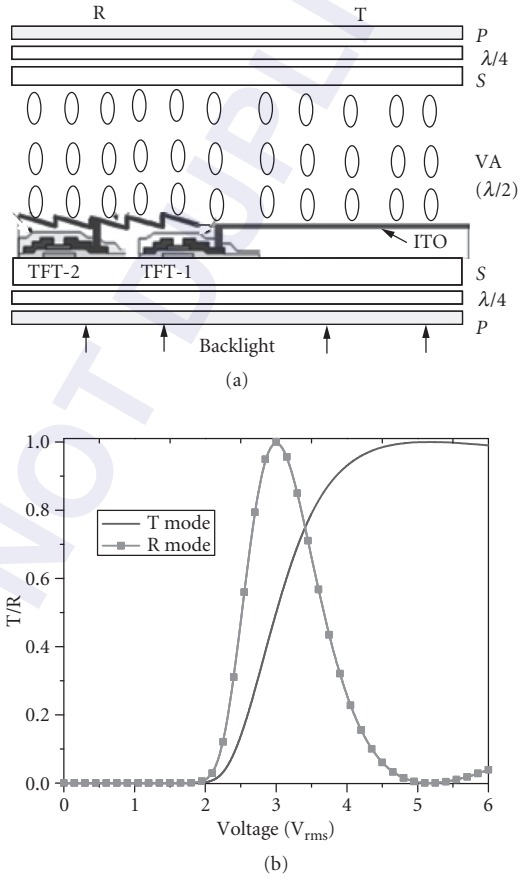

FIGURE 32 (*a*) Device structure of a dual-TFT TR-LCD and (*b*) simulated VT and VR curves using a 4.5-μm, MLC-6608 LC layer.

For a TR-LCD, the T mode should have priority over R mode. The major function of R mode is to preserve sunlight readability. In general, the viewing angle, color saturation, and contrast ratio of R mode are all inferior to T mode. In most lighting conditions except under direct sunlight, T mode is still the primary display.

Example 4: Divided-Voltage Method Figure 33*a* shows the device structure of a TR-LCD using divided voltage method.[71] The R region consists of two sub-regions: R-I and R-II. Between R-II and bottom ITO, there is a passivation layer to weaken the electric field in the R-II region. As plotted in Fig. 33*b*, the VR-II curve in the R-II region has a higher threshold voltage than the VT curve due to this voltage shielding effect. To better match the VT curve, a small area in the T region is also used for R-I. The bumpy reflector in the R-I region is connected to the bottom ITO through a channeled electrode. Because of the double passes of ambient light, the VR-I curve is sharper than the VT curve. By properly choosing the R-I and R-II areas, we can match the VT and VR curves well, as shown in Fig. 33*b*.

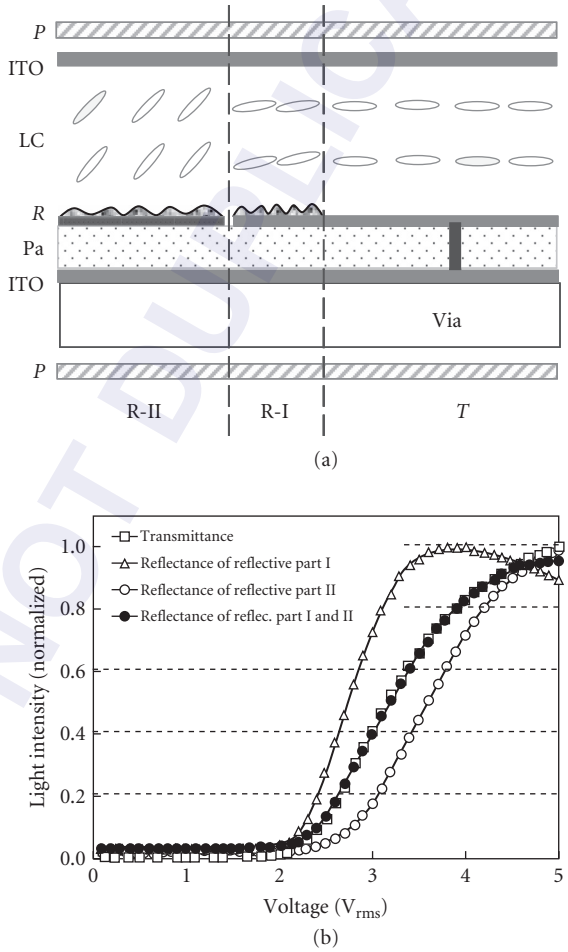

FIGURE 33 A transflective LCD using divided-voltage approach. (*a*) Device structure and (*b*) VT and VR curves at different regions. Here, *P*: polarizer, *R*: bumpy reflector, and Pa: passivation layer. (*Redrawn from Ref. 71.*)

8.8 POLYMER/LIQUID CRYSTAL COMPOSITES

Some types of liquid crystal display combine LC material and polymer material in a single device. Such LC/polymer composites are relatively new class of materials used for displays but also for light shutters or switchable windows. Typically LC/polymer components consist of calamitic low mass LCs and polymers and can be either polymer-dispersed liquid crystal (PDLC) or polymer-stabilized liquid crystals (PSLC).[72–74] The basic difference between these two types comes from concentration ratio between LC and polymer. In case of PDLC there is typically around 1:1 percentage ratio of LC and polymer. In PSLC, the LC occupies 90 percent or more of the total composition. Such difference results in different phase separation process during composites polymerization. For equal concentration of LC and polymer, the LC droplets will form. But in case the LC is a majority, polymer will build up only walls or strings which divide LC into randomly aligned domains. Both types of composites operate between transparent state and scattering state. There are two requirements on the polymer for PDLC or PSLC device to work. First, refraction index of the polymer, n_p, must be equal to the refraction index for light polarized perpendicular to the director of the liquid crystal, (ordinary refractive index of the LC). Second, the polymer must induce the director of the LC in the droplets (PDLC) or domains (PSLC) to orient parallel to the surface of the polymer (Fig. 34). In the voltage OFF state the LC molecules in the droplets are partially aligned. In addition, the average director orientation **n** of the droplets exhibits a random distribution of orientation within the cell.

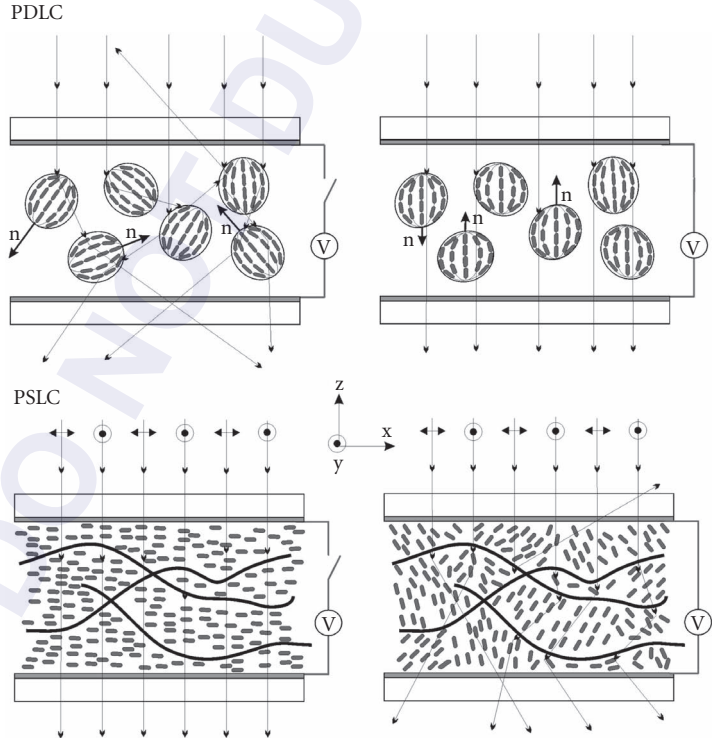

FIGURE 34 Schematic view and working principles of polymer/LC composites.

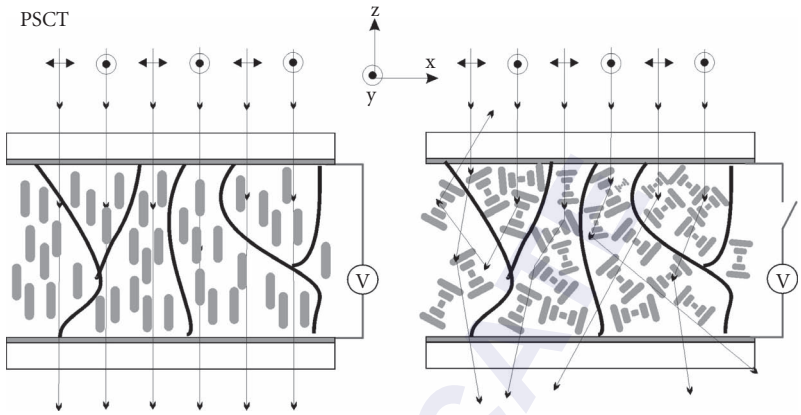

FIGURE 35 Schematic view of working principles of polymer-stabilized cholesteric LC light valve.

The incident unpolarized light is scattered if it goes through such a sample. When a sufficiently strong electric field (typically above 1 $V_{rms}/\mu m$) is applied to the cell, all the LC molecules align parallel to the electric field. If the light is also propagating in the direction parallel to the field, then the beam of light is affected by ordinary refractive index of LC which is matched with refractive index of polymer, thus cell appears transparent. When the electric field is OFF, again the LC molecules go back to the previous random positions. A polymer mixed with a chiral liquid crystal is a special case of PSLC called as polymer stabilized cholesteric texture (PSCT). The ratio between polymer and liquid crystal remains similar to the one necessary for PSLC. When the voltage is not applied to the PSCT cell liquid crystals tends to have helical structure while the polymer network tends to keep LC director parallel to it (normal-mode PSCT). Therefore, the material has a poly-domain structure, as Fig. 35 shows. In this state the incident beam is scattered. When a sufficiently high electric field is applied across the cell, the liquid crystal is switched to the homeotropic alignment and, as a result, the cell becomes transparent.

8.9 SUMMARY

Liquid crystal was discovered more than 100 years ago and is finding widespread applications. This class of organic material exhibits some unique properties, such as good chemical and thermal stabilities, low operation voltage and low power consumption, and excellent compatibility with semiconductor fabrication processing. Therefore, it has dominated direct-view and projection display markets. The forecasted annual TFT LCD market is going to exceed $100 billion by year 2011. However, there are still some technical challenges need to be overcome, for example, (1) faster response time for reducing motion picture blurs, (2) higher optical efficiency for reducing power consumption and lengthening battery life, (3) smaller color shift when viewed at oblique angles, (4) wider viewing angle with higher contrast ratio (ideally its viewing characteristics should be as good as an emissive display), and (5) lower manufacturing cost, especially for large screen TVs. In addition to displays, LC materials also share an important part of emerging photonics applications, such as spatial light modulators for laser beam steering and adaptive optics, adaptive-focus lens, variable optical attenuator for fiber-optic telecommunications, and LC-infiltrated photonic crystal fibers, just to name a few. Often neglected, lyotropic liquid crystals are important materials in biochemistry of the cell membranes.

OPTICAL FIBER COMMUNICATION TECHNOLOGY AND SYSTEM OVERVIEW

Ira Jacobs

The Bradley Department of Electrical and Computer Engineering
Virginia Polytechnic Institute and State University
Blacksburg, Virginia

9.1 INTRODUCTION

Basic elements of an optical fiber communication system include the transmitter [laser or light-emitting diode (LED)], fiber (multimode, single-mode, or dispersion-shifted), and the receiver [positive-intrinsic-negative (PIN) diode, avalanche photodiode (APD) detectors, coherent detectors, optical preamplifiers, receiver electronics]. Receiver sensitivities of digital systems are compared on the basis of the number of photons per bit required to achieve a given bit error probability, and eye degradation and error floor phenomena are described. Laser relative intensity noise and nonlinearities are shown to limit the performance of analog systems. Networking applications of optical amplifiers and wavelength-division multiplexing are considered, and future directions are discussed.

Although the light-guiding property of optical fibers has been known and used for many years, it is only relatively recently that optical fiber communications has become both a possibility and a reality.[1] Following the first prediction in 1966[2] that fibers might have sufficiently low attenuation for telecommunications, the first low-loss fiber (20 dB/km) was achieved in 1970.[3] The first semiconductor laser diode to radiate continuously at room temperature was also achieved in 1970.[4] The 1970s were a period of intense technology and system development, with the first systems coming into service at the end of the decade. The 1980s saw both the growth of applications (service on the first transatlantic cable in 1988) and continued advances in technology. This evolution continued in the 1990s with the advent of optical amplifiers and with the applications emphasis turning from point-to-point links to optical networks. The beginning of the 21st century has seen extensive fiber-to-the-home deployment as well as continued technology advances.

This chapter provides an overview of the basic technology, systems, and applications of optical fiber communication. It is an update and compression of material presented at a 1994 North Atlantic Treaty Organization (NATO) Summer School.[5] Although there have been significant advances in technology and applications in subsequent years, the basics have remained essentially the same.

9.2 BASIC TECHNOLOGY

This section considers the basic technology components of an optical fiber communications link, namely the fiber, the transmitter, and the receiver, and discusses the principal parameters that determine communications performance.

Fiber

An optical fiber is a thin filament of glass with a central core having a slightly higher index of refraction than the surrounding cladding. From a physical optics standpoint, light is guided by total internal reflection at the core-cladding boundary. More precisely, the fiber is a dielectric waveguide in which there are a discrete number of propagating modes.[6] If the core diameter and the index difference are sufficiently small, only a single mode will propagate. The condition for single-mode propagation is that the normalized frequency V be less than 2.405, where

$$V = \frac{2\pi a}{\lambda}\sqrt{n_1^2 - n_2^2} \tag{1}$$

and a is the core radius, λ is the free space wavelength, and n_1 and n_2 are the indexes of refraction of the core and cladding, respectively. Multimode fibers typically have a fractional index difference (Δ) between core and cladding of between 1 and 1.5 percent and a core diameter of between 50 and 100 μm. Single-mode fibers typically have $\Delta \approx 0.3$ percent and a core diameter of between 8 and 10 μm.

The fiber numerical aperture (NA), which is the sine of the half-angle of the cone of acceptance, is given by

$$\text{NA} = \sqrt{n_1^2 - n_2^2} = n_1\sqrt{2\Delta} \tag{2}$$

Single-mode fibers typically have an NA of about 0.1, whereas the NA of multimode fibers is in the range of 0.2 to 0.3.

From a transmission system standpoint, the two most important fiber parameters are attenuation and bandwidth.

Attenuation There are three principal attenuation mechanisms in fiber: absorption, scattering, and radiative loss. Silicon dioxide has resonance absorption peaks in the ultraviolet (electronic transitions) and in the infrared beyond 1.6 μm (atomic vibrational transitions), but is highly transparent in the visible and near-infrared.

Radiative losses are generally kept small by using a sufficiently thick cladding (communication fibers have an outer diameter of 125 μm), a compressible coating to buffer the fiber from external forces, and a cable structure that prevents sharp bends.

In the absence of impurities and radiation losses, the fundamental attenuation mechanism is Rayleigh scattering from the irregular glass structure, which results in index of refraction fluctuations over distances that are small compared to the wavelength. This leads to a scattering loss

$$\alpha = \frac{B}{\lambda^4} \quad \text{with } B \approx 0.9\frac{dB}{\text{km}}\mu\text{m}^4 \tag{3}$$

for "best" fibers. Attenuation as a function of wavelength is shown in Fig. 1. The attenuation peak at $\lambda = 1.4$ μm is a resonance absorption due to small amounts of water in the fiber, although fibers are available in which this peak is absent. Initial systems operated at a wavelength around 0.85 μm owing to the availability of sources and detectors at this wavelength. Present systems (other than some short-distance data links) generally operate at wavelengths of 1.3 or 1.55 μm. The former, in addition to being low in attenuation (about 0.32 dB/km for best fibers), is the wavelength of minimum intramodal dispersion (see next section) for standard single-mode fiber. Operation at 1.55 μm allows even lower attenuation (minimum is about 0.16 dB/km) and the use of erbium-doped-fiber amplifiers (see Sec. 9.5), which operate at this wavelength.

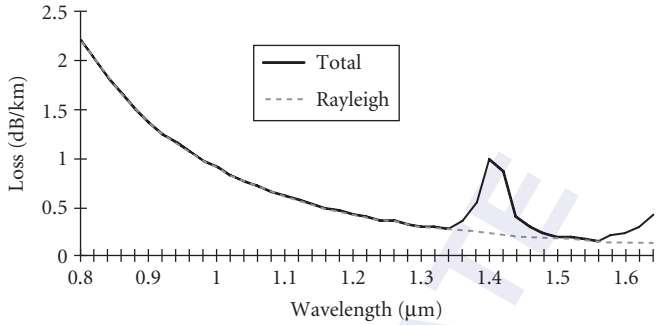

FIGURE 1 Fiber attenuation as a function of wavelength. Dashed curve shows Rayleigh scattering. Solid curve indicates total attenuation including resonance absorption at 1.38 μm from water and tail of infrared atomic resonances above 1.6 μm.

Dispersion Pulse spreading (dispersion) limits the maximum modulation bandwidth (or maximum pulse rate) that may be used with fibers. There are two principal forms of dispersion: intermodal dispersion and intramodal dispersion. In multimode fiber, the different modes experience different propagation delays resulting in pulse spreading. For graded-index fiber, the lowest dispersion per unit length is given approximately by[7]

$$\frac{\delta\tau}{L} = \frac{n_1\Delta^2}{10c} \quad \text{(intermodal)} \tag{4}$$

[Grading of the index of refraction of the core in a nearly parabolic function results in an approximate equalization of the propagation delays. For a step-index fiber, the dispersion per unit length is $\delta\tau/L = n_1\Delta/c$, which for $\Delta = 0.01$ is 1000 times larger than that given by Eq. (4).]

Bandwidth is inversely proportional to dispersion, with the proportionally constant dependent on pulse shape and how bandwidth is defined. If the dispersed pulse is approximated by a Gaussian pulse with $\delta\tau$ being the full width at the half-power point, then the –3-dB bandwidth B is given by

$$B = 0.44/\delta\tau \tag{5}$$

Multimode fibers are generally specified by their bandwidth in a 1-km length. Typical specifications are in the range from 200 MHz to 1 GHz. Fiber bandwidth is a sensitive function of the index profile and is wavelength dependent, and the scaling with length depends on whether there is mode mixing.[8] Also, for short-distance links, the bandwidth is dependent on the launch conditions. Multimode fibers are generally used only when the bit rates and distances are sufficiently small that accurate characterization of dispersion is not of concern, although this may be changing with the advent of graded-index plastic optical fiber for high-bit-rate short-distance data links.

Although there is no intermodal dispersion in single-mode fibers,* there is still dispersion within the single mode (intramodal dispersion) resulting from the finite spectral width of the source and the dependence of group velocity on wavelength. The intramodal dispersion per unit length is given by

$$\begin{aligned} \delta\tau/L &= D\,\delta\lambda \qquad \text{for } D \neq 0 \\ &= 0.2S_o(\delta\lambda)^2 \qquad \text{for } D = 0 \end{aligned} \tag{6}$$

*A single-mode fiber actually has two degenerate modes corresponding to the two principal polarizations. Any asymmetry in the transmission path removes this degeneracy and results in polarization dispersion. This is typically very small (in the range of 0.1 to 1 ps/km$^{1/2}$), but is of concern in long-distance systems using linear repeaters.[9]

where D is the dispersion coefficient of the fiber, $\delta\lambda$ is the spectral width of the source, and S_o is the dispersion slope

$$S_o = \frac{dD}{d\lambda} \text{ at } \lambda = \lambda_0 \quad \text{where} \quad D(\lambda_0) = 0 \tag{7}$$

If both intermodal and intramodal dispersion are present, the square of the total dispersion is the sum of the squares of the intermodal and intramodal dispersions. For typical digital systems, the total dispersion should be less than half the interpulse period *T*. From Eq. (5) this corresponds to an effective fiber bandwidth that is at least 0.88/*T*.

There are two sources of intramodal dispersion: material dispersion, which is a consequence of the index of refraction being a function of wavelength, and waveguide dispersion, which is a consequence of the propagation constant of the fiber waveguide being a function of wavelength.

For a material with index of refraction $n(\lambda)$, the material dispersion coefficient is given by

$$D_{\text{mat}} = -\frac{\lambda}{c}\frac{d^2n}{d\lambda^2} \tag{8}$$

For silica-based glasses, D_{mat} has the general characteristics shown in Fig. 2. It is about –100 ps/km · nm at a wavelength of 820 nm, goes through zero at a wavelength near 1300 nm, and is about 20 ps/km · nm at 1550 nm.

For step-index single-mode fibers, waveguide dispersion is given approximately by[10]

$$D_{\text{wg}} \approx -\frac{0.025\lambda}{a^2 c n_2} \tag{9}$$

For conventional single-mode fiber, waveguide dispersion is small (about –5 ps/km · nm at 1300 nm). The resultant $D(\lambda)$ is then slightly shifted (relative to the material dispersion curve) to longer wavelengths, but the zero-dispersion wavelength (λ_0) remains in the vicinity of 1300 nm. However, if the waveguide dispersion is made larger negative by decreasing *a* or equivalently by tapering the index of refraction in the core the zero-dispersion wavelength may be shifted to the vicinity of 1550 nm

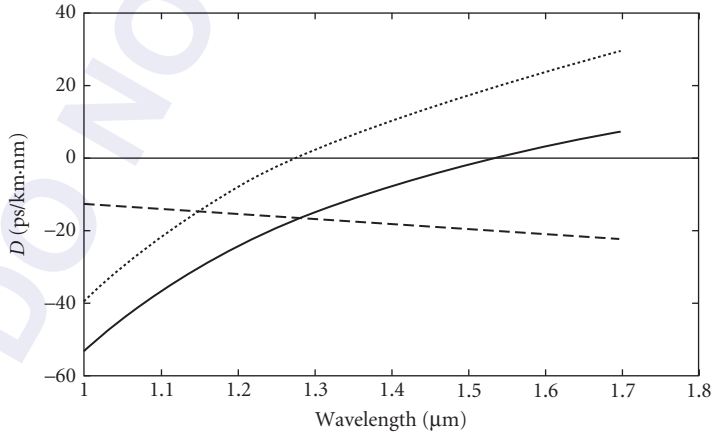

FIGURE 2 Intramodal dispersion coefficient as a function of wavelength. Dotted curve shows D_{mat}; dashed curve shows D_{wg} to achieve *D* (solid curve) with zero dispersion at 1.55 μm.

(see Fig. 2). Such fibers are called *dispersion-shifted fibers* and are advantageous because of the lower fiber attenuation at this wavelength and the advent of erbium-doped-fiber amplifiers (see Sec. 9.5). Note that dispersion-shifted fibers have a smaller slope at the dispersion minimum ($S_0 \approx 0.06$ ps/km · nm^2 compared to $S_0 \approx 0.09$ ps/km · nm^2 for conventional single-mode fiber).

With more complicated index of refraction profiles, it is possible, at least theoretically, to control the shape of the waveguide dispersion such that the total dispersion is small in both the 1300- and 1550-nm bands, leading to dispersion-flattened fibers.[11]

Transmitting Sources

Semiconductor light-emitting diodes (LEDs) or lasers are the primary light sources used in fiber-optic transmission systems. The principal parameters of concern are the power coupled into the fiber, the modulation bandwidth, and (because of intramodal dispersion) the spectral width.

Light-Emitting Diodes (LEDs) LEDs are forward-biased positive-negative (PN) junctions in which carrier recombination results in spontaneous emission at a wavelength corresponding to the energy gap. Although several milliwatts may be radiated from high-radiance LEDs, the radiation is over a wide angular range, and consequently there is a large coupling loss from an LED to a fiber. Coupling efficiency (η = ratio of power coupled to power radiated) from an LED to a fiber is given approximately by[12]

$$\eta \approx (\text{NA})^2 \qquad \text{for } r_s < a$$
$$\eta \approx (a/r_s)^2(\text{NA})^2 \qquad \text{for } r_s > a \tag{10}$$

where r_s is the radius of the LED. Use of large-diameter, high-NA multimode fiber improves the coupling from LEDs to fiber. Typical coupling losses are 10 to 20 dB for multimode fibers and more than 30 dB for single-mode fibers.

In addition to radiating over a large angle, LED radiation has a large spectral width (about 50 nm at $\lambda = 850$ nm and 100 nm at $\lambda = 1300$ nm) determined by thermal effects. Systems employing LEDs at 850 mm tend to be intramodal-dispersion-limited, whereas those at 1300 nm are intermodal-dispersion-limited.

Owing to the relatively long time constant for spontaneous emission (typically several nanoseconds), the modulation bandwidths of LEDs are generally limited to several hundred MHz. Thus, LEDs are generally limited to relatively short-distance, low-bit-rate applications.

Lasers In a laser, population inversion between the ground and excited states results in stimulated emission. In edge-emitting semiconductor lasers, this radiation is guided within the active region of the laser and is reflected at the end faces.* The combination of feedback and gain results in oscillation when the gain exceeds a threshold value. The spectral range over which the gain exceeds threshold (typically a few nanometers) is much narrower than the spectral width of an LED. Discrete wavelengths within this range, for which the optical length of the laser is an integer number of half-wavelengths, are radiated. Such a laser is termed a *multilongitudinal mode Fabry-Perot laser.* Radiation is confined to a much narrower angular range than for an LED, and consequently may be efficiently coupled into a small-NA fiber. Coupled power is typically about 1 mW.

The modulation bandwidth of lasers is determined by a resonance frequency caused by the interaction of the photon and electron concentrations.[14] Although this resonance frequency was less than 1 GHz in early semiconductor lasers, improvements in materials have led to semiconductor lasers with resonance frequencies (and consequently modulation bandwidths) in excess of 10 GHz. This not only is important for very high-speed digital systems, but now also allows semiconductor lasers to be directly modulated with microwave signals. Such applications are considered in Sec. 9.7.

*In vertical cavity surface-emitting lasers (VCSELs), reflection is from internal "mirrors" grown within the semiconductor structure.[13]

Although multilongitudinal-mode Fabry-Perot lasers have a narrower spectral spread than LEDs, this spread still limits the high-speed and long-distance capability of such lasers. For such applications, single-longitudinal-mode (SLM) lasers are used. SLM lasers may be achieved by having a sufficiently short laser (less than 50 μm), by using coupled cavities (either external mirrors or cleaved coupled cavities[15]), or by incorporating a diffraction grating within the laser structure to select a specific wavelength. The latter has proven to be most practical for commercial application, and includes the distributed feedback (DFB) laser, in which the grating is within the laser active region, and the distributed Bragg reflector (DBR) laser, where the grating is external to the active region.[16]

There is still a finite line width for SLM lasers. For lasers without special stabilization, the line width is on the order of 0.1 nm. Expressed in terms of frequency, this corresponds to a frequency width of 12.5 GHz at a wavelength of 1550 nm. (Wavelength and frequency spread are related by $\delta f/f = -\delta\lambda/\lambda$, from which it follows that $\delta f = -c\delta\lambda/\lambda^2$.) Thus, unlike electrical communication systems, optical systems generally use sources with spectral widths that are large compared to the modulation bandwidth.

The finite line width (phase noise) of a laser is due to fluctuations of the phase of the optical field resulting from spontaneous emission. In addition to the phase noise contributed directly by the spontaneous emission, the interaction between the photon and electron concentrations in semiconductor lasers leads to a conversion of amplitude fluctuations to phase fluctuations, which increases the line width.[17] If the intensity of a laser is changed, this same phenomenon gives rise to a change in the frequency of the laser (*chirp*). Uncontrolled, this causes a substantial increase in line width when the laser is modulated, which may cause difficulties in some system applications, possibly necessitating external modulation. However, the phenomenon can also be used to advantage. For appropriate lasers under small signal modulation, a change in frequency proportional to the input signal can be used to frequency-modulate and/or to tune the laser. Tunable lasers are of particular importance in networking applications employing wavelength-division multiplexing (WDM).[18]

Photodetectors

Fiber-optic systems generally use PIN or APD photodetectors. In a reverse-biased PIN diode, absorption of light in the intrinsic region generates carriers that are swept out by the reverse-bias field. This results in a photocurrent (I_p) that is proportional to the incident optical power (P_R), where the proportionality constant is the responsivity ($\Re$) of the photodetector; that is, $\Re = I_P/P_R$. Since the number of photons per second incident on the detector is power divided by the photon energy, and the number of electrons per second flowing in the external circuit is the photocurrent divided by the charge of the electron, it follows that the quantum efficiency (η = electrons/photons) is related to the responsivity by

$$\eta = \frac{hc}{q\lambda}\frac{I_p}{P_R} = \frac{1.24(\mu\text{m}\cdot\text{V})}{\lambda}\Re \tag{11}$$

For wavelengths shorter than 900 nm, silicon is an excellent photodetector, with quantum efficiencies of about 90 percent. For longer wavelengths, InGaAs is generally used, with quantum efficiencies typically around 70 percent. Very high bandwidths may be achieved with PIN photodetectors. Consequently, the photodetector does not generally limit the overall system bandwidth.

In an avalanche photodetector (APD), a larger reverse voltage accelerates carriers, causing additional carriers by impact ionization resulting in a current $I_{\text{APD}} = MI_p$, where M is the current gain of the APD. As we will note in Sec. 9.3, this can result in an improvement in receiver sensitivity.

9.3 RECEIVER SENSITIVITY

The receiver in a direct-detection fiber-optic communication system consists of a photodetector followed by electrical amplification and signal-processing circuits intended to recover the communications signal. Receiver sensitivity is defined as the average received optical power needed to

achieve a given communication rate and performance. For analog communications, the communication rate is measured by the bandwidth of the electrical signal to be transmitted (B), and performance is given by the signal-to-noise ratio (SNR) of the recovered signal. For digital systems, the communication rate is measured by the bit rate (R_b) and performance is measured by the bit error probability (P_e).

For a constant optical power transmitted, there are fluctuations of the received photocurrent about the average given by Eq. (11). The principal sources of these fluctuations are signal shot noise (quantum noise resulting from random arrival times of photons at the detector), receiver thermal noise, APD excess noise, and relative intensity noise (RIN) associated with fluctuations in intensity of the source and/or multiple reflections in the fiber medium.

Digital On-Off-Keying Receiver

It is instructive to define a normalized sensitivity as the average number of photons per bit ($\bar{N}_p$) to achieve a given error probability, which we take here to be $P_e = 10^{-9}$. Given $\bar{N}_p$, the received power when a 1 is transmitted is obtained from

$$P_R = 2\bar{N}_p R_b \frac{hc}{\lambda} \tag{12}$$

where the factor of 2 in Eq. (12) is because P_R is the peak power, and $\bar{N}_p$ is the average number of photons per bit.

Ideal Receiver In an ideal receiver individual photons may be counted, and the only source of noise is the fluctuation of the number of photons counted when a 1 is transmitted. This is a Poisson random variable with mean $2\bar{N}_p$. No photons are received when a 0 is transmitted. Consequently, an error is made only when a 1 is transmitted and no photons are received. This leads to the following expression for the error probability

$$P_e = \frac{1}{2}\exp(-2\bar{N}_p) \tag{13}$$

from which it follows that $\bar{N}_p = 10$ for $P_e = 10^{-9}$. This is termed the *quantum limit.*

PIN Receiver In a PIN receiver, the photodetector output is amplified, filtered, and sampled, and the sample is compared with a threshold to decide whether a 1 or 0 was transmitted. Let I be the sampled current at the input to the decision circuit scaled back to the corresponding value at the output of the photodetector. (It is convenient to refer all signal and noise levels to their equivalent values at the output of the photodetector.) I is then a random variable with means and variances given by

$$\mu_1 = I_p \qquad \mu_0 = 0 \tag{14a}$$

$$\sigma_1^2 = 2qI_pB + \frac{4kTB}{R_e} \qquad \sigma_0^2 = \frac{4kTB}{R_e} \tag{14b}$$

where the subscripts 1 and 0 refer to the bit transmitted, kT is the thermal noise energy, and R_e is the effective input noise resistance of the amplifier. Note that the noise values in the 1 and 0 states are different owing to the shot noise in the 1 state.

Calculation of error probability requires knowledge of the distribution of I under the two hypotheses. Under the assumption that these distributions may be approximated by gaussian distributions

with means and variances given by Eq. (14), the error probability may be shown to be given by (Chap. 4 in Ref. 19)

$$P_e = K\left(\frac{\mu_1 - \mu_0}{\sigma_1 + \sigma_0}\right) \tag{15}$$

where

$$K(Q) = \frac{1}{\sqrt{2\pi}} \int_Q^\infty dx \exp(-x^2/2) = \frac{1}{2}\operatorname{erfc}(Q/\sqrt{2}) \tag{16}$$

It can be shown from Eqs. (11), (12), (14), and (15) that

$$\bar{N}_p = \frac{B}{\eta R_b} Q^2 \left[1 + \frac{1}{Q}\sqrt{\frac{8\pi k T C_e}{q^2}}\right] \tag{17}$$

where

$$C_e = \frac{1}{2\pi R_e B} \tag{18}$$

is the effective noise capacitance of the receiver, and from Eq. (16), $Q = 6$ for $P_e = 10^{-9}$. The minimum bandwidth of the receiver is half the bit rate, but in practice B/R_b is generally about 0.7.

The gaussian approximation is expected to be good when the thermal noise is large compared to the shot noise. It is interesting, however, to note that Eq. (17) gives $\bar{N}_p = 18$, when $C_e = 0$, $B/R_b = 0.5$, $\eta = 1$, and $Q = 6$. Thus, even in the shot noise limit, the gaussian approximation gives a surprisingly close result to the value calculated from the correct Poisson distribution. It must be pointed out, however, that the location of the threshold calculated by the gaussian approximation is far from correct in this case. In general, the gaussian approximation is much better in estimating receiver sensitivity than in establishing where to set receiver thresholds.

Low-input-impedance amplifiers are generally required to achieve the high bandwidths required for high-bit-rate systems. However, a low input impedance results in high thermal noise and poor sensitivity. High-input-impedance amplifiers may be used, but this narrows the bandwidth, which must be compensated for by equalization following the first-stage amplifier. Although this may result in a highly sensitive receiver, the receiver will have a poor dynamic range owing to the high gains required in the equalizer.[20] Receivers for digital systems are generally implemented with transimpedance amplifiers having a large feedback resistance. This reduces the effective input noise capacitance to below the capacitance of the photodiode, and practical receivers can be built with $C_e \approx 0.1\ pF$. Using this value of capacitance and $B/R_b = 0.7$, $\eta = 0.7$, and $Q = 6$, Eq. (17) gives $\bar{N}_p \approx 2600$. Note that this is about 34 dB greater than the value given by the quantum limit.

APD Receiver In an APD receiver, there is additional shot noise owing to the excess noise factor F of the avalanche gain process. However, thermal noise is reduced because of the current multiplication gain M before thermal noise is introduced. This results in a receiver sensitivity given approximately by*

$$\bar{N}_p = \frac{B}{\eta R_b} Q^2 \left[F + \frac{1}{Q}\sqrt{\frac{8\pi k T C_e}{q^2 M^2}}\right] \tag{19}$$

*The gaussian approximation is not as good for an APD as for a PIN receiver owing to the nongaussian nature of the excess APD noise.

The excess noise factor is an increasing function of M, which results in an optimum M to minimize $\bar{N}_p$.[20] Good APD receivers at 1300 and 1550 nm typically have sensitivities of the order of 1000 photons per bit. Owing to the lower excess noise of silicon APDs, sensitivity of about 500 photons per bit can be achieved at 850 nm.

Impairments There are several sources of impairment that may degrade the sensitivity of receivers from the values given by Eqs. (17) and (19). These may be grouped into two general classes: eye degradations and signal-dependent noise.

An eye diagram is the superposition of all possible received sequences. At the sampling point, there is a spread of the values of a received 1 and a received 0. The difference between the minimum value of a received 1 and the maximum value of the received 0 is known as the *eye opening*. This is given by $(1-\varepsilon)I_p$ where ε is the eye degradation. The two major sources of eye degradation are intersymbol interference and finite laser extinction ratio. Intersymbol interference results from dispersion, deviations from ideal shaping of the receiver filter, and low-frequency cutoff effects that result in direct current (DC) offsets.

Signal-dependent noises are phenomena that give a variance of the received photocurrent that is proportional to I_p^2 and consequently lead to a maximum signal-to-noise ratio at the output of the receiver. Principal sources of signal-dependent noise are laser relative intensity noise (RIN), reflection-induced noise, mode partition noise, and modal noise. RIN is a consequence of inherent fluctuations in laser intensity resulting from spontaneous emission. This is generally sufficiently small that it is not of concern in digital systems, but is an important limitation in analog systems requiring high signal-to-noise ratios (see Sec. 9.7). Reflection-induced noise is the conversion of laser phase noise to intensity noise by multiple reflections from discontinuities (such as at imperfect connectors.) This may result in a substantial RIN enhancement that can seriously affect digital as well as analog systems.[21] Mode partition noise occurs when Fabry-Perot lasers are used with dispersive fiber. Fiber dispersion results in changing phase relation between the various laser modes, which results in intensity fluctuations. The effect of mode partition noise is more serious than that of dispersion alone.[22] Modal noise is a similar phenomenon that occurs in multimode fiber when relatively few modes are excited and these interfere.

Eye degradations are accounted for by replacing Eq. (14*a*) by

$$\mu_1 - \mu_0 = (1-\varepsilon)I_p \tag{20a}$$

and signal-dependent noise by replacing Eq. (14*b*) by

$$\sigma_1^2 = 2qI_pB + \frac{4kTB}{R_e} + \alpha^2 I_p^2 B \qquad \sigma_0^2 = \frac{4kTB}{R_e} + \alpha^2 I_p^2 B \tag{20b}$$

where α^2 is the relative spectral density of the signal-dependent noise. (It is assumed that the signal-dependent noise has a large bandwidth compared to the signal bandwidth B.) With these modifications, the sensitivity of an APD receiver becomes

$$\bar{N}_p = \frac{\dfrac{B}{\eta R_b}\left(\dfrac{Q}{1-\varepsilon}\right)^2\left[F + \left(\dfrac{1-\varepsilon}{Q}\right)\sqrt{\dfrac{8\pi kTC_e}{q^2M^2}}\right]}{1 - \alpha^2 B\left(\dfrac{Q}{1-\varepsilon}\right)^2} \tag{21}$$

The sensitivity of a PIN receiver is obtained by setting $F = 1$ and $M = 1$ in Eq. (21). It follows from Eq. (21) that there is a minimum error probability (*error floor*) given by

$$P_{e,\min} = K(Q_{\max}) \text{ where } Q_{\max} = \frac{1-\varepsilon}{\alpha\sqrt{B}} \tag{22}$$

The existence of eye degradations and signal-dependent noise causes an increase in the receiver power (called *power penalty*) required to achieve a given error probability.

9.4 BIT RATE AND DISTANCE LIMITS

Bit rate and distance limitations of digital links are determined by loss and dispersion limitations. The following example is used to illustrate the calculation of the maximum distance for a given bit rate. Consider a 2.5 Gbit/s system at a wavelength of 1550 nm. Assume an average transmitter power of 0 dBm coupled into the fiber. Receiver sensitivity is taken to be 3000 photons per bit, which from Eq. (12) corresponds to an average receiver power of –30.2 dBm. Allowing a total of 8 dB for margin and for connector and cabling losses at the two ends gives a loss allowance of 22.2 dB. If the cabled fiber loss, including splices, is 0.25 dB/km, this leads to a loss-limited transmission distance of 89 km.

Assuming that the fiber dispersion is $D = 15\ \text{ps/km}\cdot\text{nm}$ and source spectral width is 0.1 nm, this gives a dispersion per unit length of 1.5 ps/km. Taking the maximum allowed dispersion to be half the interpulse period, this gives a maximum dispersion of 200 ps, which then yields a maximum dispersion-limited distance of 133 km. Thus, the loss-limited distance is controlling.

Consider what happens if the bit rate is increased to 10 Gbit/s. For the same number of photons per bit at the receiver, the receiver power must be 6 dB greater than that in the preceding example. This reduces the loss allowance by 6 dB, corresponding to a reduction of 24 km in the loss-limited distance. The loss-limited distance is now 65 km (assuming all other parameters are unchanged). However, dispersion-limited distance scales inversely with bit rate, and is now 22 km. The system is now dispersion-limited. Dispersion-shifted fiber would be required to be able to operate at the loss limit.

Increasing Bit Rate

There are two general approaches for increasing the bit rate transmitted on a fiber: time-division multiplexing (TDM), in which the serial transmission rate is increased, and wavelength-division multiplexing (WDM), in which separate wavelengths are used to transmit independent serial bit streams in parallel. TDM has the advantage of minimizing the quantity of active devices but requires higher-speed electronics as the bit rate is increased. Also, as indicated by the preceding example, dispersion limitations will be more severe.

WDM allows use of existing lower-speed electronics, but requires multiple lasers and detectors as well as optical filters for combining and separating the wavelengths. Technology advances, including tunable lasers, transmitter and detector arrays, high-resolution optical filters, and optical amplifiers (Sec. 9.5) have made WDM more attractive, particularly for networking applications (Sec. 9.6).

Longer Repeater Spacing

In principal, there are three approaches for achieving longer repeater spacing than that calculated in the preceding text: lower fiber loss, higher transmitter powers, and improved receiver sensitivity (smaller ($\overline{N}_p$). Silica-based fiber is already essentially at the theoretical Rayleigh scattering loss limit. There has been research on new fiber materials that would allow operation at wavelengths longer than 1.6 μm, with consequent lower theoretical loss values.[23] There are many reasons, however, why achieving such losses will be difficult, and progress in this area has been slow.

Higher transmitter powers are possible, but there are both nonlinearity and reliability issues that limit transmitter power. Since present receivers are more than 30 dB above the quantum limit, improved receiver sensitivity would appear to offer the greatest possibility. To improve the receiver sensitivity, it is necessary to increase the photocurrent at the output of the detector without introducing significant excess loss. There are two main approaches for doing so: optical amplification and optical mixing. Optical preamplifiers result in a theoretical sensitivity of 38 photons per bit[24] (6 dB above the quantum limit), and experimental systems have been constructed with sensitivities of about 100 photons per bit.[25] This will be discussed further in Sec. 9.5. Optical mixing (coherent receivers) will be discussed briefly in the following text.

Coherent Systems A photodetector provides an output current proportional to the magnitude square of the electric field that is incident on the detector. If a strong optical signal (*local oscillator*) coherent in phase with the incoming optical signal is added prior to the photodetector, then the photocurrent will contain a component at the difference frequency between the incoming and local oscillator signals. The magnitude of this photocurrent, relative to the direct detection case, is increased by the ratio of the local oscillator to the incoming field strengths. Such a coherent receiver offers considerable improvement in receiver sensitivity. With on-off keying, a heterodyne receiver (signal and local oscillator frequencies different) has a theoretical sensitivity of 36 photons per bit, and a homodyne receiver (signal and local oscillator frequencies the same) has a sensitivity of 18 photons per bit. Phase-shift keying (possible with coherent systems) provides a further 3-dB improvement. Coherent systems, however, require very stable signal and local oscillator sources (spectral linewidths need to be small compared to the modulation bandwidth) and matching of the polarization of the signal and local oscillator fields.[26] Differentially coherent systems (e.g., DPSK) in which the prior bit is used as a phase reference are simpler to implement and are beginning to find application.[27]

An advantage of coherent systems, more so than improved receiver sensitivity, is that because the output of the photodetector is linear in the signal field, filtering for WDM demultiplexing may be done at the difference frequency (typically in the microwave range).* This allows considerably greater selectivity than is obtainable with optical filtering techniques. The advent of optical amplifiers has slowed the interest in coherent systems, but there has been renewed interest in recent years.[28]

9.5 OPTICAL AMPLIFIERS

There are two types of optical amplifiers: laser amplifiers based on stimulated emission and parametric amplifiers based on nonlinear effects (Chap. 10 in Ref. 32). The former are currently of most interest in fiber-optic communications. A laser without reflecting end faces is an amplifier, but it is more difficult to obtain sufficient gain for amplification than it is (with feedback) to obtain oscillation. Thus, laser oscillators were available much earlier than laser amplifiers.

Laser amplifiers are now available with gains in excess of 30 dB over a spectral range of more than 30 mm. Output saturation powers in excess of 10 dBm are achievable. The amplified spontaneous emission (ASE) noise power at the output of the amplifier, in each of two orthogonal polarizations, is given by

$$P_{\text{ASE}} = n_{\text{sp}} \frac{hc}{\lambda} B_o (G - 1) \tag{23}$$

where G is the amplifier gain, B_o is the bandwidth, and the spontaneous emission factor n_{sp} is equal to 1 for ideal amplifiers with complete population inversion.

Comparison of Semiconductor and Fiber Amplifiers

There are two principal types of laser amplifiers: semiconductor laser amplifiers (SLAs) and doped-fiber amplifiers. The erbium-doped-fiber amplifier (EDFA), which operates at a wavelength of 1.55 μm, is of most current interest.

The advantages of the SLA, similar to laser oscillators, are that it is pumped by a DC current, it may be designed for any wavelength of interest, and it can be integrated with electrooptic semiconductor components.

*The difference frequency must be large compared to the modulation bandwidth. As modulation bandwidths have increased beyond 10 GHz this may neccessitate difference frequencies greater than 100 GHz which may be difficult to implement.

The advantages of the EDFA are that there is no coupling loss to the transmission fiber, it is polarization-insensitive, it has lower noise than SLAs, it can be operated at saturation with no intermodulation owing to the long time constant of the gain dynamics, and it can be integrated with fiber devices. However, it does require optical pumping, with the principal pump wavelengths being either 980 or 1480 nm.

Communications Application of Optical Amplifiers

There are four principal applications of optical amplifiers in communication systems.[29,30]

1. Transmitter power amplifiers
2. Compensation for splitting loss in distribution networks
3. Receiver preamplifiers
4. Linear repeaters in long-distance systems

The last application is of particular importance for long-distance networks (particularly undersea systems), where a bit-rate-independent linear repeater allows subsequent upgrading of system capacity (either TDM or WDM) with changes only at the system terminals. Although amplifier noise accumulates in such long-distance linear systems, transoceanic lengths are achievable with amplifier spacings of about 60 km corresponding to about 15-dB fiber attenuation between amplifiers.

However, in addition to the accumulation of ASE, there are other factors limiting the distance of linearly amplified systems, namely dispersion and the interaction of dispersion and nonlinearity.[31] There are two alternatives for achieving very long-distance, very high-bit-rate systems with linear repeaters: *solitons,* which are pulses that maintain their shape in a dispersive medium,[32] and dispersion compensation.[33]

9.6 FIBER-OPTIC NETWORKS

Networks are communication systems used to interconnect a number of terminals within a defined geographic area—for example, local area networks (LANs), metropolitan area networks (MANs), and wide area networks (WANs). In addition to the transmission function discussed throughout the earlier portions of this chapter, networks also deal with the routing and switching aspects of communications.

Passive optical networks utilize couplers to distribute signals to users. In an $N \times N$ ideal star coupler, the signal on each input port is uniformly distributed among all output ports. If an average power P_T is transmitted at a transmitting port, the power received at a receiving port (neglecting transmission losses) is

$$P_R = \frac{P_T}{N}(1-\delta_N) \tag{24}$$

where δ_N is the excess loss of the coupler. If N is a power of 2, an $N \times N$ star may be implemented by $\log_2 N$ stages of 2×2 couplers. Thus, it may be conservatively assumed that

$$1-\delta_N = (1-\delta_2)^{\log_2 N} = N^{\log_2(1-\delta_2)} \tag{25}$$

The maximum bit rate per user is given by the average received power divided by the product of the photon energy and the required number of photons per bit (N_p). The throughput Y is the product of the number of users and the bit rate per user, and from Eqs. (24) and (25) is therefore given by

$$Y = \frac{P_T}{N_P}\frac{\lambda}{hc}N^{\log_2(1-\delta_2)} \tag{26}$$

Thus, the throughput (based on power considerations) is independent of N for ideal couplers ($\delta_2 = 0$) and decreases slowly with $N(N^{-0.17})$ for 10 log $(1-\delta_2) = 0.5$ dB. It follows from Eq. (26) that for a power of 1 mW at $\lambda = 1.55$ μm and with $N_p = 3000$, the maximum throughput is 2.6 Tbit/s.

This may be contrasted with a tapped bus, where it may be shown that optimum tap weight to maximize throughput is given by 1/N, leading to a throughput given by[34]

$$Y = \frac{P_T}{N_P}\frac{\lambda}{hc}\frac{1}{Ne^2}\exp(-2N\delta) \tag{27}$$

Thus, even for ideal ($\delta = 0$) couplers, the throughput decreases inversely with the number of users. If there is excess coupler loss, the throughput decreases exponentially with the number of users and is considerably less than that given by Eq. (26). Consequently, for a power-limited transmission medium, the star architecture is much more suitable than the tapped bus. The same conclusion does not apply to metallic media, where bandwidth rather than power limits the maximum throughput.

Although the preceding text indicates the large throughput that may be achieved in principle with a passive star network, it doesn't indicate how this can be realized. Most interest is in WDM networks.[35] The simplest protocols are those for which fixed-wavelength receivers and tunable transmitters are used. However, the technology is simpler when fixed-wavelength transmitters and tunable receivers are used, since a tunable receiver may be implemented with a tunable optical filter preceding a wideband photodetector. Fixed-wavelength transmitters and receivers involving multiple passes through the network are also possible, but this requires utilization of terminals as relay points. Protocol, technology, and application considerations for gigabit networks (networks having access at gigabit rates and throughputs at terabit rates) is an extensive area of research.[36]

9.7 ANALOG TRANSMISSION ON FIBER

Most interest in fiber-optic communications is centered around digital transmission, since fiber is generally a power-limited rather than a bandwidth-limited medium. There are applications, however, where it is desirable to transmit analog signals directly on fiber without converting them to digital signals. Examples are cable television (CATV) distribution and microwave links such as entrance links to antennas and interconnection of base stations in mobile radio systems.

Carrier-to-Noise Ratio (CNR)

Optical intensity modulation is generally the only practical modulation technique for incoherent-detection fiber-optic systems. Let $f(t)$ be the carrier signal that intensity modulates the optical source. For convenience, assume that the average value of $f(t)$ is equal to 0, and that the magnitude of $f(t)$ is normalized to be less than or equal to 1. The received optical power may then be expressed as

$$P(t) = P_o[1 + mf(t)] \tag{28}$$

where m is the optical modulation index

$$m = \frac{P_{\max} - P_{\min}}{P_{\max} + P_{\min}} \tag{29}$$

The carrier-to-noise ratio is then given by

$$\text{CNR} = \frac{\frac{1}{2}m^2\Re^2P_o^2}{\text{RIN}\,\Re^2P_o^2B + 2q\Re P_oB + <i_{\text{th}}^2> B} \tag{30}$$

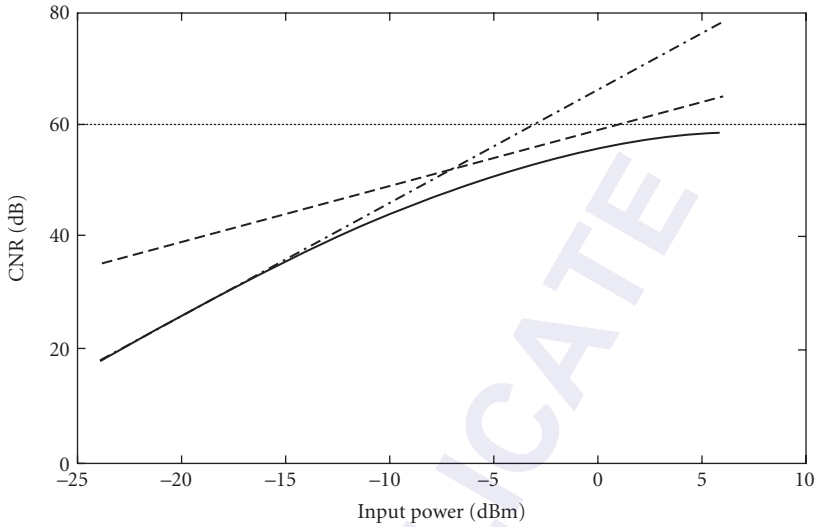

FIGURE 3 CNR as a function of input power. Straight lines indicate thermal noise (-·-·-), shot noise (–), and RIN (.....) limits.

where $\Re$ is the photodetector responsivity, RIN is the relative intensity noise spectral density (denoted by α^2 in Sec. 9.3), and $<i_{th}^2>$ is the thermal noise spectral density (expressed as $4kT/R_e$ in Sec. 9.3). CNR is plotted in Fig. 3 as a function of received optical power for a bandwidth of $B = 4$ MHz (single video channel), optical modulation index $m = 0.05$, $\Re = 0.8$ A/W, RIN $= -155$ dB/Hz, and $\sqrt{<i_{th}^2>} = 7$ pA/$\sqrt{\text{Hz}}$. At low received powers (typical of digital systems) the CNR is limited by thermal noise. However, to obtain the higher CNR generally needed by analog systems, shot noise and then ultimately laser RIN become limiting.

Analog Video Transmission on Fiber[37]

It is helpful to distinguish between single-channel and multiple-channel applications. For the single-channel case, the video signal may directly modulate the laser intensity [amplitude-modulated (AM) system], or the video signal may be used to frequency-modulate an electrical subcarrier, with this subcarrier then intensity-modulating the optical source [frequency-modulated (FM) system]. Equation (30) gives the CNR of the recovered subcarrier. Subsequent demodulation of the FM signal gives an additional increase in signal-to-noise ratio. In addition to this FM improvement factor, larger optical modulation indexes may be used than in AM systems. Thus FM systems allow higher signal-to-noise ratios and longer transmission spans than AM systems.

Two approaches have been used to transmit multichannel video signals on fiber. In the first (AM systems), the video signals undergo electrical frequency-division multiplexing (FDM), and this combined FDM signal intensity modulates the optical source. This is conceptually the simplest system, since existing CATV multiplexing formats may be used.

In FM systems, the individual video channels frequency-modulate separate microwave carriers (as in satellite systems). These carriers are linearly combined and the combined signal intensity modulates a laser. Although FM systems are more tolerant than AM systems to intermodulation distortion and noise, the added electronics costs have made such systems less attractive than AM systems for CATV application.

Multichannel AM systems are of interest not only for CATV application but also for mobile radio applications to connect signals from a microcellular base station to a central processing station.

Relative to CATV applications, the mobile radio application has the additional complication of being required to accommodate signals over a wide dynamic power range.

Nonlinear Distortion

In addition to CNR requirements, multichannel analog communication systems are subject to intermodulation distortion. If the input to the system consists of a number of tones at frequencies ω_i, then nonlinearities result in intermodulation products at frequencies given by all sums and differences of the input frequencies. Second-order intermodulation gives intermodulation products at frequencies $\omega_i \pm \omega_j$, whereas third-order intermodulation gives frequencies $\omega_i \pm \omega_j \pm \omega_k$. If the signal frequency band is such that the maximum frequency is less than twice the minimum frequency, then all second-order intermodulation products fall outside the signal band, and third-order intermodulation is the dominant nonlinearity. This condition is satisfied for the transport of microwave signals (e.g., mobile radio signals) on fiber, but is not satisfied for wideband CATV systems, where there are requirements on composite second-order (CSO) and composite triple-beat (CTB) distortion.

The principal causes of intermodulation in multichannel fiber-optic systems are laser threshold nonlinearity,[38] inherent laser gain nonlinearity, and the interaction of chirp and dispersion.

9.8 TECHNOLOGY AND APPLICATIONS DIRECTIONS

Fiber-optic communication application in the United States began with metropolitan and short-distance intercity trunking at a bit rate of 45 Mbit/s, corresponding to the DS-3 rate of the North American digital hierarchy. Technological advances, primarily higher-capacity transmission and longer repeater spacings, extended the application to long-distance intercity transmission, both terrestrial and undersea. Also, transmission formats are now based on the synchronous digital hierarchy (SDH), termed synchronous optical network (SONET) in the U.S. OC-192 system* operating at 10 Gbit/s are widely deployed, with OC-768 40 Gbit/s systems also available. All of the signal processing in these systems (multiplexing, switching, performance monitoring) is done electrically, with optics serving solely to provide point-to-point links.

For long-distance applications, 10 Gbit/s dense wavelength-division multiplexing (DWDM), with channel spacings of 50 GHz and with upward of 100 wavelength channels, has extended the bit rate capability of fiber to greater than 1 Tbit/s in commercial systems and more than 3 Tbit/s in laboratory trials.[39] For local access, there is extensive interest in fiber directly to the premises[40] as well as hybrid combinations of optical and electronic technologies and transmission media.[41,42]

The huge bandwidth capability of fiber optics (measured in tens of terahertz) is not likely to be utilized by time-division techniques alone, and DWDM technology and systems are receiving considerable emphasis, although work is also under way on optical time-division multiplexing (OTDM) and optical code-division multiplexing (OCDM).

Nonlinear phenomena, when uncontrolled, generally lead to system impairments. However, controlled nonlinearities are the basis of devices such as parametric amplifiers and switching and logic elements. Nonlinear optics will consequently continue to receive increased emphasis.

NONLINEAR EFFECTS IN OPTICAL FIBERS

John A. Buck

Georgia Institute of Technology
School of Electrical and Computer Engineering
Atlanta, Georgia

Fiber nonlinearities are important in optical communications, both as useful attributes and as characteristics to be avoided. They must be considered when designing long-range high-data-rate systems that involve high optical power levels and in which signals at multiple wavelengths are transmitted. The consequences of nonlinear transmission can include (1) the generation of additional signal bandwidth within a given channel, (2) modifications of the phase and shape of pulses, (3) the generation of light at other wavelengths at the expense of power in the original signal, and (4) crosstalk between signals at different wavelengths and polarizations. The first two, arising from self-phase modulation, can be used to advantage in the generation of *solitons*—pulses whose nonlinear phase modulation compensates for linear group dispersion in the fiber link[1] or in fiber gratings,[2] leading to pulses that propagate without changing shape or width (see Chap. 22). The third and fourth effects arise from stimulated Raman or Brillouin scattering or four-wave mixing. These can be used to advantage when it is desired to generate or amplify additional wavelengths, but they must usually be avoided in systems.

10.1 KEY ISSUES IN NONLINEAR OPTICS IN FIBERS

Optical fiber waveguides, being of glass compositions, do not possess large nonlinear coefficients. Nonlinear processes can nevertheless occur with high efficiencies since intensities are high and propagation distances are long. Even though power levels are usually modest (a few tens of milliwatts), intensities within the fiber are high due to the small cross-sectional areas involved. This is particularly true in single-mode fiber, where the LP_{01} mode typically presents an effective cross-sectional area of between 10^{-7} and 10^{-8} cm^2, thus leading to intensities on the order of MW/cm^2. Despite this, long interaction distances are usually necessary to achieve nonlinear mixing of any significance, so processes must be phase matched, or nearly so. Strategies to avoid unwanted nonlinear effects usually involve placing upper limits on optical power levels, and if possible, choosing other parameters such that phase mismatching occurs. Such choices may include wavelengths or wavelength spacing in wavelength-division multiplexed systems, or may be involved in special fiber waveguide designs.[3]

The generation of light through nonlinear mixing arises through polarization of the medium, which occurs through its interaction with intense light. The polarization consists of an array of phased dipoles in which the dipole moment is a nonlinear function of the applied field strength. In the classical picture, the dipoles, once formed, reradiate light to form the nonlinear output. The medium polarization is conveniently expressed through a power series expansion involving products of real electric fields:

$$\mathscr{P} = \varepsilon_0[\chi^{(1)} \cdot \mathscr{E} + \chi^{(2)} \cdot \mathscr{E}\mathscr{E} + \chi^{(3)} \cdot \mathscr{E}\mathscr{E}\mathscr{E} + \ldots.] = \mathscr{P}_L + \mathscr{P}_{\mathrm{NL}} \tag{1}$$

in which the χ terms are the linear, second-, and third-order susceptibilities. Nonlinear processes are described through the product of two or more optical fields to form the nonlinear polarization, $\mathscr{P}_{\mathrm{NL}}$, consisting of all terms of second order and higher in Eq. (1).

The second-order term in Eq. (1) [involving $\chi^{(2)}$] describes three-wave mixing phenomena, such as second-harmonic generation. The third-order term describes four-wave mixing (FWM) processes and stimulated scattering phenomena. In the case of optical fibers, second-order processes are generally not possible, since these effects require noncentrosymmetric media.[4] In amorphous fiber waveguides, third-order effects [involving $\chi^{(3)}$] are usually seen exclusively, although second-harmonic generation can be observed in special instances.[5]

The interactions between fields and polarizations are described by the nonlinear wave equation:

$$\nabla^2\mathscr{E} + n_0^2\mu_0\varepsilon_0\frac{\partial^2\mathscr{E}}{\partial t^2} = \mu_0\frac{\partial^2\mathscr{P}_{\mathrm{NL}}}{\partial t^2} \tag{2}$$

where $\mathscr{E}$ and $\mathscr{P}$ are the sums of all electric fields and nonlinear polarizations that are present, and n_0 is the refractive index of the medium. The second-order differential equation is usually reduced to first order through the slowly varying envelope approximation (SVEA):

$$\left|\frac{\partial^2 E}{\partial z^2}\right| \ll \left|\frac{2\pi}{\lambda}\frac{\partial E}{\partial z}\right| \tag{3}$$

where E is the complex field amplitude. The interpretation of the SVEA is that the changes in field amplitude that occur over distances on the order of a wavelength are very large compared to variations in the rate of change over the same distance. The wave equation will separate according to frequencies or propagation directions, yielding sets of coupled differential equations that, under the SVEA, are first order. These describe the growth or decay of fields involved in the mixing process.

The requirement for phase matching is that the nonlinear polarization wave and the electric field associated with the generated wave propagate with the same phase constant; that is, their phase velocities are equal. Phase-matched processes in fiber include those that involve (1) interacting waves at the same wavelength and polarization, such as self- and cross-phase modulation, as well as other degenerate Kerr-type interactions, and (2) stimulated scattering processes (Raman and Brillouin), in addition to cross-phase modulation involving two wavelengths. Four-wave mixing processes involving light at different wavelengths can occur that are not precisely phase matched but that can nevertheless yield high efficiencies. Matters are further complicated by the fact that different nonlinear processes can occur simultaneously, with each affecting the performance of the other. Nonlinear effects are usually favored to occur under pulsed operation, since high peak powers can be achieved with comparatively modest average powers. Consequently, group velocity matching is desirable (although not always required) to achieve efficient mixing between pulses.

10.2 SELF- AND CROSS-PHASE MODULATION

Self-phase modulation (SPM) can occur whenever a signal having a time-varying amplitude is propagated in a nonlinear material. The origin of the effect is the refractive index of the medium, which will change with the instantaneous signal intensity. The complex nonlinear polarization for the process is:

$$P_{\mathrm{NL}} = \frac{3}{4}\varepsilon_0 \chi^{(3)} |E_0(z,t)|^2 E_0(z,t) \exp[i(\omega t - \beta z)] \tag{4}$$

where $E_0(t)$ is the time-varying electric field amplitude that describes the pulse or signal envelope, and where the frequency ω is the same as that of the input light. Incorporating this polarization and the field into the wave equation leads to a modified refractive index over the original zero-field value n_0. The net index becomes:[6]

$$n = n_0 + n_2' |E_0(z,t)|^2 \tag{5}$$

where the nonlinear refractive index is given by $n_2' = Re\{3\chi^{(3)}/8n_0\}$. In fused silica it has the value $n_2' = 6.1\times10^{-23}\,\mathrm{m}^2/\mathrm{V}^2$.[7] Equation (5) can also be expressed in terms of light intensity through $n(I) = n_0 + n_2 I(z,t)$, where $n_2 = 3.2\times10^{-20}\,\mathrm{m}^2/\mathrm{W}$. In optical fibers the index is modified from the effective mode index of the single-mode fiber n_{eff} (which assumes the role of n_0).

The complex field as it propagates through the medium can be expressed as:

$$E = E_0(z,t) \exp(i\{\omega_0 t - [n_0 + n_2 I(z,t)] k_0 z\}) \tag{6}$$

which exhibits phase modulation that follows the shape of the intensity envelope. The instantaneous frequency is found through the time derivative of the phase:

$$\omega' = \omega_0 - n_2 k_0 z \frac{\partial I}{\partial t} \tag{7}$$

The effects of self-phase modulation on pulse propagation can be qualitatively observed from Eqs. (6) and (7). First, additional frequency components are placed on the pulse, thus increasing its spectral width. Second, a frequency sweep (chirp) is imposed on the pulse, the direction of which depends on the sign of $\partial I/\partial t$. The latter feature is particularly important in optical fibers, since the imposed frequency sweep from SPM will either add to or subtract from the chirp imposed by linear group dispersion. If the chirp directions for self-phase modulation and group dispersion are opposite, an effective cancellation may occur, leading to the formation of an optical soliton. In more conventional systems in which solitons are not employed, SPM must be considered as a possible benefit or detriment to performance, as some pulse shaping (which could include broadening or compression) can occur;[8,9] however, such systems can in theory yield excellent performance.[10] Furthermore, in systems employing fiber amplifiers, the change in refractive index associated with the signal-induced upper state population in erbium has been shown to be an important performance factor.[11] An additional effect can occur when pulse spectra lie within the anomalous group dispersion regime of the fiber; pulse breakup can occur as a result of *modulation instability,* in which the interplay between dispersive and nonlinear contributions to pulse shaping becomes unstable.[12]

Cross-phase modulation (XPM) is similar to SPM, except that two overlapping but distinguishable pulses (having, for example, different frequencies or polarizations) are involved. One pulse will modulate the index of the medium, which then leads to phase modulation of an overlapping pulse. XPM thus becomes a cross-talk mechanism between two channels if phase encoding is employed or if intensity modulation is used in dispersive systems.[13,14] No transfer of energy occurs between channels, however, which distinguishes the process from other crosstalk mechanisms in which growth

of signal power in one channel occurs at the expense of power in another. The strength of the effect is enhanced by a factor of 2 over that which can be obtained by a single field acting on itself (the nonlinear refractive index n_2 is effectively doubled in XPM). The XPM process, while twice as strong as SPM, is effectively weakened by the fact that pulses of differing frequencies or polarizations are generally not group velocity matched, and so cannot maintain overlap indefinitely. The efficiency is further reduced if the interaction occurs between cross-polarized waves; in this case the nonlinear tensor element (and thus the effective nonlinear index) is a factor of $\frac{1}{3}$ less than the tensor element that describes copolarized waves.[6]

Self- and cross-phase modulation are analyzed by way of coupled equations of the *nonlinear Schrödinger* form,[16] which describes the evolution over time and position of the electric field envelopes of two pulses, E_{0a} and E_{0b}, where SVEA is used and where pulse widths are on the order of 1 ps or greater:

$$\frac{\partial E_{0a}}{\partial z} + \beta_{1a}\frac{\partial E_{0a}}{\partial t} = -\frac{i}{2}\beta_{2a}\frac{\partial^2 E_{0a}}{\partial t^2} + i\gamma_a|E_{0a}|^2E_{0a} + i\delta\gamma_a|E_{0b}|^2E_{0a} - \frac{\alpha_a}{2}E_{0a} \tag{8}$$

$$\frac{\partial E_{0b}}{\partial z} + \beta_{1b}\frac{\partial E_{0b}}{\partial t} = -\frac{i}{2}\beta_{2b}\frac{\partial^2 E_{0b}}{\partial t^2} + i\gamma_b|E_{0b}|^2E_{0b} + i\delta\gamma_b|E_{0a}|^2E_{0b} - \frac{\alpha_b}{2}E_{0b} \tag{9}$$

In these equations, $\beta_{1j}(j=a,b)$ are the group delays of the pulses at the two frequencies or polarizations over a unit distance; β_{2j} are the group dispersion parameters associated with the two pulses; and $\gamma_j = n_2'\omega_j/(cA_{\text{eff}})$, where A_{eff} is the effective cross-sectional area of the fiber mode. The coefficient δ is equal to 2 for copolarized pulses of different frequencies and is $\frac{2}{3}$ if the pulses are cross-polarized. Propagation loss characterized by coefficients α_j is assumed. The equation form that describes the propagation with SPM of a single pulse—E_{0a}, for example—is found from Eq. (8) by setting $E_{0b}=0$. The terms on the right sides of Eqs. (8) and (9) describe in order the effects of group dispersion, SPM, XPM, and loss. The equations can be solved using numerical techniques that are described in Refs. 15 and 16.

For subpicosecond pulses, the accuracy of Eqs. (8) and (9) begins to degrade as pulse band-widths increase with decreasing temporal width. Additional terms are usually incorporated in the equations as pulse widths are reduced to the vicinity of 100 fs. These embody (1) cubic dispersion, which becomes important as bandwidth increases, and (2) changes in group velocity with intensity. This latter effect can result in *self-steepening,* in which the pulse trailing edge shortens to the point of forming an optical shock front under appropriate conditions. An additional consequence of broad pulse spectra is that power conversion from high-frequency components within a pulse to those at lower frequencies can occur via stimulated Raman scattering, provided the interacting components are sufficiently separated in wavelength. The effect is an overall red shift of the spectrum. At sufficiently high intensities, cross-coupling between pulses having different center wavelengths can also occur through Raman scattering, regardless of pulse width.

10.3 STIMULATED RAMAN SCATTERING

In *stimulated Raman scattering* (SRS), coupling occurs between copropagating light waves whose frequency difference is in the vicinity of resonances of certain molecular oscillation modes. In silica-based fibers, stretch vibrational resonances occur between Si and O atoms in several possible modes within the glass matrix (see Ref. 17 for illustrations of the important modes in pure silica). In the Stokes process, light at frequency ω_2 (pump wave) is downshifted to light at ω_1 (Stokes wave), with the excess energy being absorbed by the lattice vibrational modes (manifested in the generation of optical phonons). The process is either spontaneous, in which the Stokes wave builds up from noise, or is stimulated, in which both waves are present in sufficient strength to generate a beat frequency that excites the oscillators and promotes coupling. A fiber Raman amplifier works on this principle, in which an input signal at ω_1 experiences gain in the presence of pump light at ω_2. Figure 1 shows

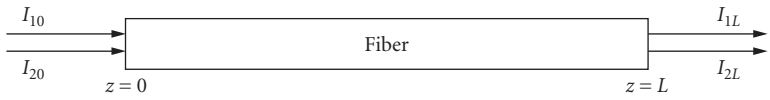

FIGURE 1 Beam geometry for stimulated Raman scattering in an optical fiber.

the beam geometry in which an input wave at ω_1 and intensity I_{10} can emerge at the far end with amplified value I_{1L}. This occurs in the presence of the pump wave at ω_2 that has initial intensity I_{20} and that emerges with depleted intensity I_{2L}.

Back-conversion from ω_1 to ω_2 (the inverse Raman effect) will also occur once the Stokes wave reaches sufficient intensity, but gain will only occur for the Stokes wave. Both processes are phase matched, and so occur with high efficiency in long fibers. The back-conversion process is to be distinguished from anti-Stokes scattering, in which pump light at ω_2 is upshifted to frequency ω_3, with the additional energy being supplied by optical phonons associated with the previously excited medium. The anti-Stokes process is rarely seen in fiber transmission because (1) it is phase mismatched and (2) it requires a substantial population of excited oscillators, which is not the case at thermal equilibrium.

Figure 2 shows the measured Raman gain for the Stokes wave in fused silica. The gain is plotted as a function of difference frequency between the interacting waves measured in cm^{-1} (to convert this to wavelength shift, use the formula $\Delta\lambda = \lambda_p^2 \Delta f(\text{cm}^{-1})$, where λ_p is the pump wavelength). Other fiber constituents such as GeO_2, P_2O_5, and B_2O_3 exhibit their own Raman resonances, which occur at successively greater wavelength shifts;[19] the effects of these will be weak, since their concentration in the fiber is generally small. Thus the dominant Raman shifts in optical fiber are associated with SiO_2, and occur within the range of 440 to 490 cm^{-1}, as is evident in Fig. 2.

Nonlinear polarizations at frequencies ω_1 and ω_2 can be constructed that are proportional to products of the Stokes and pump fields, $E_1^{\omega_1}$ and $E_2^{\omega_2}$. These are of the form $P_{\text{NL}}^{\omega_1} \propto |E_2^{\omega_2}|^2 E_1^{\omega_1}$ (Stokes

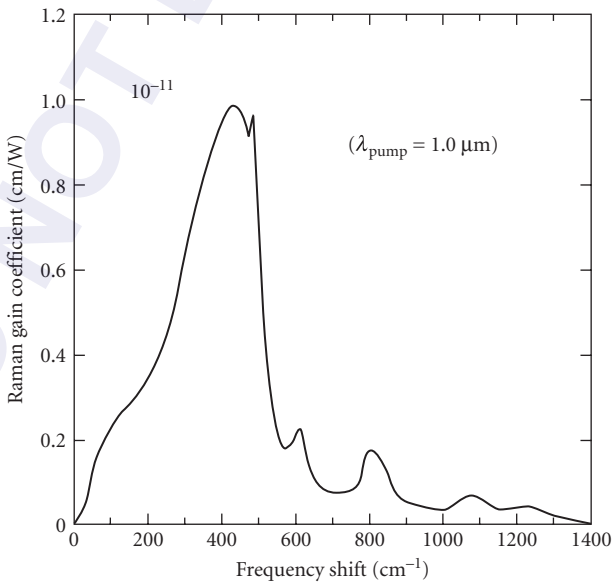

FIGURE 2 Raman gain spectrum in fused silica. (*Adapted from Ref. 22. © 1980 IEEE.*)

generation) and $P_{NL}^{\omega_2} \propto |E_1^{\omega_1}|^2 E_2^{\omega_2}$ (the inverse Raman effect). Substituting these polarizations and the two fields into the wave equation, using the SVEA, and assuming copolarized fields leads to the following coupled equations involving the Stokes and pump wave intensities I_1 and I_2:[18]

$$\frac{dI_1}{dz} = g_r I_1 I_2 - \alpha I_1 \tag{10}$$

$$\frac{dI_2}{dz} = -\frac{\omega_2}{\omega_1} g_r I_1 I_2 - \alpha I_2 \tag{11}$$

where the loss terms involving α (the fiber loss per unit distance) are added phenomenologically. The Raman gain function g_r is expressed in a general way as

$$g_r = \frac{A}{\lambda_2} f(\lambda_1 - \lambda_2) \tag{12}$$

where A is a function of the material parameters and $f(\lambda_1 - \lambda_2)$ is a normalized line shape function, which is either derived from theory or experimentally measured (determined from Fig. 2, for example). With λ_2 expressed in μm, $A = 1.0 \times 10^{-11}$ cm − μm/W.[20] The solutions of Eqs. (10) and (11) are:

$$I_1(z) = \frac{\omega_1}{\omega_2} I_0 \exp(-\alpha z) \frac{\psi_r}{1 + \psi_r} \tag{13}$$

$$I_2(z) = I_0 \exp(-\alpha z) \frac{1}{1 + \psi_r} \tag{14}$$

In these equations, $I_0 = I_{20} + (\omega_1/\omega_2) I_{10}$, where I_{10} and I_{20} are the Stokes and pump intensities at the fiber input. The coupling parameter ψ_r assumes different forms, depending upon whether the input Stokes intensity I_{10} is present or not. If I_{10} is present, and if its magnitude is much greater than light from spontaneous Raman scattering, we have:

$$\psi_r = \frac{\omega_1}{\omega_2} \frac{I_{10}}{I_{20}} \exp(G_0) \tag{15}$$

When no Stokes input is present, the signal builds up from spontaneous Raman scattering, and the coupling parameter in this case becomes:

$$\psi_r = \frac{\hbar \omega_2 \Delta\omega_r}{4\sqrt{\pi}} \frac{1}{I_{20} A_{\text{eff}}} G_2^{-1/2} \exp(G_2) \tag{16}$$

with the gain parameters defined through $G_0 = g_r I_0 L_{\text{eff}}$ and $G_2 = g_r I_{20} L_{\text{eff}}$. The effective length of the fiber accounts for the reduction of Stokes and pump intensities as a result of loss, and is defined as

$$L_{\text{eff}} = \int_0^L \exp(-\alpha z) dz = \frac{1 - \exp(-\alpha L)}{\alpha} \tag{17}$$

The effective area of a single-mode fiber A_{eff} calculated through πr_0^2, where r_0 is the mode field radius. For a multimode fiber, A_{eff} is usually taken as the core area, assuming that the power is uniformly distributed over the core. The power in the fiber is then $P_{1,2} = I_{1,2} A_{\text{eff}}$.

Two basic issues concerning SRS are of interest in fiber communication systems. First, pump-to-Stokes coupling provides a mechanism for crosstalk from short- to long-wavelength channels. This will occur most efficiently if the channel frequency spacing is in the vicinity of that associated with the maximum Raman gain. The Raman gain peak at approximately 500 cm^{-1} corresponds to a frequency spacing of 15 THz, meaning that operation at 1.55 μm produces a Stokes wave of about 1.67 μm

wavelength. Two-channel operation at these wavelengths would lead to a maximum allowable signal level of about 50 mW.[21] In WDM systems, within the 1.53- to 1.56-μm erbium-doped fiber amplifier window, channel spacings of 50 or 100 GHz are used. Raman gain is thus considerably reduced, but is still sufficient to cause appreciable crosstalk, which can lead to system penalties of between 1 and 3 dB depending on the number of channels.[22] Second, and of more importance to single-wavelength systems, is the conversion to Stokes power from the original signal—a mechanism by which signal power can be depleted. A related problem is walkoff[23] occurring between the signal and Stokes pulses, since these will have different group delays. Walkoff is a means for aliasing to occur in digital transmission, unless the signal is filtered at the output. If pulses are of subpicosecond widths, additional complications arise due to the increased importance of SPM and XPM.[24] In any event, an upper limit must be placed on the signal power if significant conversion to Stokes power is to be avoided. In single-wavelength systems, where crosstalk is not an issue, pulse peak powers must be kept below about 500 mW to avoid significant SRS conversion.[25]

A useful criterion is the so-called critical condition (or Raman threshold), defined as the condition under which the output Stokes and signal powers are equal. This occurs when $\psi_r = 1$, which, from Eq. (16), leads to $G_2 \approx 16$. SRS can also be weakened by taking advantage of the gain reduction that occurs as signal (pump) wavelengths increase, as shown in Eq. (12). For example, operation at 1.55 μm yields less SRS for a given signal power than operation at 1.3 μm.

Apart from the need to reduce SRS, the effect can be used to advantage in wavelength conversion and in amplification. Fiber Raman lasers have proven to be good sources of tunable radiation and operate at multiple Stokes wavelengths.[26] Specifically, a Stokes wave can serve as a pump to generate an additional (higher-order) Stokes wave at a longer wavelength.[27] Fiber Raman amplifiers are used routinely in long-haul systems.[28]

10.4 STIMULATED BRILLOUIN SCATTERING

The stimulated Brillouin scattering (SBS) process involves the input of a single intense optical wave at frequency ω_2, which initiates a copropagating acoustic wave at frequency ω_p. The acoustic wave is manifested as a traveling index grating in the fiber, which back-diffracts a portion of the original input. The backward (Stokes) wave is Doppler-shifted to a lower frequency ω_1 and is proportional to the phase conjugate of the input.[29] The backward wave is amplified as it propagates, with the gain increasing with increasing input (pump) power.

The beam interaction geometry is shown in Fig. 3. Usually, the Stokes wave builds up spontaneously, but can be inputted at the far end. The effect can be understood by considering a case in which counter-propagating Stokes and pump waves exist that together form a moving interference pattern whose velocity is proportional to the difference frequency $\omega_2 - \omega_1$. Coupling between the waves will occur via SBS when the interference pattern velocity is in the vicinity of the acoustic wave velocity v_p. It is the interference pattern that forms and reinforces the acoustic wave through electrostriction. With a single input, spontaneous scattering from numerous shock waves occurs, with preferential feedback from the acoustic wave that matches the condition just described. With the Stokes wave generated (although it is initially weak), the acoustic wave is reinforced, and so backscattering increases.

In terms of the wave vector magnitudes, the condition for phase matching is given by $k_p = k_1 + k_2$. Since the sound frequency is much less than those of the two optical waves, we can write $k_p \approx 2k_2$. Then, since $k_p = \omega_p / v_p$, it follows that $\omega_p \approx 2n\omega_2 v_p / c$, where n is the refractive index (assumed to

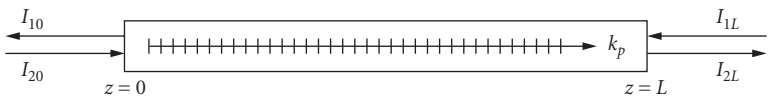

FIGURE 3 Beam geometry for stimulated Brillouin scattering in an optical fiber.

be the same value at both optical frequencies). The Brillouin frequency shift under phase-matched conditions thus becomes

$$\omega_2 - \omega_1 \approx 2n\omega_2 \frac{v_p}{c} \tag{18}$$

This yields a value of about 11 GHz, with $v_p \approx 6$ km/s in fused silica and $\lambda_2 = 1.55\,\mu$m.

The process can be described by the nonlinear polarization produced by the product of complex fields, E_1, E_2^*, and E_2; this yields a polarization at ω_1 that propagates with wavevector k_1 in the direction of the Stokes wave. Another polarization, describing back-coupling from Stokes to pump, involves the product $E_1 E_1^* E_2$. Substituting fields and polarizations into the wave equation yields the following coupled equations that describe the evolution of the optical intensities with distance (pp. 287–290 of Ref. 18):

$$\frac{dI_1}{dz} = -g_b I_1 I_2 + \alpha I_1 \tag{19}$$

$$\frac{dI_2}{dz} = -g_b I_1 I_2 - \alpha I_2 \tag{20}$$

where α is the linear loss coefficient. The Brillouin gain is given by

$$g_b = g_{b0}\left(1 + \frac{4(\omega_1 - \omega_{10})^2}{v_p^2 \alpha_p^2}\right)^{-1} \tag{21}$$

where ω_{10} is the Stokes frequency at precise phase matching, α_p is the loss coefficient for the acoustic wave, and the peak gain g_{b0} is a function of the material parameters. The Brillouin line width, defined as the full width at half-maximum of g_b, is $\Delta\omega_b = v_p \alpha_p$. In optical fibers, $\Delta f_b = \Delta\omega_b / 2\pi$ is typically between 10 and 30 MHz and $g_{b0} = 4.5 \times 10^{-9}$ cm/W.[20] Signal bandwidths in high-data-rate communication systems greatly exceed the Brillouin line width, and so SBS is typically too weak to be considered a source of noise or signal depletion. This is to be compared to stimulated Raman scattering, which supports considerable gain over approximately 5 THz. Consequently, SRS is a much more serious problem in high-data-rate systems.

Using analysis methods similar to those employed in SRS, a critical condition (or threshold) can be defined for SBS, at which the backscattered power is equal to the input power:[30]

$$\frac{\omega_1 k_B T \Delta\omega_b}{4\sqrt{\pi}\omega_p I_{20} A_{\text{eff}}} G_b^{-3/2} \exp(G_b) = 1 \tag{22}$$

where k_B is the Boltzmann's constant and T is the temperature in Kelvin. The gain parameter is:

$$G_b = g_b I_{20} L_{\text{eff}} \tag{23}$$

with L_{eff} as defined in Eq. (17). Equation (22) is approximately satisfied when $G_b \simeq 21$.[30] In practice, the backscattered power will always be less than the input power, since pump depletion will occur. Nevertheless, this condition is used as a benchmark to determine the point at which SBS becomes excessive in a given system.[31] In one study, it was found that $G_b \approx 21$ yields the pump power required to produce an SBS output that is at the level of Rayleigh back-scattering.[32] Pump powers required to achieve threshold can be on the order of a few milliwatts for CW or narrowband signals, but these increase substantially for broadband signals.[33] Reduction of SBS is accomplished in practice by

lowering the input signal power (I_{20}) or by taking advantage of the reduction in g_b that occurs when signal bandwidths ($\Delta\omega$) exceed the Brillouin line width. Specifically, if $\Delta\omega >> \Delta\omega_b$,

$$g_b(\Delta\omega) \approx g_b \frac{\Delta\omega_b}{\Delta\omega} \tag{24}$$

10.5 FOUR-WAVE MIXING

The term *four-wave mixing* in fibers is generally applied to wave coupling through the electronic nonlinearity in which at least two frequencies are involved and in which frequency conversion is occurring. The fact that the electronic nonlinearity is involved distinguishes four-wave mixing interactions from stimulated scattering processes because in the latter the medium was found to play an active role through the generation or absorption of optical phonons (in SRS) or acoustic phonons (in SBS). If the nonlinearity is electronic, bound electron distributions are modified according to the instantaneous optical field configurations. For example, with light at two frequencies present, electron positions can be modulated at the difference frequency, thus modulating the refractive index. Additional light will encounter the modulated index and can be up- or downshifted in frequency. In such cases, the medium plays a passive role in the interaction, as it does not absorb applied energy or release energy previously stored. The self- and cross-phase modulation processes also involve the electronic nonlinearity, but in those cases, power conversion between waves is not occurring—only phase modulation.

As an illustration of the process, consider the interaction of two strong waves at frequencies ω_1 and ω_2, which mix to produce a downshifted (Stokes) wave at ω_3 and an upshifted (anti-Stokes) wave at ω_4. The frequencies have equal spacing, that is, $\omega_1 - \omega_3 = \omega_2 - \omega_1 = \omega_4 - \omega_2$ (Fig. 4). All fields assume the real form:

$$\mathscr{E}_j = \frac{1}{2} E_{oj} \exp[i(\omega_j t - \beta_j z) + c.c. \; j = 1 - 4 \tag{25}$$

The nonlinear polarization will be proportional to $\mathscr{E}^3$, where $\mathscr{E} = \mathscr{E}_1 + \mathscr{E}_2 + \mathscr{E}_3 + \mathscr{E}_4$. With all fields copolarized, complex nonlinear polarizations at ω_3 and ω_4 appear that have the form:

$$P_{\mathrm{NL}}^{\omega_3} - \frac{3}{4}\varepsilon_0 \chi^{(3)} E_{01}^2 E_{02}^* \exp[i(2\omega_1 - \omega_2)t] \exp[-i(2\beta^{\omega_1} - \beta^{\omega_2})z] \tag{26}$$

$$P_{\mathrm{NL}}^{\omega_4} - \frac{3}{4}\varepsilon_0 \chi^{(3)} E_{02}^2 E_{01}^* \exp[i(2\omega_2 - \omega_1)t] \exp[-i(2\beta^{\omega_2} - \beta^{\omega_1})z] \tag{27}$$

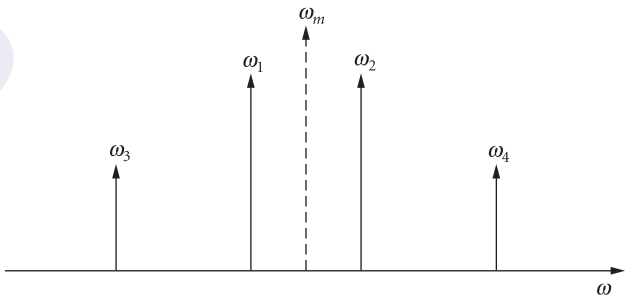

FIGURE 4 Frequency diagram for four-wave mixing, showing pump frequencies (ω_1 and ω_2) and sideband frequencies (ω_3 and ω_4).

where $\omega_3 = 2\omega_1 - \omega_2$, $\omega_4 = 2\omega_1 - \omega_1$, and $\chi^{(3)}$ is proportional to the nonlinear refractive index n_2'. The significance of these polarizations lies not only in the fact that waves at the sideband frequencies ω_3 and ω_4 can be generated, but that preexisting waves at those frequencies can experience gain in the presence of the two pump fields at ω_1 and ω_2 thus forming a parametric amplifier. The sideband waves will contain the amplitude and phase information on the pumps, thus making this process an important crosstalk mechanism in multiwavelength communication systems. Under phase-matched conditions, the gain associated with FWM is more than twice the peak gain in SRS.[34]

The wave equation, when solved in steady state, yields the output intensity at either one of the sideband frequencies.[35] For a medium of length L, having loss coefficient α, the sideband intensities are related to the pump intensities through

$$I^{\omega_3} \propto \left(\frac{n_2 L_{\text{eff}}}{\lambda_m}\right)^2 I^{\omega_2}(I^{\omega_1})^2 \eta \exp(-\alpha L) \tag{28}$$

$$I^{\omega_4} \propto \left(\frac{n_2 L_{\text{eff}}}{\lambda_m}\right)^2 I^{\omega_1}(I^{\omega_2})^2 \eta \exp(-\alpha L) \tag{29}$$

where L_{eff} is defined in Eq. (17), and where

$$\eta = \frac{\alpha^2}{\alpha^2 + \Delta\beta^2}\left(1 + \frac{4\exp(-\alpha L)\sin^2(\Delta\beta L/2)}{(1 - \exp(-\alpha L)^2}\right) \tag{30}$$

Other FWM interactions can occur, involving products of intensities at three different frequencies rather than two as demonstrated here. In such cases, the output wave intensities are increased by a factor of 4 over those indicated in Eqs. (28) and (29).

One method of suppressing four-wave mixing in WDM systems includes the use of unequal channel spacing.[36] This ensures, for example, that $\omega_3 \neq 2\omega_1 + \omega_2$, where ω_1, ω_2, and ω_3 are assigned channel frequencies. More common methods involve phase-mismatching the process in some way. This is accomplished by increasing $\Delta\beta$, which has the effect of decreasing η in Eqs. (28) and (29). Note that in the low-loss limit, where $\alpha \to 0$, Eq. (30) reduces to $\eta = (\sin^2(\Delta\beta L/2)/(\Delta\beta L/2)^2$. The $\Delta\beta$ expressions associated with wave generation at ω_3 and ω_4 are given by

$$\Delta\beta(\omega_3) = 2\beta^{\omega_1} - \beta^{\omega_2} - \beta^{\omega_3} \tag{31}$$

and

$$\Delta\beta(\omega_4) = 2\beta^{\omega_2} - \beta^{\omega_1} - \beta^{\omega_4} \tag{32}$$

It is possible to express Eqs. (31) and (32) in terms of known fiber parameters by using a Taylor series for the propagation constant, where the expansion is about frequency ω_m as indicated in Fig. 4, where $\omega_m = (\omega_2 + \omega_1)/2$

$$\beta \approx \beta_0 + (\omega - \omega_m)\beta_1 + \frac{1}{2}(\omega - \omega_m)^2\beta_2 + \frac{1}{6}(\omega - \omega_m)^3\beta_3 \tag{33}$$

In Eq. (33), β_1, β_2, and β_3 are, respectively, the first, second, and third derivatives of β with respect to ω, evaluated at ω_m. These in turn relate to the fiber dispersion parameter D (ps/nm · km) and its first derivative with respect to wavelength through $\beta_2 = -(\lambda_m^2/2\pi c)D(\lambda_m)$ and $\beta_3 = (\lambda_m^3/2\pi^2 c^2)[D(\lambda_m) + (\lambda_m/2)(dD/d\lambda)|_{\lambda_m}]$ where $\lambda_m = 2\pi c/\omega_m$. Using these relations along with Eq. (33) in Eqs. (31) and (32) results in:

$$\Delta\beta(\omega_3, \omega_4) \approx 2\pi c \frac{\Delta\lambda^2}{\lambda_m^2}\left[D(\lambda_m) \pm \frac{\Delta\lambda}{2}\frac{dD}{d\lambda}|\lambda_m\right] \tag{34}$$

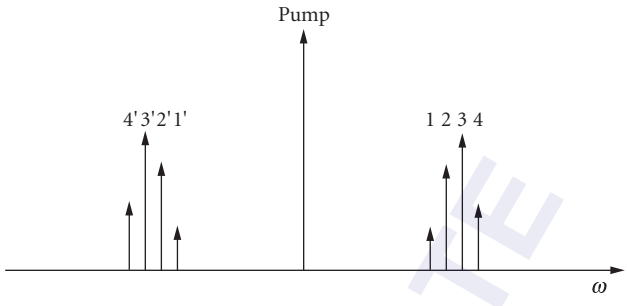

FIGURE 5 Frequency diagram for spectral inversion using four-wave mixing with a single pump frequency.

where the plus sign is used for $\Delta\beta(\omega_3)$, the minus sign is used for $\Delta\beta(\omega_4)$, and $\Delta\lambda = \lambda_1 - \lambda_2$. Phase matching is not completely described by Eq. (34), since cross-phase modulation plays a subtle role, as discussed in Ref. 16. Nevertheless, Eq. (34) does show that the retention of moderate values of dispersion D is a way to reduce FWM interactions that would occur, for example, in WDM systems. As such, modern commercial fiber intended for use in WDM applications will have values of D that are typically in the vicinity of 4 ps/nm · km.[37] With WDM operation in conventional dispersion-shifted fiber (with the dispersion zero near 1.55 μm), having a single channel at the zero dispersion wavelength can result in significant four-wave mixing.[38] Methods that were found to reduce four-wave mixing in such cases include the use of cross-polarized signals in dispersion-managed links[39] and operation within a longer-wavelength band near 1.6 μm[40] at which dispersion is appreciable and where gain-shifted fiber amplifiers are used.[41]

Examples of other cases involving four-wave mixing include single-wavelength systems, in which the effect has been successfully used in a demultiplexing technique for TDM signals.[42] In another case, coupling through FWM can occur between a signal and broadband amplified spontaneous emission (ASE) in links containing erbium-doped fiber amplifiers.[43] As a result, the signal becomes spectrally broadened and exhibits phase noise from the ASE. The phase noise becomes manifested as amplitude noise under the action of dispersion, producing a form of modulation instability.

An interesting application of four-wave mixing is spectral inversion. Consider a case that involves the input of a strong single-frequency pump wave along with a relatively weak wave having a spectrum of finite width positioned on one side of the pump frequency. Four-wave mixing leads to the generation of a wave whose spectrum is the "mirror image" of that of the weak wave, in which the mirroring occurs about the pump frequency. Figure 5 depicts a representation of this, where four frequency components comprising a spectrum are shown along with their imaged counterparts. An important application of this is pulses that have experienced broadening with chirping after propagating through a length of fiber exhibiting linear group dispersion.[44] Inverting the spectrum of such a pulse using four-wave mixing has the effect of reversing the direction of the chirp (although the pulse center wavelength is displaced to a different value). When the spectrally inverted pulse is propagated through an additional length of fiber having the same dispersive characteristics, the pulse will compress to nearly its original input width. Compensation for nonlinear distortion has also been demonstrated using this method.[45]

10.6 CONCLUSION

An overview of fiber nonlinear effects has been presented here in which emphasis is placed on the basic concepts, principles, and perspectives on communication systems. Space is not available to cover the more subtle details of each effect or the interrelations between effects that often occur. The

text by Agrawal[16] is recommended for further in-depth study, which should be supplemented by the current literature. Nonlinear optics in fibers and in fiber communication systems comprises an area whose principles and implications are still not fully understood. It thus remains an important area of current research.

PHOTONIC CRYSTAL FIBERS

Philip St. J. Russell and Greg J. Pearce
Max-Planck Institute for the Science of Light
Erlangen, Germany

11.1 GLOSSARY

A_i	nonlinear effective area of subregion i
c	velocity of light in vacuum
d	hole diameter
D	$\frac{\partial}{\partial\lambda}\frac{1}{v_g}=\frac{\partial^2\beta_m}{\partial\lambda\partial\omega}$ the group velocity dispersion of mode m in engineering units (ps/nm · km)
k	vacuum wavevector $2\pi/\lambda=\omega/c$
n_2^i	nonlinear refractive index of subregion i
$n_{\max}$	maximum index supported by the PCF cladding (fundamental space-filling mode)
n_z	z-component of refractive index
n_q^∞	$\sqrt{\sum_i n_i^2 A_i / \sum_i A_i}$ the area-averaged refractive index of an arbitrary region q of a microstructured fiber, where n_i and A_i are respectively the refractive indices and total area of subregion i
V	$k\rho\sqrt{n_{\text{co}}^2-n_{\text{cl}}^2}$ the normalized frequency for a step-index fiber
V_{gen}	$k\Lambda\sqrt{n_1^2-n_2^2}$ a generalized form of V for a structure made from two materials of index n_1 and n_2
β	component of wavevector along the fiber axis
β_m	axial wavevector of guided mode
$\beta_{\max}$	maximum possible axial component of wavevector in the PCF cladding
Δ	$(n_{\text{co}}-n_{\text{cl}})/n_{\text{cl}}$, where n_{co} and n_{cl} are, respectively, the core and cladding refractive indices of a conventional step-index fiber
Δ_∞	$(n_{\text{co}}^\infty-n_{\text{cl}}^\infty)/n_{\text{cl}}^\infty$, where n_{co}^∞ and n_{cl}^∞ are the refractive indices of core and cladding in the long wavelength limit
γ	$\text{W}^{-1}\text{km}^{-1}$ nonlinear coefficient of an optical fiber
$\varepsilon(\mathbf{r}_T)$	relative dielectric constant of a PCF as a function of transverse position $\mathbf{r}_T=(x,y)$
λ	vacuum wavelength
λ_{eff}^i	$2\pi/\sqrt{k^2n_i^2-\beta^2}$ the effective transverse wavelength in subregion i

Λ interhole spacing, period, or pitch
ρ core radius
ω angular frequency of light

11.2 INTRODUCTION

Photonic crystal fibers (PCFs)—fibers with a periodic transverse microstructure—have been in practical existence as low loss waveguides since early 1996.[1–4] The initial demonstration took 4 years of technological development, and since then the fabrication techniques have become more and more sophisticated. It is now possible to manufacture the microstructure in air-glass PCF to accuracies of 10 nm on the scale of 1 μm, which allows remarkable control of key optical properties such as dispersion, birefringence, nonlinearity, and the position and width of the photonic bandgaps (PBGs) in the periodic "photonic crystal" cladding. PCF has in this way extended the range of possibilities in optical fibers, both by improving well-established properties and introducing new features such as low loss guidance in a hollow core.

Standard single-mode telecommunications fiber (SMF), with a normalized core-cladding refractive index difference Δ approximately 0.4 percent, a core radius of ρ approximately 4.5 μm, and of course a very high optical clarity (better than 5 km/dB at 1550 nm), is actually quite limiting for many applications. Two major factors contribute to this. The first is the smallness of Δ, which causes bend loss (0.5 dB at 1550 nm in Corning SMF-28 for one turn around a mandrel 32 mm in diameter[10]) and limits the degree to which group velocity dispersion and birefringence can be manipulated. Although much higher values of Δ can be attained (modified chemical vapor deposition yields an index difference of 0.00146 per mol % GeO_2, up to a maximum $\Delta \sim 10\%$ for 100 mol %[11]), the single-mode core radius becomes very small and the attenuation rises through increased absorption and Rayleigh scattering. The second factor is the reliance on total internal reflection (TIR), so that guidance in a hollow core is impossible, however useful it would be in fields requiring elimination of glass-related nonlinearities or enhancement of laser interactions with dilute or gaseous media. PCF has made it possible to overcome these limitations, and as a result many new applications of optical fibers are emerging.

Outline of Chapter

In the next section a brief history of PCF is given, and in Sec. 11.4 fabrication techniques are reviewed. Numerical modeling and analysis are covered in Sec. 11.5 and the optical properties of the periodic photonic crystal cladding in Sec. 11.6. The characteristics of guidance are discussed in Sec. 11.7. In Sec. 11.8 the nonlinear characteristics of guidance are reviewed and intrafiber devices (including cleaving and splicing) are discussed in Sec. 11.9. Brief conclusions, including a list of applications, are drawn in Sec. 11.10.

11.3 BRIEF HISTORY

The original motivation for developing PCF was the creation of a new kind of dielectric waveguide—one that guides light by means of a two-dimensional PBG. In 1991, the idea that the well-known "stop-bands" in multiply periodic structures (for a review see Ref. 12) could be extended to eliminate all photonic states[13] was leading to attempts worldwide to fabricate three-dimensional PBG materials. At that time the received wisdom was that the refractive index difference needed to create a PBG

in two dimensions was large—of order 2.2:1. It was not widely recognized that the refractive index difference requirements for PBG formation in two dimensions are greatly relaxed if, as in a fiber, propagation is predominantly along the third axis—the direction of invariance.

Photonic Crystal Fibers

The original 1991 idea, then, was to trap light in a hollow core by means of a two-dimensional "photonic crystal" of microscopic air capillaries running along the entire length of a glass fiber.[14] Appropriately designed, this array would support a PBG for incidence from air, preventing the escape of light from a hollow core into the photonic crystal cladding and avoiding the need for TIR.

The first 4 years of work on understanding and fabricating PCF were a journey of exploration. The task of solving Maxwell's equations numerically made good progress, culminating in a 1995 paper that showed that photonic bandgaps did indeed exist in two-dimensional silica-air structures for "conical" incidence from vacuum—this being an essential prerequisite for hollow-core guidance.[15] Developing a suitable fabrication technique took rather longer. After 4 years of trying different approaches, the first successful silica-air PCF structure was made in late 1995 by stacking 217 silica capillaries (8 layers outside the central capillary), specially machined with hexagonal outer and a circular inner cross sections. The diameter-to-pitch ratio d/Λ of the holes in the final stack was approximately 0.2, which theory showed was too small for PBG guidance in a hollow core, so it was decided to make a PCF with a solid central core surrounded by 216 air channels (Fig. 1*a*).[2,5,6]

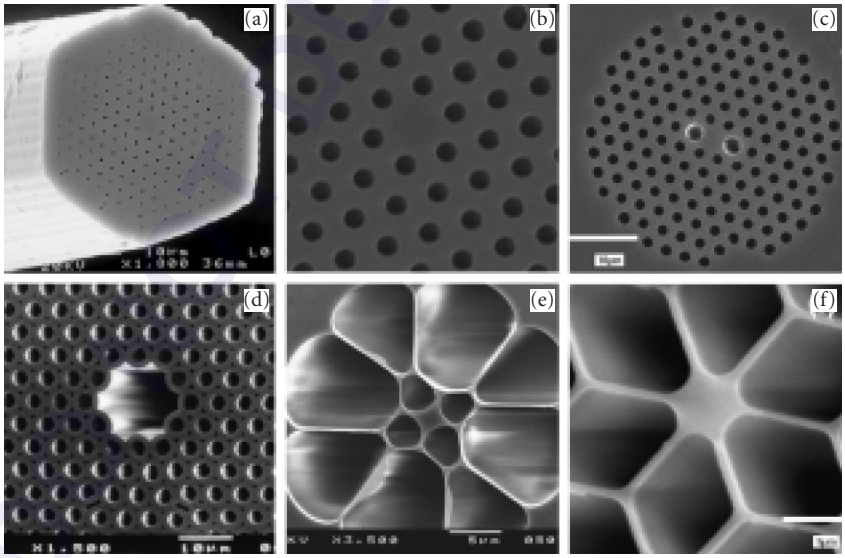

FIGURE 1 Selection of scanning electron micrographs of PCF structures. (*a*) The first working PCF—the solid glass core is surrounded by a triangular array of 300 nm diameter air channels, spaced 2.3 μm apart;[5,6] (*b*) detail of a low loss solid-core PCF (interhole spacing ~2 μm); (*c*) birefringent PCF (interhole spacing 2.5 μm); (*d*) the first hollow-core PCF (core diameter ~10 μm);[7] (*e*) a PCF extruded from Schott SF6 glass with a core approximately 2 μm in diameter;[8] and (*f*) PCF with very small core (diameter 800 nm) and zero GVD wavelength 560 nm.[9]

This led to the discovery of endlessly single-mode PCF, which, if it guides at all, only supports the fundamental guided mode.[16] The success of these initial experiments led rapidly to a whole series of new types of PCF—large mode area,[17] dispersion-controlled,[9,18] hollow core,[7] birefringent,[19] and multicore.[20]

These initial breakthroughs led quickly to applications, perhaps the most celebrated being the report in 2000 of supercontinuum generation from unamplified Ti:sapphire fs laser pulses in a PCF with a core small enough to give zero dispersion at 800 nm wavelength (subsection "Supercontinuum Generation" in Sec. 11.8).[21]

Bragg Fibers

In the late 1960s and early 1970s, theoretical proposals were made for another kind of fiber with a periodically structured cross section.[22,23] This was a cylindrical "Bragg" fiber that confines light within an annular array of rings of high and low refractive index arranged concentrically around a central core. A group in France has made a solid-core version of this structure using modified chemical vapor deposition.[24] Employing a combination of polymer and chalcogenide glass, researchers in the United States have realized a hollow-core version of a similar structure,[25] reporting 1 dB/m loss at 10 μm wavelength (the losses at telecom wavelengths are as yet unspecified). This structure guides light in the TE_{01} mode, used in microwave telecommunications because of its ultralow loss; the field moves away from the attenuating waveguide walls as the frequency increases, resulting in very low losses, although the guide must be kept very straight to avoid the fields entering the cladding and experiencing high absorption.

11.4 FABRICATION TECHNIQUES

Photonic crystal fiber (PCF) structures are currently produced in many laboratories worldwide using a variety of different techniques (see Fig. 2 for schematic drawings of some example structures). The first stage is to produce a "preform"—a macroscopic version of the planned microstructure in the drawn PCF. There are many ways to do this, including stacking of capillaries and rods,[5] extrusion,[8,26–28] sol-gel casting,[29] injection molding and drilling. The materials used range from silica to compound glasses, chalcogenide glasses, and polymers.[30]

The most widely used technique is stacking of circular capillaries (Fig. 3). Typically, meter-length capillaries with an outer diameter of approximately 1 mm are drawn from a starting tube of high-purity synthetic silica with a diameter of approximately 20 mm. The inner/outer diameter of the starting tube, which typically lies in the range from 0.3 up to beyond 0.9, largely determines the d/Λ value in the drawn fiber. The uniformity in diameter and circularity of the capillaries must be controlled to at least 1 percent of the diameter. They are stacked horizontally, in a suitably shaped jig, to form the desired crystalline arrangement. The stack is bound with wire before being inserted into a jacketing tube, and the whole assembly is then mounted in the preform feed unit for drawing down to fiber. Judicious use of pressure and vacuum during the draw allows some limited control over the final structural parameters, for example the d/Λ value.

Extrusion offers an alternative route to making PCF, or the starting tubes, from bulk glass; it permits formation of structures that are not readily made by stacking. While not suitable for silica (no die material has been identified that can withstand the ~2000°C processing temperatures without contaminating the glass), extrusion is useful for making PCF from compound silica glasses, tellurites, chalcogenides, and polymers—materials that melt at lower temperatures. Figure 1*e* shows the cross section of a fiber extruded, through a metal die, from a commercially available glass (Schott SF6).[8] PCF has also been extruded from tellurite glass, which has excellent IR transparency out to beyond 4 μm, although the reported fiber losses (a few dB/m) are as yet rather high.[27,31–33] Polymer PCFs, first developed in Sydney, have been successfully made using many different approaches, for example extrusion, casting, molding, and drilling.[30]

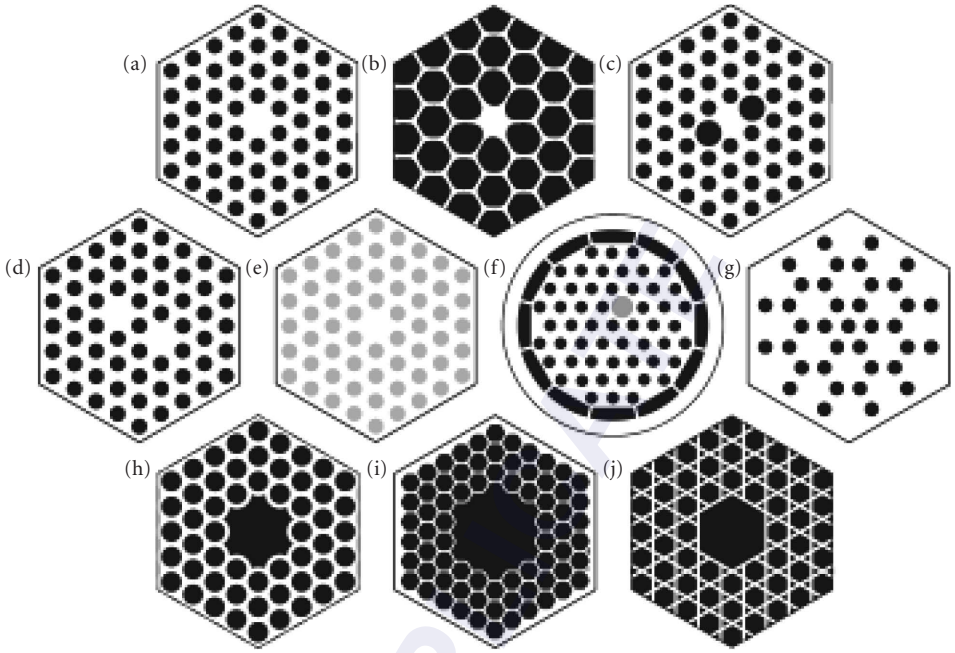

FIGURE 2 Representative sketches of different types of PCF. The black regions are hollow, the white regions are pure glass, and the gray regions doped glass. (*a*) Endlessly single-mode solid core; (*b*) highly nonlinear (high air-filling fraction, small core, characteristically distorted holes next to the core); (*c*) birefringent; (*d*) dual-core; (*e*) all-solid glass with raised-index doped glass strands (colored gray) in the cladding; (*f*) double-clad PCF with off-set doped lasing core and high numerical aperture inner cladding for pumping (the photonic crystal cladding is held in place by thin webs of glass); (*g*) "carbon-ring" array of holes for PBG guidance in core with extra hole; (*h*) seven-cell hollow core; (*i*) 19-cell hollow core with high air-filling fraction (in a real fiber, surface tension smoothes out the bumps on the core surround); and (*j*) hollow-core with Kagomé lattice in the cladding.

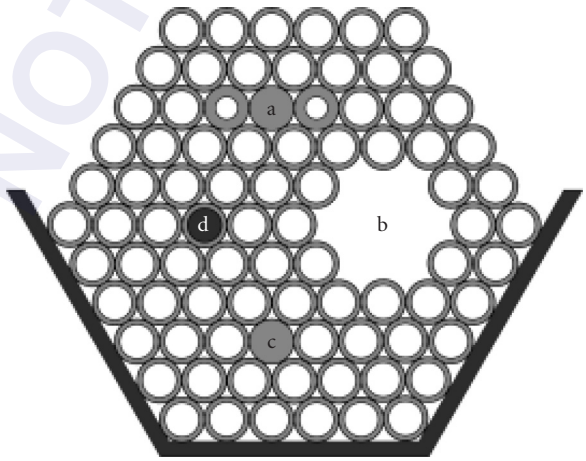

FIGURE 3 Preform stack containing (*a*) birefringent solid core; (*b*) seven-cell hollow core; (*c*) solid isotropic core; and (*d*) doped core. The capillary diameters are approximately 1 mm—large enough to ensure that they remain stiff for stacking.

Design Approach

The successful design of a PCF for a particular application is not simply a matter of using numerical modeling (see next section) to calculate the parameters of a structure that yields the required performance. This is because the fiber drawing process is not lithographic, but introduces its own highly reproducible types of distortion through the effects of viscous flow, surface tension, and pressure. As a result, even if the initial preform stack precisely mimics the theoretically required structure, several modeling and fabrication iterations are usually needed before a successful design can be reached.

11.5 MODELING AND ANALYSIS

The complex structure of PCF—in particular the large refractive index difference between glass and air—makes its electromagnetic analysis challenging. Maxwell's equations must usually be solved numerically, using one of a number of specially developed techniques.[15,34–38] Although standard optical fiber analyses and number of approximate models are occasionally helpful, these are only useful as rough guidelines to the exact behavior unless checked against accurate numerical solutions.

Maxwell's Equations

In most practical cases, a set of equal frequency modes is more useful than a set of modes of different frequency sharing the same value of axial wavevector component β. It is therefore convenient to arrange Maxwell's equations with β^2 as eigenvalue

$$\left(\nabla^2 + k^2\varepsilon(\mathbf{r}_T) + \left[\nabla \ln \varepsilon(\mathbf{r}_T)\right] \wedge \nabla \wedge\right)\mathbf{H}_T = \beta^2 \mathbf{H}_T \tag{1}$$

where all the field vectors are taken in the form $\mathbf{Q} = \mathbf{Q}_T(\mathbf{r}_T)\mathrm{e}^{-j\beta z}$, $\varepsilon_T(\mathbf{r}_T)$ is the dielectric constant, $\mathbf{r}_T = (x, y)$ is position in the transverse plane, and $k = \omega/c$ is the vacuum wavevector. This form allows material dispersion to be easily included, something which is not possible if the equations are set up with k^2 as eigenvalue. Written out explicitly in cartesian coordinates Eq. (1) yields two equations relating h_x and h_y

$$\begin{aligned}
&\frac{\partial^2 h_x}{\partial y^2} + \frac{\partial^2 h_x}{\partial x^2} - \frac{\partial \ln \varepsilon}{\partial y}\left(\frac{\partial h_x}{\partial y} - \frac{\partial h_y}{\partial x}\right) + (\varepsilon k^2 - \beta^2)h_x = 0 \\
&\frac{\partial^2 h_y}{\partial x^2} + \frac{\partial^2 h_y}{\partial y^2} + \frac{\partial \ln \varepsilon}{\partial x}\left(\frac{\partial h_x}{\partial y} - \frac{\partial h_y}{\partial x}\right) + (\varepsilon k^2 - \beta^2)h_y = 0
\end{aligned} \tag{2}$$

and a third differential equation relating h_x h_y, and h_z, which is however not required to solve Eq. (2).

Scalar Approximation

In the paraxial scalar approximation the second term inside the operator in Eq. (1), which gives rise to the middle terms in Eq. (2) that couple between the vector components of the field, can be neglected, yielding a scalar wave equation

$$\nabla^2 \mathbf{H}_T + [k^2\varepsilon(\mathbf{r}_T) - \beta^2]\mathbf{H}_T = 0 \tag{3}$$

This leads to a scaling law, similar to the one used in standard analyses of step-index fiber,[39] that can be used to parameterize the fields.[40] Defining Λ as the interhole spacing and n_1 and n_2 the refractive indices of the two materials used to construct a particular geometrical shape of photonic crystal, the mathematical forms of the fields and the dispersion relations are identical provided the generalized V-parameter

$$V_{\text{gen}} = k\Lambda\sqrt{n_1^2 - n_2^2} \tag{4}$$

is held constant. This has the interesting (though in the limit not exactly practical) consequence that bandgaps can exist for vanishingly small index differences, provided the structure is made sufficiently large (see subsection "All-Solid Structures" in Sec. 11.7).

Numerical Techniques

A common technique for solving Eq. (1) employs a Fourier expansion to create a basis set of plane waves for the fields, which reduces the problem to the inversion of a matrix equation, suitable for numerical computation.[37] Such an implicitly periodic approach is especially useful for the study of the intrinsic properties of PCF claddings. However, in contrast to versions of Maxwell's equations with k^2 as eigenvalue,[41] Eq. (1) is non-Hermitian, which means that standard matrix inversion methods for Hermitian problems cannot straightforwardly be applied. An efficient iterative scheme can, however, be used to calculate the inverse of the operator by means of fast Fourier transform steps. This method is useful for accurately finding the modes guided in a solid-core PCF, which are located at the upper edge of the eigenvalue spectrum of the inverted operator. In hollow-core PCF, however (or other fibers relying on a cladding bandgap to confine the light), the modes of interest lie in the interior of the eigenvalue spectrum. A simple transformation can, however, be used to move the desired interior eigenvalues to the edge of the spectrum, greatly speeding up the calculations and allowing as many as a million basis waves to be incorporated.[42,43] To treat PCFs with a central guiding core in an otherwise periodic lattice, a supercell is constructed, its dimensions being large enough so that, once tiled, the guided modes in adjacent cores do not significantly interact.

The choice of a suitable numerical method often depends on fiber geometry, as some methods can exploit symmetries or regularity of structure to increase efficiency. Other considerations are whether material dispersion is significant (more easily included in fixed-frequency methods), and whether leakage losses or a treatment of leaky modes (requiring suitable boundaries on the computational domain) are desired. If the PCF structure consists purely of circular holes, for example, the multipole or Rayleigh method is a particularly fast and efficient method.[34,35] It uses Mie theory to evaluate the scattering of the field incident on each hole. Other numerical techniques include expanding the field in terms of Hermite-Gaussian functions,[38,44] the use of finite-difference time-domain (FDTD) analysis (a simple and versatile tool for exploring waveguide geometries[45]) or finite-difference method in the frequency domain,[46] and the finite-element approach.[47] Yet another approach is a source-model technique which uses two sets of fictitious elementary sources to approximate the fields inside and outside circular cylinders.[48]

11.6 CHARACTERISTICS OF PHOTONIC CRYSTAL CLADDING

The simplest photonic crystal cladding is a biaxially periodic, defect-free, composite material with its own well-defined dispersion and band structure. These properties determine the behavior of the guided modes that form at cores (or "structural defects" in the jargon of photonic crystals).

A convenient graphical tool is the propagation diagram—a map of the ranges of frequency and axial wavevector component β where light is evanescent in all transverse directions regardless of its polarization state (Fig. 4).[15] The vertical axis is the normalized frequency $k\Lambda$, and the horizontal axis is the normalized axial wavevector component $\beta\Lambda$. Light is unconditionally cutoff from propagating (due to either TIR or a PBG) in the black regions.

In any subregion of isotropic material (glass or air) at fixed optical frequency, the maximum possible value of $\beta\Lambda$ is given by $k\Lambda n$, where n is the refractive index (at that frequency) of the region under consideration. For $\beta < kn$ light is free to propagate, for $\beta > kn$ it is evanescent and at $\beta = kn$ the critical angle is reached—denoting the onset of TIR for light incident from a medium of index larger than n.

The slanted guidelines (Fig. 4) denote the transitions from propagation to evanescence for air, the photonic crystal, and glass. At fixed optical frequency for $\beta < k$, light propagates freely in every subregion of the structure. For $k < \beta < kn_g$ (n_g is the index of the glass), light propagates in the glass substrands and is evanescent in the hollow regions. Under these conditions the "tight binding" approximation holds, and the structure may be viewed as an array of coupled glass waveguides.

The photonic bandgap "fingers" in Fig. 4 are most conveniently investigated by plotting the photonic density of states (DOS),[43] which shows graphically the density of allowed modes in the PCF cladding relative to vacuum (Fig. 5). Regions of zero DOS are photonic bandgaps, and by plotting a quantity such as $(\beta - k)\Lambda$ it is possible to see clearly how far a photonic bandgap extends below the light line.

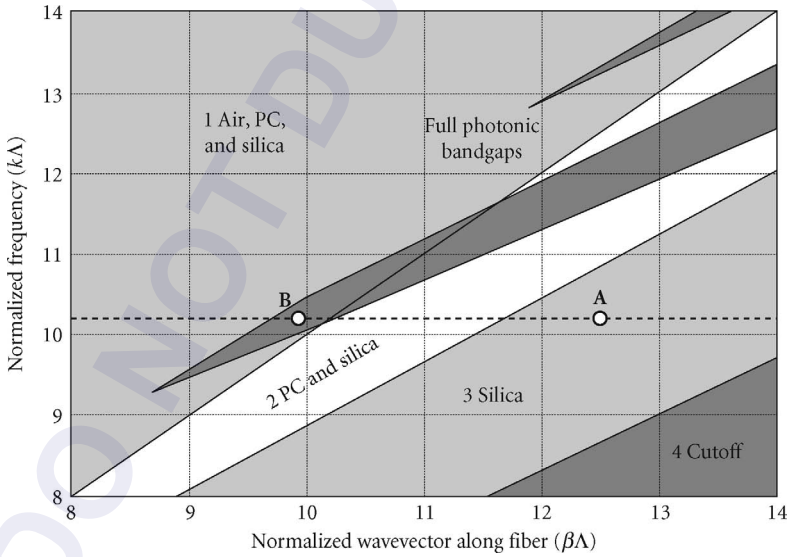

FIGURE 4 Propagation diagram for a triangular array of circular air holes (radius $\rho = 0.47\Lambda$) in silica glass, giving an air-filling fraction of 80 percent. Note the different regions where light is (4) cutoff completely (dark), (3) able to propagate only in silica glass (light gray), (2) able to propagate also in the photonic crystal cladding (white), and (1) able to propagate in all regions (light gray). Guidance by total internal reflection in a silica core is possible at point A. The "fingers" indicate the positions of full two-dimensional photonic bandgaps, which can be used to guide light in air at positions such as B where a photonic bandgap crosses the light line $k = \beta$.

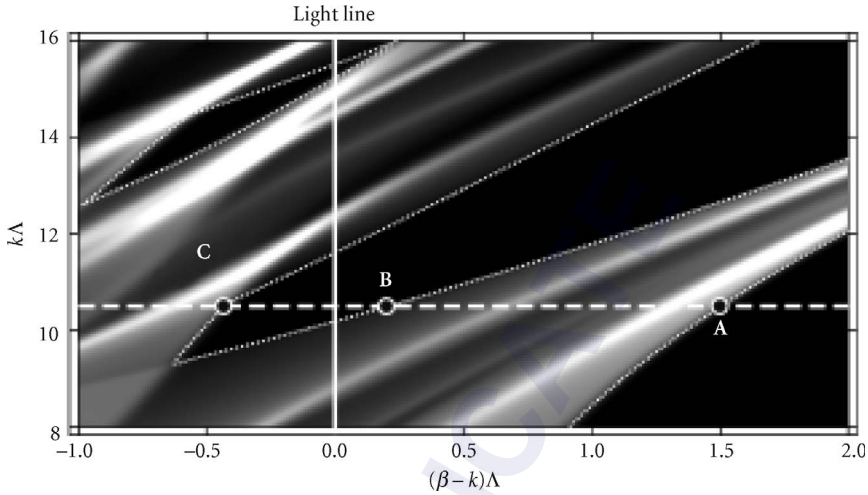

FIGURE 5 Photonic density of states (DOS) for the fiber structure described in Fig. 4, where black regions show zero DOS and lighter regions show higher DOS. The edges of full two-dimensional photonic bandgaps and the band edge of the fundamental space-filling mode are highlighted with thin dotted white lines. The vertical white line is the light line, and the labeled points mark band edges at the frequency of the thick dashed white line, discussed in the section "Maximum Refractive Index and Band Edges."

Maximum Refractive Index and Band Edges

The maximum axial refractive index $n_{max} = \beta_{max}/k$ in the photonic crystal cladding lies in the range $k < \beta < kn_g$ as expected of a composite glass-air material. This value coincides with the z-pointing "peaks" of the dispersion surfaces in reciprocal space, where multiple values of transverse wavevector are allowed, one in each tiled Brillouin zone. For a constant value of β slightly smaller than β_{max}, these wavevectors lie on small approximately circular loci, with a transverse component of group velocity that points normal to the circles in the direction of increasing frequency. Thus, light can travel in *all* directions in the transverse plane, even though its wavevectors are restricted to values lying on the circular loci. The real-space distribution of this field is shown in Fig. 6, together with the fields at two other band edges.

The maximum axial refractive index n_{max} depends strongly on frequency, even though neither the air nor the glass are assumed dispersive in the analysis; microstructuring itself creates dispersion, through a balance between transverse energy storage and energy flow that is highly dependent upon frequency.

By averaging the square of the refractive index in the photonic crystal cladding it is simple to show that

$$n_{max} \to \sqrt{(1-F)n_g^2 - Fn_a^2} \qquad k\Lambda \to 0 \tag{5}$$

in the long-wavelength limit for a scalar approximation, where F is the air-filling fraction and n_a is the index in the holes (which we take to be 1 for the rest of this subsection).

As the wavelength of the light falls, the optical fields are better able to distinguish between the glass regions and the air. The light piles up more and more in the glass, causing the effective n_{max} "seen" by

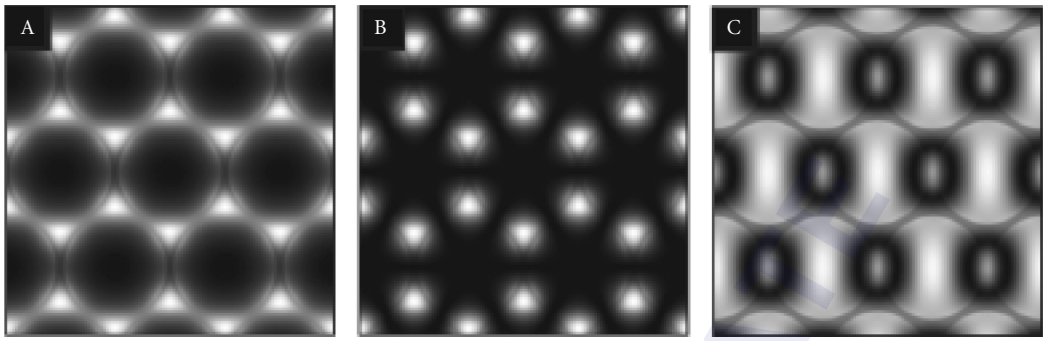

FIGURE 6 Plots showing the magnitude of the axial Poynting vector at band edges A, B, and C as shown in Fig. 5. White regions have large Poynting vector magnitude. A is the fundamental space-filling mode, for which the field amplitudes are in phase between adjacent unit cells. In B (the "dielectric" edge) the field amplitudes change sign between antinodes, and in C (the "air" edge) the central lobe has the opposite sign from the six surrounding lobes.

it to change. In the limit of small wavelength $k\Lambda \to \infty$ light is strongly excluded from the air holes by TIR, and the field profile "freezes" into a shape that is independent of wavelength. The variation of $n_{\max}$ with frequency may be estimated by expanding fields centered on the air holes in terms of Bessel functions and applying symmetry.[16] Defining the normalized parameters

$$u = \Lambda\sqrt{k^2 n_g^2 - \beta^2} \qquad v = k\Lambda\sqrt{n_g^2 - 1} \tag{6}$$

the analysis yields the polynomial fit (see Sec. 11.11):

$$\begin{aligned} u(v) = (&0.00151 + 2.62v^{-1} + 0.0155v \\ &-0.000402v^2 + 3.63\times10^{-6}v^3)^{-1} \end{aligned} \tag{7}$$

for $d/\Lambda = 0.4$ and $n_g = 1.444$. This polynomial is accurate to better than 1 percent in the range $0 < v < 50$. The resulting expression for $n_{\max}$ is plotted in Fig. 7 against the parameter v.

Transverse Effective Wavelength

The transverse effective wavelength in the ith material is defined as follows:

$$\lambda_{\text{eff}}^{i} = \frac{2\pi}{\sqrt{k^2 n_i^2 - \beta^2}} \tag{8}$$

where n_i is its refractive index. This wavelength can be many times the vacuum value, tending to infinity at the critical angle $\beta \to kn_i$, and being imaginary when $\beta > kn_i$. It is a measure of whether or not the light is likely to be resonant within a particular feature of the structure, for example, a hole or a strand of glass, and defines PCF as a wavelength-scale structure.

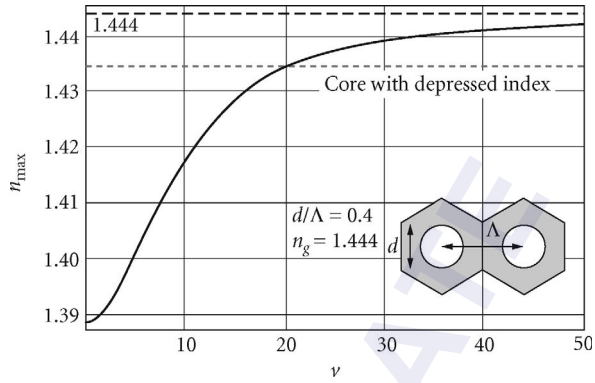

FIGURE 7 Maximum axial refractive index in the photonic crystal cladding as a function of the normalized frequency parameter ν for $d/\lambda = 0.4$ and $n_g = 1.444$. For this filling fraction of air (14.5%), the value at long wavelength ($\nu \to 0$) is $n_{max} = 1.388$, in agreement with Eq. (5). The horizontal dashed gray line represents the case when the core is replaced with a glass of refractive index $n_{co} = 1.435$ (below that of silica), when guidance ceases for $\nu > 20$.

Photonic Bandgaps

Full two-dimensional PBGs exist in the black finger-shaped regions on Fig. 4. Some of these extend into the region $\beta < k$ where light is free to propagate in vacuum, confirming the feasibility of trapping light within a hollow core.

The bandgap edges coincide with points where resonances in the cladding unit cells switch on and off, that is, the eigenvalues of the unitary inter-unit-cell field transfer matrices change from $\exp(\pm j\phi)$ (propagation) to $\exp(\pm\gamma)$ (evanescence). At these transitions, depending on the band edge, the light is to a greater or lesser degree preferentially redistributed into the low or high index subregions. For example, at fixed optical frequency and small values of β, leaky modes peaking in the low index channels form a pass-band that terminates when the standing wave pattern has 100 percent visibility (Fig. 6*c*). For the high index strands (Fig. 6*a* and *b*) on the other hand, the band of real states is bounded by a lower value of β where the field amplitude changes sign between selected pairs of adjacent strands (depending on the lattice geometry), and an upper bound where the field amplitude does not change sign between the strands (this field distribution yields n_{max}).

11.7 LINEAR CHARACTERISTICS OF GUIDANCE

In SMF, guided modes form within the range of axial refractive indices $n_{cl} < n_z < n_{co}$, when light is evanescent in the cladding ($n_z = \beta/k$; core and cladding indices are n_{co} and n_{cl}). In PCF, three distinct guidance mechanisms exist: a modified form of TIR,[16,49] photonic bandgap guidance[7,50] and a low leakage mechanism based on a Kagomé cladding structure.[51,52] In the following subsections we explore the role of resonance and antiresonance, and discuss chromatic dispersion, attenuation mechanisms, and guidance in cores with refractive indices raised and lowered relative to the "mean" cladding value.

Resonance and Antiresonance

It is helpful to view the guided modes as being confined (or not confined) by resonance and antiresonance in the unit cells of the cladding crystal. If the core mode finds no states in the cladding with which it is phase-matched, light cannot leak out. This is a familiar picture in many areas of photonics. What is perhaps not so familiar is the use of the concept in two dimensions, where a repeating unit is tiled to form a photonic crystal cladding. This allows the construction of an intuitive picture of "cages," "bars," and "windows" for light and actually leads to a blurring of the distinction between guidance by modified TIR and photonic bandgap effects.

Positive Core-Cladding Index Difference

This type of PCF may be defined as one where the mean cladding refractive index in the long wavelength limit, $k \to 0$, [Eq. (5)] is lower than the core index (in the same limit). Under the correct conditions (high air-filling fraction), PBG guidance may also occur in this case, although experimentally the TIR-guided modes will dominate.

Controlling Number of Modes A striking feature of this type of PCF is that it is "endlessly single-mode" (ESM), that is, the core does not become multimode in the experiments, no matter how short the wavelength of the light.[16] Although the guidance in some respects resembles conventional TIR, it turns out to have some interesting and unique features that distinguish it markedly from step-index fiber. These are due to the piecewise discontinuous nature of the core boundary—sections where (for $n_z > 1$) air holes strongly block the escape of light are interspersed with regions of barrier-free glass. In fact, the cladding operates in a regime where the transverse effective wavelength, Eq. (8), in silica is comparable with the glass substructures in the cladding. The zone of operation in Fig. 4 is $n_{\max} < n_z < n_g$ (point A).

In a solid-core PCF, taking the core radius $\rho = \Lambda$ and using the analysis in Ref. 16, the effective V-parameter can be calculated. This yields the plot in Fig. 8, where the full behavior from very low to very high frequency is predicted (the glass index was kept constant at 1.444). As expected, the number of guided modes approximately $V_{\text{PCF}}^2/2$ is almost independent of wavelength at high frequencies;

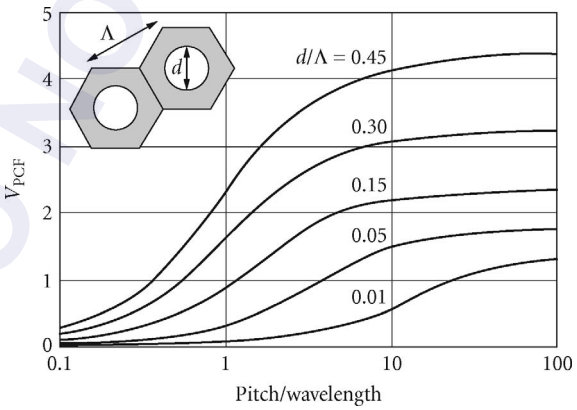

FIGURE 8 V-parameter for solid-core PCF (triangular lattice) plotted against the ratio of hole spacing to vacuum wavelength for different values of d/Λ. Numerical modeling shows that ESM behavior is maintained for $V_{\text{PCF}} \leq 4$ or $d/\Lambda \leq 0.43$.

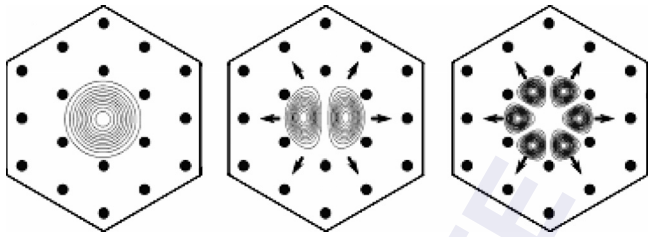

FIGURE 9 Schematic of modal filtering in a solid-core PCF: (*a*) The fundamental mode is trapped whereas (*b*) and (*c*) higher-order modes leak away through the gaps between the air holes.

the single-mode behavior is determined solely by the geometry. Numerical modeling shows that if $d/\Lambda < 0.43$ the fiber never supports any higher-order guided modes, that is, it is ESM.

This behavior can be understood by viewing the array of holes as a modal filter or "sieve" (Fig. 9). The fundamental mode in the glass core has a transverse effective wavelength $\lambda_{\text{eff}}^{g} \approx 4\Lambda$. It is thus unable to "squeeze through" the glass channels between the holes, which are $\Lambda - d$ wide and thus below the Rayleigh resolution limit $\approx \lambda_{\text{eff}}^{g}/2 = 2\Lambda$. Provided the relative hole size d/Λ is small enough, higher-order modes are able to escape their transverse effective wavelength is shorter so they have higher resolving power. As the holes are made larger, successive higher-order modes become trapped.

ESM behavior may also be viewed as being caused by strong wavelength dispersion in the photonic crystal cladding, which forces the core-cladding index step to fall as the wavelength gets shorter (Fig. 7).[16,49] This counteracts the usual trend toward increasingly multimode behavior at short wavelengths. In the limit of very short wavelength the light strikes the glass-air interfaces at glancing incidence, and is strongly rejected from the air holes. In this regime the transverse single-mode profile does not change with wavelength. As a consequence the angular divergence (roughly twice the numerical aperture) of the emerging light is proportional to wavelength; in SMFs it is approximately constant owing to the appearance of more and more higher-order guided modes as the frequency increases.

Thus, the refractive index of the photonic crystal cladding increases with optical frequency, tending toward the index of silica glass in the short wavelength limit. If the core is made from a glass of refractive index lower than that of silica (e.g., fluorine-doped silica), guidance is lost at wavelengths shorter than a certain threshold value (see Fig. 7).[53] Such fibers have the unique ability to prevent transmission of short wavelength light—in contrast to conventional fibers which guide more and more modes as the wavelength falls.

Ultra-Large Area Single-Mode The modal filtering in ESM-PCF is controlled only by the geometry (d/Λ for a triangular lattice). A corollary is that the behavior is quite independent of the absolute size of the structure, permitting single-mode fiber cores with arbitrarily large areas. A single-mode PCF with a core diameter of 22 μm at 458 nm was reported in 1998.[17] In conventional step-index fibers, where $V < 2.405$ for single-mode operation, this would require uniformity of core refractive index to approximately part in 10^5—very difficult to achieve if MCVD is used to form the doped core. Larger mode areas allow higher power to be carried before the onset of intensity-related nonlinearities or damage, and have obvious benefits for delivery of high laser power, fiber amplifiers, and fiber lasers. The bend-loss performance of such large-core PCFs is discussed in subsection "Bend Loss" in Sec. 11.7.

Fibers with Multiple Cores The stacking procedure makes it straightforward to produce multicore fiber. A preform stack is built up with a desired number of solid (or hollow) cores, and drawn down to fiber in the usual manner.[20] The coupling strength between the cores depends on

the sites chosen, because the evanescent decay rate of the fields changes with azimuthal direction. Applications include curvature sensing.[54] More elaborate structures can be built up, such as fibers with a central single-mode core surrounded by a highly multimode cladding waveguide are useful in applications such as high power cladding-pumped fiber lasers[55,56] and two-photon fluorescence sensors[57] (see Fig. 2*f*).

Negative Core-Cladding Index Difference

Since TIR cannot operate under these circumstances, low loss waveguiding is only possible if a PBG exists in the range $\beta < kn_{co}$.

Hollow-Core Silica/Air In silica-air PCF, larger air-filling fractions and small interhole spacings are necessary to achieve photonic bandgaps in the region $\beta < k$. The relevant operating region on Fig. 4 is to the left of the vacuum line, inside one of the bandgap fingers (point B). These conditions ensure that light is free to propagate, and form guided modes, within the hollow core while being unable to escape into the cladding. The number N of such modes is controlled by the depth and width of the refractive index "potential well" and is approximately given by

$$N \approx k^2\rho^2(n_{high}^2 - n_{low}^2)/2 \tag{9}$$

where n_{high} and n_{low} are the refractive indices at the edges of the PBG at fixed frequency and ρ is the core radius. Since the bandgaps are quite narrow ($n_{high}^2 - n_{low}^2$ is typically a few percent) the hollow core must be sufficiently large if a guided mode is to exist at all. In the first hollow-core PCF, reported in 1999,[7] the core was formed by omitting seven capillaries from the preform stack (Fig. 1*d*). An electron micrograph of a more recent structure, with a hollow core made by removing 19 missing capillaries from the stack, is shown in Fig. 10.[58]

In hollow-core PCF, guidance can only occur when a photonic bandgap coincides with a core resonance. This means that only restricted bands of wavelength are guided. This feature can be very useful for suppressing parasitic transitions by filtering away the unwanted wavelengths, for example, in fiber lasers and in stimulated Raman scattering in gases.[59]

Higher Refractive Index Glass Achieving a bandgap in higher refractive index glasses for $\beta < k$ presents at first glance a dilemma. Whereas a larger refractive index contrast generally yields wider bandgaps, the higher "mean" refractive index seems likely to make it more difficult to achieve bandgaps

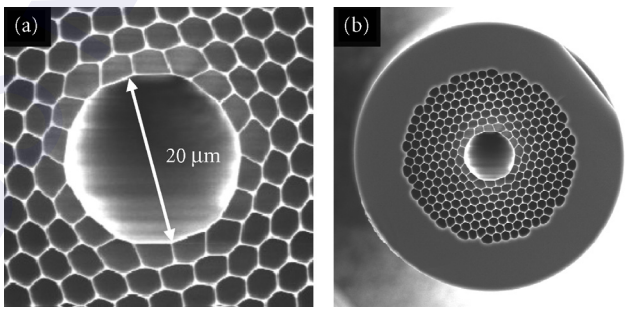

FIGURE 10 Scanning electron micrographs of a low loss hollow PCF (manufactured by BlazePhotonics Ltd.) with attenuation approximately 1 dB/km at 1550 nm wavelength: (*a*) detail of the core (diameter 20.4 μm) and (*b*) the complete fiber cross section.

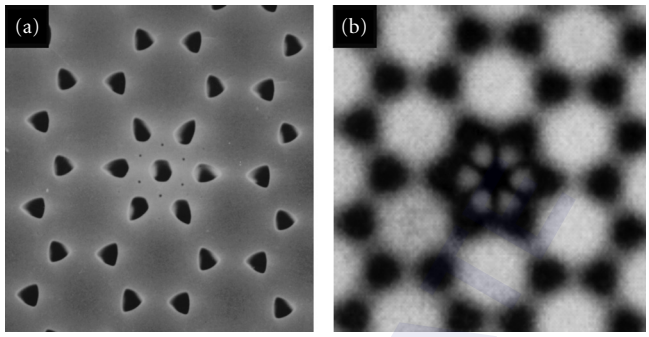

FIGURE 11 (*a*) A PCF with a "carbon-ring" lattice of air holes and an extra central hole to form a low index core. (*b*) When white light is launched, only certain bands of wavelength are transmitted in the core—here a six-lobed mode (in the center of the image, blue in the original near-field image) emerges from the end-face.[50]

for incidence from vacuum. Although this argument holds in the scalar approximation, the result of calculations show that vector effects become important at higher levels of refractive index contrast (e.g., 2:1 or higher) and a new species of bandgap appears for smaller filling fractions of air than in silica-based structures. The appearance of this new type of gap means that it is actually easier to obtain wide bandgaps with higher index glasses such as tellurites or chalcogenides.[43]

Surface States on Core-Cladding Boundary The first PCF that guided by photonic bandgap effects consisted of a lattice of air holes arranged in the same way as the carbon rings in graphite. The core was formed by introducing an extra hole at the center of one of the rings, its low index precluding the possibility of TIR guidance.[50] When white light was launched into the core region, a colored mode was transmitted—the colors being dependent on the absolute size to which the fiber was drawn. The modal patterns had six equally strong lobes, disposed in a flower-like pattern around the central hole. Closer examination revealed that the light was guided not in the air holes but in the six narrow regions of glass surrounding the core (Fig. 11). The light remained in these regions, despite the close proximity of large "rods" of silica, full of modes. This is because, for particular wavelengths, the phase velocity of the light in the core is not coincident with any of the phase velocities available in the transmission bands created by nearest-neighbor coupling between rod modes. Light is thus unable to couple over to them and so remains trapped in the core.

Similar guided modes are commonly seen in hollow-core PCF, where they form surface states (analogous with electronic surface states in semiconductor crystals) on the rim of the core, confined on the cladding side by photonic bandgap effects. These surface states become phase-matched to the air-guided mode at certain wavelengths, and if the two modes share the same symmetry they couple to form an anticrossing on the frequency-wavevector diagram (Figs. 12 and 13). Within the anticrossing region, the modes share the characteristics of both an air-guided mode and a surface mode, and this consequently perturbs the group velocity dispersion and contributes additional attenuation (see subsection "Absorption and Scattering" in Sec. 11.7).[60–62]

All-Solid Structures In all-solid bandgap guiding fibers the core is made from low index glass and is surrounded by an array of high index glass strands.[63–65] Since the mean core-cladding index contrast is negative, TIR cannot operate, and photonic bandgap effects are the only possible guidance mechanism. These structures have some similarities with one-dimensional "ARROW" structures, where antiresonance plays an important role.[66]

When the cladding strands are antiresonant, light is confined to the central low index core by a mechanism not dissimilar to the modal filtering picture in subsection "Controlling Number of

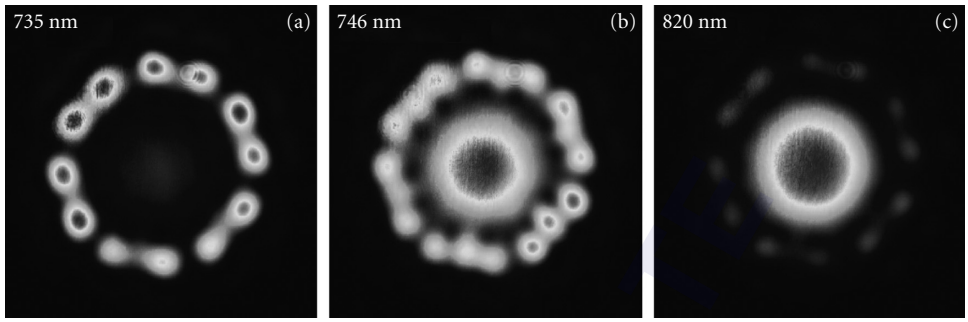

FIGURE 12 Near-field end-face images of the light transmitted in hollow-core PCF designed for 800 nm transmission. For light launched in the core mode, at 735 nm an almost pure surface mode is transmitted, at 746 nm a coupled surface-core mode, and at 820 nm an almost pure core mode.[60] (The ring-shaped features are an artifact caused by converting from false color to gray scale; the intensity *increases* toward the dark centers of the rings.) (*Images courtesy G. Humbert, University of Bath*).[60]

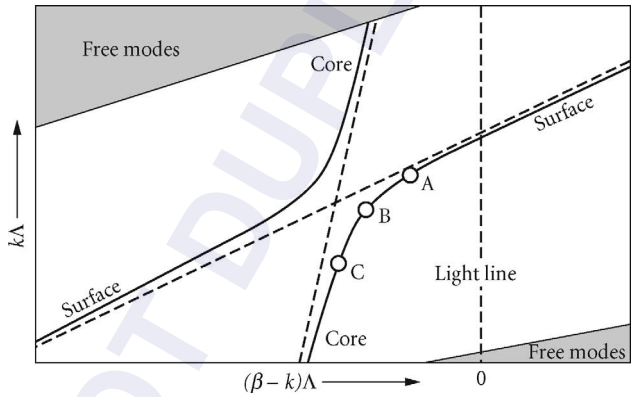

FIGURE 13 Example mode trajectories showing the anticrossing of a core-guided mode with a surface mode in a hollow-core PCF. The dotted lines show the approximate trajectories of the two modes in the absence of coupling (for instance if the modes are of different symmetries), and the vertical dashed line is the air line. The gray regions, within which the mode trajectories are not shown, are the band edges; the white region is the photonic bandgap. Points A, B, and C are the approximate positions of the modes shown in Fig. 12.

Modes" in Sec. 11.7;[52] the high index cores act as the "bars of a cage," so that no features in the cladding are resonant with the core mode, resulting in a low loss guided mode. Guidance is achieved over wavelength ranges that are punctuated with high loss windows where the cladding "bars" become resonant (Fig. 14). Remarkably, it is possible to achieve photonic bandgap guidance by this mechanism even at index contrasts of 1 percent,[63,67] with losses as low as 20 dB/km at 1550 nm.[68]

Low Leakage Guidance The transmission bands are greatly widened in hollow-core PCFs with a kagomé lattice in the cladding[52] (Fig. 2*j*). The typical attenuation spectrum of such a fiber has a loss of order 1 dB/m over a bandwidth of 1000 nm or more. Numerical simulations show that, while the cladding structure supports no bandgaps, the density of states is greatly reduced near the vacuum

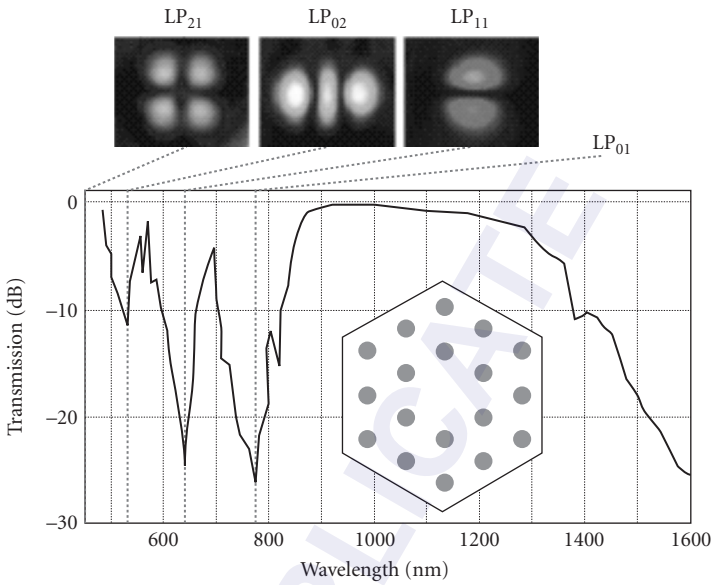

FIGURE 14 Lower: Measured transmission spectrum (using a white-light supercontinuum source) for a PCF with a pure silica core and a cladding formed by an array of Ge-doped strands ($d/\Lambda = 0.34$ hole spacing ~7 μm, index contrast 1.05:1). The transmission is strongly attenuated when the core mode becomes phase-matched to different LP_{nm} "resonances" in the cladding strands. Upper: Experimental images [left to right, taken with blue (500 nm), green (550 nm), and red (650 nm) filters] of the near-field profiles in the cladding strands at three such wavelengths. The fundamental LP_{01} resonance occurs at approximately 820 nm and the four-lobed blue resonance lies off the edge of the graph.

line. The consequential poor overlap between the core states, together with the greatly reduced number of cladding states, appears to slow down the leakage of light—though the precise mechanism is still a matter of debate.[52]

Birefringence

The modes of a perfect sixfold symmetric core and cladding structure are not birefringent.[69] In practice, however, the large glass-air index difference means that even slight accidental distortions in the structure yield a degree of birefringence. Therefore, if the core is deliberately distorted so as to become twofold symmetric, extremely high values of birefringence can be achieved. For example, by introducing capillaries with different wall thicknesses above and below a solid glass core (Figs. 1*c* and 2*g*), values of birefringence some 10 times larger than in conventional fibers can be obtained.[70] It is even possible to design and fabricate strictly single-polarization PCFs in which only one polarization state is guided.[71] By filling selected holes with a polymer, the birefringence can be thermally tuned.[72] Hollow-core PCF with moderate levels of birefringence ($\sim 10^{-4}$) can be realized either by forming an elliptical core or by adjusting the structural design of the core surround.[73,74]

Experiments show that the birefringence in PCF is some 100 times less sensitive to temperature variations than in conventional fibers, which is important in many applications.[75–77] This is because traditional "polarization maintaining" fibers (bow-tie, elliptical core, or Panda) contain at least two different glasses, each with a different thermal expansion coefficient. In such structures, the resulting temperature-dependent stresses make the birefringence a strong function of temperature.

Group Velocity Dispersion

Group velocity dispersion (GVD)—which causes different frequencies of light to travel at different group velocities—is a factor crucial in the design of telecommunications systems and in all kinds of nonlinear optical experiments. PCF offers greatly enhanced control of the magnitude and sign of the GVD as a function of wavelength. In many ways this represents an even greater opportunity than a mere enhancement of the effective nonlinear coefficient.

Solid Core As the optical frequency increases, the GVD in SMF changes sign from anomalous ($D>0$) to normal ($D<0$) at approximately 1.3 μm. In solid-core PCF as the holes get larger, the core becomes more and more isolated, until it resembles an isolated strand of silica glass (Fig. 15). If the whole structure is made very small (core diameters <1 μm have been made) the zero dispersion point of the fundamental guided mode can be shifted to wavelengths in the visible.[9,18] For example, the PCF in Fig. 1*f* has a dispersion zero at 560 nm.

By careful design, the wavelength dependence of the GVD can also be reduced in PCFs at much lower air-filling fractions. Figure 16 shows the flattened GVD profiles of three PCFs with cores several μm in diameter.[78,79] These fibers operate in the regime where SMF is multimoded. Although the fundamental modes in both SMF and PCF have similar dispersion profiles, the presence of higher-order modes (not guided in the PCF, which is endlessly single mode) makes the use of SMF impractical.

A further degree of freedom in GVD design may be gained by working with multicomponent glasses, such as Schott SF6, where the intrinsic zero dispersion point occurs at approximately 1.8 μm.[8] In highly nonlinear small-core PCF, this shifts the whole dispersion landscape to longer wavelengths than in a silica-based PCF with the same core size and geometry.

Hollow Core Hollow-core fiber behaves in many respects rather like a circular-cylindrical hollow metal waveguide, which has anomalous dispersion (the group velocity increases as the frequency rises). The main difference, however, is that the dispersion changes sign at the high frequency edge, owing to the approach of the photonic band edge and the weakening of the confinement (Fig. 17).[80]

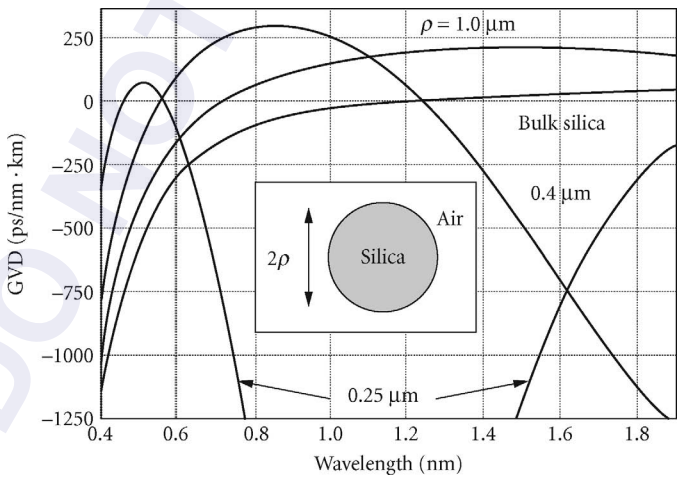

FIGURE 15 The calculated group velocity dispersion of three circular strands of silica glass, radii 0.25, 0.4, and 1.0 μm, compared with the dispersion of bulk glass. The narrower strands have two dispersion zeros within the transparency window of silica.

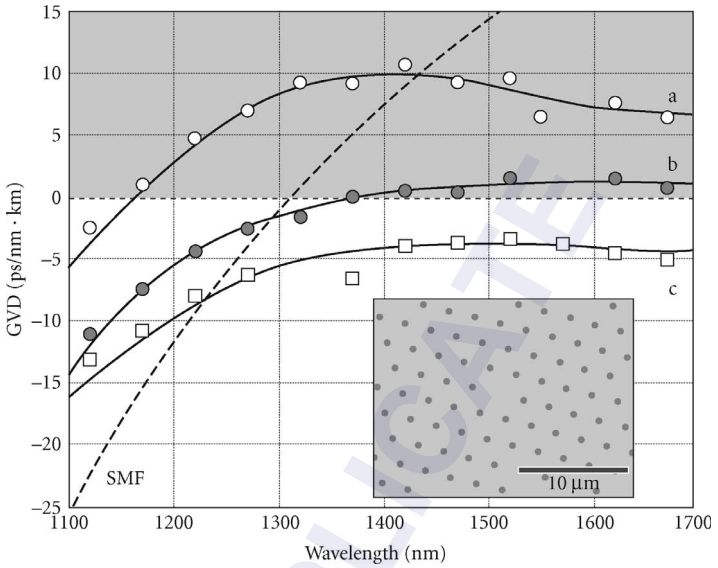

FIGURE 16 Group velocity dispersion profiles, against wavelength, for three different PCFs designed to have lowlevel ultraflattened GVD.[78,79] The curve for Corning SMF-28 is included for comparison.

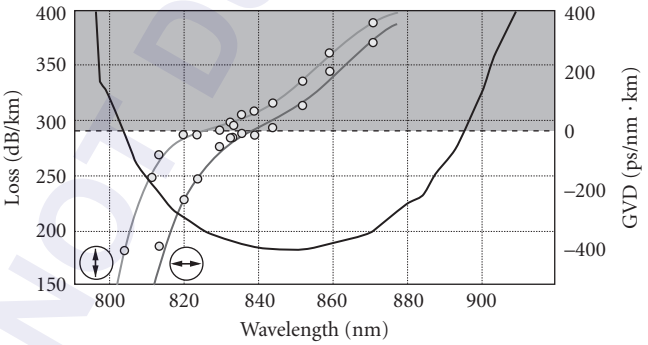

FIGURE 17 Measured attenuation and GVD spectra for a hollow-core PCF designed for 850 nm transmission.[80] The core is slightly elliptical, so the dispersion in each eigenstate of polarization is different.

Attenuation Mechanisms

An advantage common to all fibers is the very large extension ratio from preform to fiber, which has the effect of smoothing out imperfections, resulting in a transverse structure that is extremely invariant with distance along the fiber. This is the chief reason for the ultralow attenuation displayed by fibers, compared to other waveguide structures. In PCF the losses are governed by two main parameters: the fraction of light in glass and the roughness at the glass-air interfaces. The light-in-glass fraction can be controlled by judicious design, and ranges from close to 100 percent in solid core fibers to less than 1 percent in the best hollow-core fibers.

Absorption and Scattering The best reported loss in solid-core PCF, from a group in Japan, stands at 0.28 dB/km at 1550 nm, with a Rayleigh scattering coefficient of 0.85 $dB \cdot km^{-1} \cdot \mu m^{-4}$. A 100 km length of this fiber was used in the first PCF-based penalty-free dispersion-managed soliton transmission system at 10 Gb/s.[81,82] The slightly higher attenuation compared to SMF is due to roughness at the glass-air interfaces.[61]

It is hollow-core PCF, however, that has the greatest potential for extremely low loss, since the light is traveling predominantly in empty (or gas-filled) space. Although the best reported attenuation in hollow-core PCF stands at 1.2 dB/km,[58] values below 0.2 dB/km or even lower seem feasible with further development of the technology. The prospect of improving on conventional fiber, at the same time greatly reducing the nonlinearities associated with a solid glass core, is intriguing. By using infrared glasses, transmission can be extended into the infrared[83] and recent work shows that silica hollow-core PCF can even be used with acceptable levels of loss in the mid-IR,[84] owing to the very low overlap between the optical field and the glass.

In the latest hollow-core silica PCF, with loss levels approaching 1 dB/km at 1550 nm, very small effects can contribute significantly to the attenuation floor. The ultimate loss limit in such fibers is determined by surface roughness caused by thermally driven capillary waves, which are present at all length scales. These interface ripples freeze in when the fiber cools, introducing high scattering losses for modes that are concentrated at the interfaces, such as surface modes guided on the edge of the core. The pure core mode does not itself "feel" the ripples very strongly, except at anticrossing wavelengths where it becomes phase-matched to surface modes, causing light to move to the surface and experience enhanced scattering.

The result is a transmission spectrum consisting of windows of high transparency punctuated with bands of high attenuation (Fig. 18). This picture has been confirmed by measurements of the surface roughness in hollow-core PCFs, the angular distribution of the power scattered out of the core, and the wavelength dependence of the minimum loss of fibers drawn to different scales.[58] The thin glass shell surrounding the hollow core can be designed to be antiresonant with the core mode, permitting further exclusion of light from the glass.[85]

Ignoring material dispersion, the whole transmission landscape shifts linearly in wavelength in proportion to the overall size of the structure (a consequence of Maxwell's equations). This means

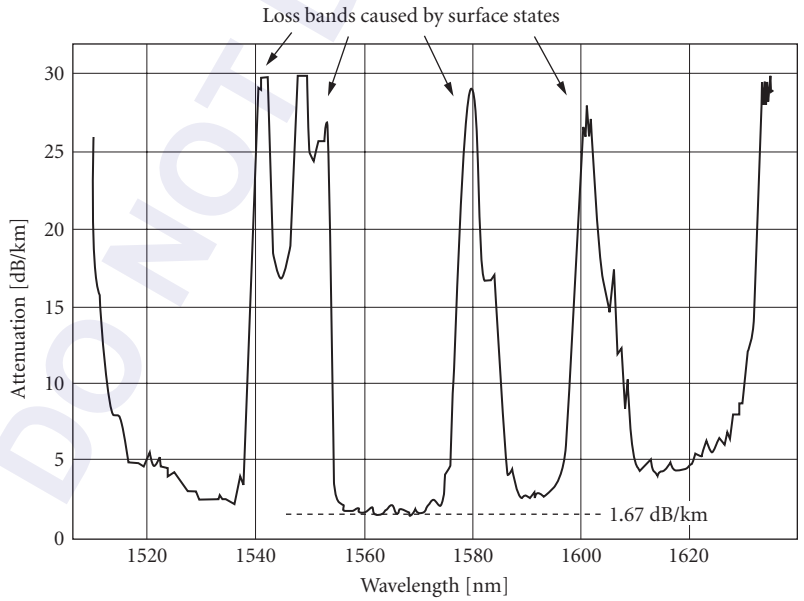

FIGURE 18 Attenuation spectrum of a typical ultralow loss hollow-core PCF designed for operation in the 1550 nm telecommunications band (see micrographs in Fig. 10).

that the smallest loss at a given wavelength will be obtained by drawing a fiber to a particular diameter. The optical overlap with the surface roughness scales inversely with the size with the fiber, and the scattering itself may be regarded as being governed by the density of states into which scattering can occur, which in three-dimensions scales as λ^{-2}. Thus the wavelength of minimum loss scales as λ^{-3}, in contrast to the λ^{-4} dependence of Rayleigh scattering in bulk glass.

Bend Loss Conventional fibers suffer additional loss if bent beyond a certain critical radius R_c, which depends on wavelength, core-cladding refractive index step and—most notably—the third power of core radius ρ.[3,39] For wavelengths longer than a certain value (the "long wavelength bend edge") all guidance is effectively lost.

A starting point for understanding bend loss in solid core ESM-PCF (perhaps the most interesting case) is the long wavelength limit. ESM behavior occurs when $d/\Lambda < 0.43$, which sets the highest air-filling fraction at 16.8 percent and yields an area-averaged cladding refractive index of 1.388 (silica index of 1.444)—valid in the limit $k \to 0$. This index step is some 10 times higher than in Corning SMF-28, making ESM-PCF relatively much less susceptible to bend loss at long wavelengths. For a step-index fiber with a Ge-doped core, 40 mol % of GeO_2 would be needed to reach the same index step (assuming 0.0014 index change per mol % GeO_2).[11] The result is that the long-wavelength bend edge in ESM-PCF is in the infrared beyond the transparency window of silica glass, even when the core radius is large.[86]

ESM-PCF also exhibits a *short* wavelength bend edge, caused by bend-induced coupling from the fundamental to higher-order modes, which of course leak out of the core.[16] The critical bend radius for this loss varies as

$$R_c \sim \Lambda^3/\lambda^2 \tag{10}$$

compared to R_c approximately λ for SMF. The reciprocal dependence on λ^2 makes it inevitable that a short-wavelength bend edge will appear in ESM-PCF. Following[86] in taking the pre-factor in Eq. (10) as unity, R_c can be plotted against wavelength for different values of core radius (≈ interhole spacing). This is illustrated in Fig. 19. A step-index fiber, with the same core-cladding index step as

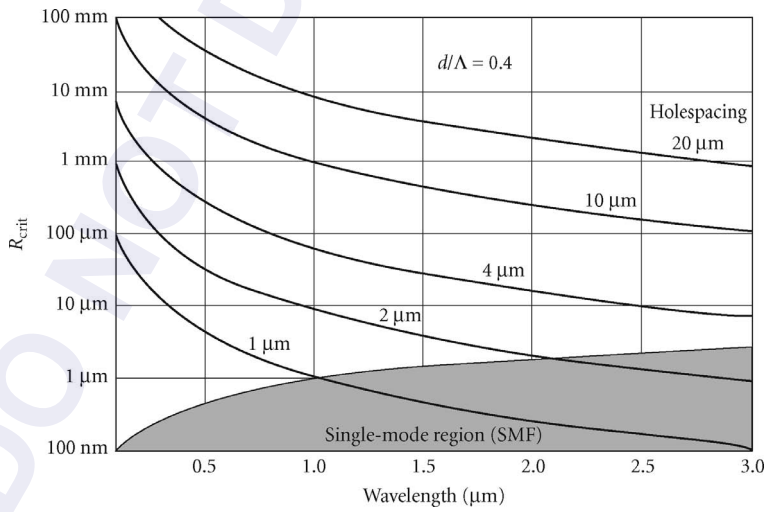

FIGURE 19 Short-wavelength critical bend radii for ESM-PCF with $d/\Lambda = 0.4$ plotted against vacuum wavelength for different values of hole-spacing (approximately equal to the core radius). As the wavelength increases at constant core size, a step-index fiber with the same core:cladding index as the PCF in the long-wavelength limit [1.444:1.388 using Eq. (5)] becomes single-mode when the curves enter the shaded region. The step-index fiber is multimode over wide parameter ranges where ESM-PCF has negligible short-wavelength bend loss.

ESM-PCF in the long wavelength limit, is multimode over wide parameter ranges where ESM-PCF has negligible bend loss.

In contrast, hollow-core PCF is experimentally very insensitive to bend loss—in many cases no appreciable drop in transmission is observed until the fiber breaks. This is because the effective depth of "potential well" for the guided light (see section "Negative Core-Cladding Index Difference"), given by the distance $\Delta\beta$ between the edges of the photonic bandgap, is substantially larger than in SMF.

Confinement Loss The photonic crystal cladding in a realistic PCF is of course finite in extent. For a guided mode, the Bloch waves in the cladding are evanescent, just like the evanescent plane waves in the cladding of a conventional fiber. If the cladding is not thick enough, the evanescent field amplitudes at the cladding/coating boundary can be substantial, causing attenuation. In the solid core case for small values of d/Λ the resulting loss can be large unless a sufficiently large number of periods is used.[78]

Very similar losses are observed in hollow-core fibers, where the "strength" of the photonic bandgap (closely related to its width in β) determines how many periods are needed to reduce confinement loss to acceptable levels. Numerical modeling is useful for giving an indication of how many periods are needed to reach a required loss level. The cladding field intensity in the ultralow loss PCF reported in[58] falls by approximately 9 dB per period, reaching −63 dB at the edge of the photonic crystal region.

11.8 NONLINEAR CHARACTERISTICS OF GUIDANCE

The ability to enhance or reduce the effective nonlinear coefficients, and at the same time control the magnitude and wavelength dependence of the GVD, makes PCF a versatile vehicle for studies of nonlinear effects.

Kerr Nonlinearities

The optical Kerr effect drives effects such as four-wave mixing, self-phase modulation, modulation instability, and soliton formation. To take account of the differing proportions of light in glass and air,[87] it is necessary to derive an expression for the effective nonlinear γ coefficient, which in the scalar approximation takes the form

$$\gamma = \frac{k\iint n(x,y)n_2(x,y)\psi^4(x,y)dxdy}{n_m\left(\iint \psi^2(x,y)dxdy\right)^2} \quad \mathrm{W^{-1}m^{-1}} \tag{11}$$

where ψ is the transverse field amplitude profile, $n(x,y)$ and $n_2(x,y)$ are the linear and nonlinear refractive index profiles, and n_m is the modal phase index. The integrals must be evaluated over the entire transverse plane, which in practice means over the area where the field amplitudes are nonnegligible. Equation (11) can be reexpressed for a composite PCF made from two or more homogeneous materials

$$\gamma = k\sum_i \frac{n_2^i}{A_i} \tag{12}$$

where n_2^i is the nonlinear refractive index of material i and A_i its nonlinear effective area

$$A_i = \frac{n_m\left(\iint \psi^2(x,y)dxdy\right)^2}{\iint u_i(x,y)\psi^4(x,y)dxdy} \tag{13}$$

where $u_i(x,y)$ equals n_i in regions made from material i and zero elsewhere.

The nonlinear refractive indices of silica glass and air are, respectively, 2.5×10^{-20} m^2W^{-1} and 2.9×10^{-23} m^2W^{-1}. Multicomponent glasses typically have values an order of magnitude or more higher, and the hollow channels can of course be filled with another gas with a different nonlinear coefficient.

The highest nonlinear coefficient available in conventional step-index fibers is γ: 20 $W^{-1}km^{-1}$ at 1550 nm.[88] By comparison, a solid-core PCF similar to the one in Fig. 1*f* but with a core diameter 1 μm has a nonlinearity of γ: 240 $W^{-1}km^{-1}$, at 850 nm, and values as high as $\gamma = 550$ $W^{-1}km^{-1}$ at 1550 nm have been measured for PCFs made from multicomponent glasses.[89] In complete contrast, hollow-core PCF has extremely low levels of nonlinearity, owing to the small overlap between the glass and the light. In a recent example, a fiber was reported with a nonlinear coefficient $\gamma = 0.023$ $W^{-1}km^{-1}$ (some $10^4\times$ smaller than in a typical highly nonlinear solid-core PCF).[90,91]

Although the level of nonlinearity is clearly important, the actual nonlinear effects that appear in a particular case are also strongly dependent on the magnitude, sign and wavelength dependence of the GVD as well as on the characteristics of the pump laser.[92] They are determined by the relative values of the nonlinear length $L_{nl} = \gamma^{-1}P_0^{-1}$, where P_0 is the peak power, the dispersion length $L_D = \tau^2/|\beta_2|$, where τ is the pulse duration and the effective fiber length $L_{eff} = [1 - \exp(-\alpha L)]/\alpha$ where α m^{-1} is the power attenuation coefficient.[93] For a solid-core PCF with γ: 240 $W^{-1}km^{-1}$, a peak power of 10 kW yields $L_{nl} < 0.5$ mm. For typical values of loss (usually between 1 and 100 dB/km) $L_{eff} >> L_{nl}$ and the nonlinearity dominates. For dispersion values in the range $-300 < \beta_2 < 300$ ps^2/km and pulse durations $\tau = 200$ fs, $L_D > 0.1$ m. Since both these lengths are much longer than the nonlinear length, it is easy to observe strong nonlinear effects.

Supercontinuum Generation One of the most successful applications of nonlinear PCF is to supercontinuum (SC) generation from ps and fs laser pulses. When high power pulses travel through a material, their frequency spectrum can be broadened by a range of interconnected nonlinear effects.[94] In bulk materials, the preferred pump laser is a regeneratively amplified Ti:sapphire system producing high (mJ) energy fs pulses at 800 nm wavelength and kHz repetition rate. Supercontinua have also previously been generated in SMF by pumping at 1064 or 1330 nm,[95] the spectrum broadening out to longer wavelengths mainly due to stimulated Raman scattering (SRS). Then in 2000, it was observed that highly nonlinear PCF, designed with zero GVD close to 800 nm, massively broadens the spectrum of low (few nJ) energy unamplified Ti:sapphire pulses launched into just a few cm of fiber.[21,96,97] Removal of the need for a power amplifier, the hugely increased (~100 MHz) repetition rate, and the spatial and temporal coherence of the light emerging from the core, makes this source unique. The broadening extends both to higher and to lower frequencies because four-wave mixing operates more efficiently than SRS when the dispersion profile is appropriately designed. This SC source has applications in optical coherence tomography,[98,99] frequency metrology,[100,101] and all kinds of spectroscopy. It is particularly useful as a bright lowcoherence source in measurements of group delay dispersion based on a Mach-Zehnder interferometer.

A comparison of the bandwidth and spectrum available from different broad-band light sources is shown in Fig. 20; the advantages of PCF-based SC sources are evident. Supercontinua have been generated in different PCFs at 532 nm,[102] 647 nm,[103] 1064 nm,[104] and 1550 nm.[8] Using inexpensive microchip lasers at 1064 or 532 nm with an appropriately designed PCF, compact SC sources are now available with important applications across many areas of science. A commercial ESM-PCF based source uses a 10-W fiber laser delivering 5 ps pulses at 50 MHz repetition rate, and produces an average spectral power density of approximately 4.5 mW/nm in the range 450 to 800 nm.[105] The use of multicomponent glasses such as Schott SF6 or tellurite glass allows the balance of nonlinearity and dispersion to be adjusted, as well as offering extended transparency into the infrared.[106]

Parametric Amplifiers and Oscillators In step-index fibers the performance of optical parametric oscillators and amplifiers is severely constrained owing to the limited scope for GVD engineering. In PCF these constraints are lifted, permitting flattening of the dispersion profile and control of higher-order dispersion terms. The wide range of experimentally available group-velocity dispersion profiles has, for example, allowed studies of ultrashort pulse propagation in the 1550 nm wavelength band with flattened dispersion.[78,79] The effects of higher-order dispersion in such PCFs are subtle.[107,108] Parametric devices have been designed for pumping at 647, 1064, and 1550 nm, the small

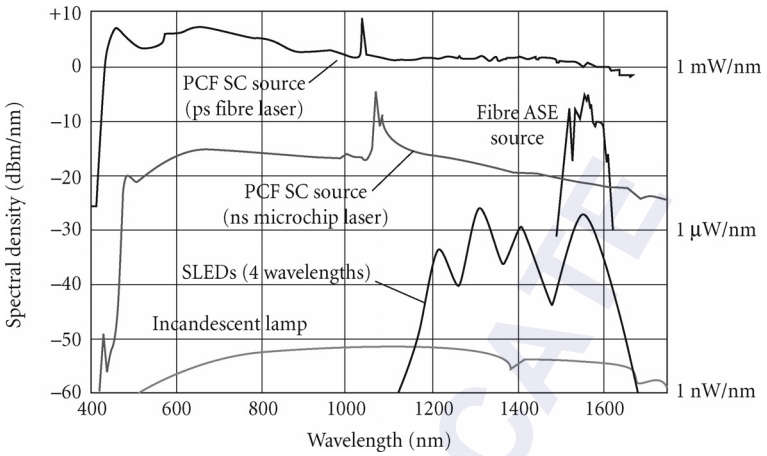

FIGURE 20 Comparison of the brightness of various broad-band light sources (SLED—superluminescent light-emitting diode; ASE—amplified spontaneous emission; SC—supercontinuum). The microchip laser SC spectrum was obtained by pumping at 1064 nm with 600 ps pulses. (*Updated version of a plot by Hendrik Sabert.*)

effective mode areas offering high gain for a given pump intensity, and PCF-based oscillators synchronously pumped by fs and ps pump pulses have been demonstrated at relatively low power levels.[109–112] Dispersion-engineered PCF is being successfully used in the production of bright sources of correlated photon pairs, by allowing the signal and idler side-bands to lie well outside the noisy Raman band of the glass. In a recent example, a PCF with zero dispersion at 715 nm was pumped by a Ti:sapphire laser at 708 nm (normal dispersion).[113] Under these conditions phase-matching is satisfied by signal and idler waves at 587 and 897 nm, and 10 million photon pairs per second were generated and delivered via single-mode fiber to Si avalanche detectors, producing approximately 3.2×10^5 coincidences per second for a pump power of 0.5 mW. These results point the way to practical and efficient sources entangled photon pairs that can be used as building blocks in future multiphoton interference experiments.

Soliton Self-Frequency Shift Cancellation The ability to create PCFs with negative dispersion slope at the zero dispersion wavelength (in SMF the slope is positive, i.e., the dispersion becomes more anomalous as the wavelength increases) has made it possible to observe Čerenkov-like effects in which solitons (which form on the anomalous side of the dispersion zero) shed power into dispersive radiation at longer wavelengths on the normal side of the dispersion zero. This occurs because higher-order dispersion causes the edges of the soliton spectrum to phase-match to linear waves. The result is stabilization of the soliton self-frequency shift, at the cost of gradual loss of soliton energy.[114] The behavior of solitons in the presence of wavelength-dependent dispersion is the subject of many recent studies.[115.]

Raman Scattering

The basic characteristics of glass-related Raman scattering in PCF, both stimulated and spontaneous, do not noticeably differ compared to SMF. One must of course take account of the differing proportions of light in glass and air (see section "Kerr Nonlinearities") to calculate the effective strength of the Raman response. A very small solid glass core allows one to enhance stimulated Raman scattering, whereas in a hollow core it is strongly suppressed.

Brillouin Scattering

The periodic micro/nanostructuring in ultrasmall core glass-air PCF strongly alters the acoustic properties compared to conventional SMF.[116–119] Sound can be guided in the core both as leaky and as tightly confined acoustic modes. In addition, the complex geometry and "hard" boundaries cause coupling between all three displacement components (radial, azimuthal, and axial), with the result that each acoustic mode has elements of both shear (S) or longitudinal (L) strain. This complex acoustic behavior strongly alters the characteristics of forward and backward Brillouin scattering.

Backward Scattering When a solid-core silica-air PCF has a core diameter of around 70 percent of the vacuum wavelength of the launched laser light, and the air-filling fraction in the cladding is very high, the spontaneous Brillouin signal displays multiple bands with Stokes frequency shifts in the 10 GHz range. These peaks are caused by discrete guided acoustic modes, each with different proportions of longitudinal and shear strain, strongly localized to the core.[120] At the same time the threshold power for stimulated Brillouin scattering increases fivefold—a rather unexpected result, since conventionally one would assume that higher intensities yield lower nonlinear threshold powers. This occurs because the effective overlap between the tightly confined acoustic modes and the optical mode is actually smaller than in a conventional fiber core; the sound field contains a large proportion of shear strain, which does not contribute significantly to changes in refractive index. This is of direct practical relevance to parametric amplifiers, which can be pumped 5 times harder before stimulated Brillouin scattering appears.

Forward Scattering The very high air-filling fraction in small-core PCF also permits sound at frequencies of a few GHz to be trapped purely in the transverse plane by phononic bandgap effects (Fig. 21). The ability to confine acoustic energy at zero axial wavevector $\beta_{ac} = 0$ means that the ratio

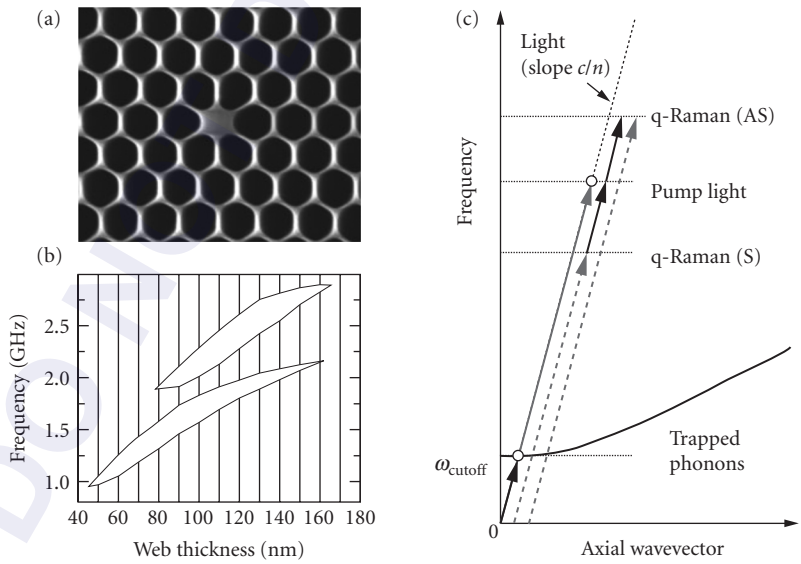

FIGURE 21 (*a*) Example of PCF used in studies of Brillouin scattering (core diameter 1.1 μm); (*b*) the frequencies of full phononic bandgaps (in-plane propagation, pure in-plane motion) in the cladding of the PCF in (*b*); and (*c*) illustrating how a trapped acoustic phonon can phase-match to light at the acoustic cutoff frequency. The result is a quasi-Raman scattering process that is automatically phase-matched. (*After Ref. 121.*)

of frequency ω_{ac} to wavevector β_{ac} becomes arbitrarily large as $\beta_{ac} \to 0$, and thus can easily match the value for the light guided in the fiber, c/n. This permits phase-matched interactions between the acoustic mode and two spatially identical optical modes of different frequency.[121] Under these circumstances the acoustic mode has a well-defined cutoff frequency ω_{cutoff} above which its dispersion curve—plotted on an (ω,β) diagram—is flat, similar to the dispersion curve for optical phonons in diatomic lattices. The result is a scattering process that is Raman-like (i.e., the participating phonons are optical-phonon-like), even though it makes use of acoustic phonons; Brillouin scattering is turned into Raman scattering, power being transferred into an optical mode of the same order, frequency shifted from the pump frequency by the cutoff frequency. Used in stimulated mode, this effect may permit generation of combs of frequencies spaced by approximately 2 GHz at 1550 nm wavelength.

11.9 INTRAFIBER DEVICES, CUTTING, AND JOINING

As PCF becomes more widely used, there is an increasing need for effective cleaves, low loss splices, multiport couplers, intrafiber devices, and mode-area transformers. The air holes provide an opportunity not available in standard fibers: the creation of dramatic morphological changes by altering the hole size by collapse (under surface tension) or inflation (under internal overpressure) when heating to the softening temperature of the glass. Thus, not only can the fiber be stretched locally to reduce its cross-sectional area, but the microstructure can itself be radically altered.

Cleaving and Splicing

PCF cleaves cleanly using standard tools, showing slight end-face distortion only when the core crystal is extremely small (interhole spacing ~1 μm) and the air-filling fraction very high (>50%). Solid glass end-caps can be formed by collapsing the holes (or filling them with sol-gel glass) at the fiber end to form a core-less structure through which light can be launched into the fiber. Solid-core PCF can be fusion-spliced successfully both to itself and to step-index fiber using resistive heating elements (electric-arcs do not allow sufficient control). The two fiber ends are placed in intimate contact and heated to softening point. With careful control, they fuse together without distortion. Provided the mode areas are well matched, splice losses of <0.2 dB can normally be achieved except when the core is extremely small (<~1.5 μm). Fusion splicing hollow-core fiber is feasible when there is a thick solid glass outer sheath (e.g., as depicted in Fig. 10*b*), although very low splice losses can be obtained simply by placing identical fibers end-to-end and clamping them (the index-matching "fluid" for hollow-core PCF is vacuum).

The ability to hermetically splice gas-filled hollow-core PCF to SMF has made it possible to produce in-line gas cells for stimulated Raman scattering in hydrogen and frequency measurement and stabilization (using acetylene). These developments may lead for the first time to practical miniature gas-laser devices that could even be coiled up inside a credit card.[122]

Mode Transformers

In many applications it is important to be able to change the mode area without losing light. This is done traditionally using miniature bulk optics—tiny lenses precisely designed to match to a desired numerical aperture and spot-size. In PCF an equivalent effect can be obtained by scanning a heat source (flame or carbon dioxide laser) along the fiber. This causes the holes to collapse, the degree of collapse depending on the dwell-time of the heat. Drawing the two fiber ends apart at the same time provides additional control. Graded transitions can fairly easily be made—mode diameter reductions as high as 5:1 have been realized with low loss.

Ferrule methods have been developed for making low loss interfaces between conventional single-mode fibers and photonic crystal fibers.[123] Adapted from the fabrication of PCF preforms from stacked tubes and rods, these techniques avoid splicing and are versatile enough to interface to virtually any type of index-guiding silica PCF. They are effective for coupling light into and out of all of the individual cores of a multicore fiber without input or output crosstalk. The technique also creates another opportunity—the use of taper transitions to couple light between a multimode fiber and several single-mode fibers. When the number of single-mode fibers matches the number of spatial modes in the multimode fiber, the transition can have low loss in both directions. This means that the high performance of single-mode fiber devices can be reached in multimode systems, for example a multimode fiber filter with the transmission spectrum of a single-mode fiber Bragg grating,[124] a device that has applications in earth-based astronomy, where the high throughput of a multimode fiber can be retained while unwanted atmospheric emission lines are filtered out.

A further degree of freedom may be gained by pressurizing the holes during the taper process.[125] The resulting hole inflation permits radical changes in the guidance characteristics. It is possible for example to transform a PCF, with a relatively large core and small air-filling fraction, into a PCF with a very small core and a large air-filling fraction, the transitions having very low loss.[126]

Heating and stretching PCF can result in quite remarkable changes in the scale of the micro/nano structures, without significant distortion. Recently a solid-core PCF was reduced 5 times in linear scale, resulting in a core diameter of 500 nm (Fig. 22). This permitted formation of a PCF with a zero dispersion wavelength that matched the 532 nm emission wavelength of a frequency doubled Nd:YAG laser[102] (this is important for supercontinuum generation—as discussed in Sec. 11.8). A further compelling advantage of the tapering approach is that it neatly side-steps the difficulty of launching light into submicron sized cores; light is launched into the entry port (in this case with core diameter 2.5 μm) and adiabatically evolves, with negligible loss, into the mode of the 500 nm core.

In-Fiber Devices

Precise use of heat and pressure induces large changes in the optical characteristics of PCF, giving rise to a whole family of new intrafiber components. Microcouplers can be made in a PCF with two optically isolated cores by collapsing the holes so as to allow the mode fields to expand and

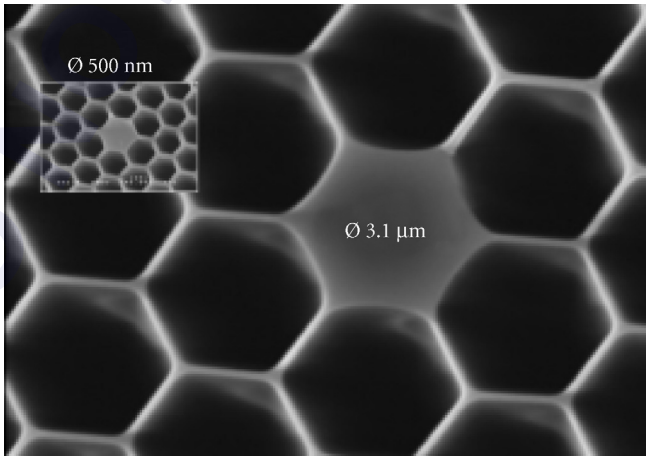

FIGURE 22 Scanning electron micrographs (depicted to the same scale) of the fiber cross sections produced by tapering a solid-core PCF. The structure is very well preserved, even down to core diameters of 500 nm.[102]

interact with each other, creating local coupling.[127] Long period gratings, which scatter the core light into cladding modes within certain wavelength bands, can be made by periodic modulation of hole size.[128] By rocking a birefringent PCF to and fro, while scanning a carbon dioxide laser along it, so-called "rocking filters" can be made, which transfer power from one polarization state to the other within a narrow band of wavelengths.[129] All these components have one great advantage over equivalent devices made in conventional fiber: being formed by permanent changes in morphology, they are highly stable with temperature and over time.

11.10 CONCLUSIONS

In moving away from the constraints of conventional fibers, photonic crystal fibers have created new opportunities spanning many areas of science and technology. Some of the more important from an every widening range of applications (as of late 2006) are discussed in Ref. 1. Compact high brightness supercontinuum sources and frequency comb systems for optical clocks are already available as commercial products. Emerging applications include constrained photochemistry or biochemistry and microfluidics, biophotonic and biomedical devices, medical imaging, astronomy, particle delivery, high power fiber lasers, gas-based fiber devices, and fiber delivery of high power laser light in manufacturing. The next decade should see many of these applications mature into fields of scientific research or even commercial products.

11.11 APPENDIX

The analysis in Ref. 16 to estimate $n_{\max}$ in a triangular lattice of air holes leads to the equation:

$$w\, I_1(a_n w)[J_1(bu)Y_0(a_n u) - J_0(a_n u)Y_1(bu)] + u\, I_0(a_n w)[J_1(bu)Y_1(a_n u) - J_1(a_n u)Y_1(bu)] = 0 \qquad (14)$$

where $a_n = d/2\Lambda$, $b = (\sqrt{3}/2\pi)^{1/2}$ (needed to ensure the correct value of $n_{\max}$ in the long wavelength limit) and $u^2 + w^2 = v^2$. The leading root of Eq. (14), evaluated for $a_n = 0.2$ and $n_g = 1.444$ (i.e., neglecting dispersion), yields the polynomial fit (7).

INFRARED FIBERS

James A. Harrington

Rutgers University

12.1 INTRODUCTION

Infrared (IR) optical fibers may be defined as fiber optics transmitting radiation with wavelengths greater than approximately 2 μm. The first IR fibers were fabricated in the mid-1960s from chalcogenide glasses such as arsenic trisulfide and had losses in excess of 10 dB/m.[1] During the mid-1970s, the interest in developing an efficient and reliable IR fiber for short-haul applications increased, partly in response to the need for a fiber to link broadband, long-wavelength radiation to remote photodetectors in military sensor applications. In addition, there was an ever-increasing need for a flexible fiber delivery system for transmitting CO_2 laser radiation in surgical applications. Around 1975, a variety of IR materials and fibers were developed to meet these needs. These included the heavy metal fluoride glass (HMFG) and polycrystalline fibers as well as hollow rectangular waveguides. While none of these fibers had physical properties even approaching those of conventional silica fibers, they were nevertheless useful in lengths less than 2 to 3 m for a variety of IR sensor and power delivery applications.[2]

IR fiber optics may logically be divided into three broad categories: glass, crystalline, and hollow waveguides. These categories may be further subdivided based on fiber material, structure, or both, as shown in Table 1. Over the past 30 years many novel IR fibers have been made in an effort to fabricate a fiber optic with properties as close as possible to those of silica, but only a relatively small number have survived. A good source of general information on these various IR fiber types may be found in the literature.[2–6] In this review only the best, most viable, and, in most cases, commercially available IR fibers are discussed. In general, both the optical and mechanical properties of IR fibers remain inferior to those of silica fibers, and therefore the use of IR fibers is still limited primarily to nontelecommunication, short-haul applications requiring only tens of meters of fiber rather than the kilometer lengths common to telecommunication applications. The short-haul nature of IR fibers results from the fact that most IR fibers have losses in the range of a few decibels per meter. An exception is fluoride glass fibers, which can have losses as low as a few decibels per kilometer. In addition, IR fibers are much weaker than silica fiber and, therefore, more fragile. These deleterious features have slowed the acceptance of IR fibers and restricted their use today to applications in chemical sensing, thermometry, and laser power delivery.

A key feature of current IR fibers is their ability to transmit longer wavelengths than most oxide glass fibers can. In some cases the transmittance of the fiber can extend well beyond 20 μm, but most applications do not require the delivery of radiation longer than about 12 μm. In Fig. 1 we give the

TABLE 1 Categories of IR Fibers with a Common Example to Illustrate Each Subcategory

Main	Subcategory	Examples
Glass	Heavy metal fluoride (HMFG)	ZrF_4-BaF_2-LaF_3-AlF_3-NAF(ZBLAN)
	Germanate	GeO_2-PbO
	Chalcogenide	As_2S_3 and AsGeTeSe
Crystal	Polycrystalline (PC)	AgBrCl
	Single crystal (SC)	Sapphire
Hollow waveguide	Metal/dielectric film	Hollow glass waveguide
	Refractive index <1	Hollow sapphire at 10.6 μm

attenuation values for some of the most common IR fibers as listed in Table 1. From the data it is clear that there is a wide variation in range of transmission for the different IR fibers and that there is significant extrinsic absorption that degrades the overall optical response. Most of these extrinsic bands can be attributed to various impurities, but, in the case of the hollow waveguides, they are due to interference effects resulting from the thin film coatings used to make the guides.

Some of the other physical properties of IR fibers are listed in Table 2. For comparison, the properties of silica fibers are also listed. The data in Table 2 and in Fig. 1 reveal that, compared to silica, IR fibers usually have higher losses, larger refractive indices and *dn/dT* values, lower melting or softening points, and greater thermal expansion. For example, chalcogenide and polycrystalline Ag halide fibers have refractive indices greater than 2. This means that the Fresnel loss exceeds 20 percent for two fiber ends. The higher *dn/dT* and low melting or softening point lead to thermal lensing and low laser-induced damage thresholds for some of the fibers. Finally, a number of these fibers do not have cladding analogous to clad oxide glass fibers. Nevertheless, core-only IR fibers such as sapphire and chalcogenide fibers can still be useful because their refractive indices are sufficiently high. For these high-index fibers, the energy is largely confined to the core of the fiber as long as the unprotected fiber core does not come in contact with an absorbing medium.[12]

The motivation to develop a viable IR fiber stems from many proposed applications. A summary of the most important current and future applications and the associated candidate IR fiber that will best meet each need is given in Table 3. We may note several trends from this table. The first is that

TABLE 3 Examples of IR Fiber Candidates for Various Sensor and Power Delivery Applications

Application	Comments	Suitable IR fibers
Fiber-optic chemical sensors	Evanescent wave principle—liquids Hollow core waveguides—gases	AgBrCl, sapphire, chalcogenide, HMFG Hollow glass waveguides
Radiometry	Blackbody radiation, temperature measurements	Hollow glass waveguides, AgBrCl, chalcogenide, sapphire
Er:YAG laser power delivery	3-μm transmitting fibers with high damage threshold	Hollow glass waveguides, sapphire, germanate glass
CO_2 laser power delivery	10-μm transmitting fibers with high damage threshold	Hollow glass waveguides
Thermal imaging	Coherent bundles	HMFG, chalcogenide
Fiber amplifiers and lasers	Doped IR glass fibers	HMFG, chalcogenide

hollow waveguides are an ideal candidate for laser power delivery at all IR laser wavelengths. The air core of these special fibers or waveguides gives an inherent advantage over solid-core fibers, whose damage threshold is frequently very low for these IR-transmissive materials. The high refractive index of chalcogenide fibers is ideal for chemical sensing via evanescent wave coupling of a small portion of the light from the core into an IR-absorbing medium. For the measurement of temperature through the simple transmission of blackbody radiation, IR fibers that transmit beyond about 8 μm, such as the Ag halide, chalcogenide, and hollow waveguides, are excellent candidates for use in measuring temperatures below 50°C. This is because the peak for room-temperature blackbody radiation is about 10 μm.

12.2 NONOXIDE AND HEAVY-METAL OXIDE GLASS IR FIBERS

There are two IR-transmitting glass fiber systems that are relatively similar to conventional silica-containing glass fibers. One is the HMFG and the other is heavy-metal germanate glass fibers based on GeO_2. The germanate glass fibers generally do not contain fluoride compounds; instead, they

contain heavy metal oxides to shift the IR absorption edge to longer wavelengths. The advantage of germanate fibers over HMFG fibers is that germanate glass has a higher glass transition temperature and, therefore, higher laser damage thresholds. But the level of loss for the HMFG fibers is lower. Finally, chalcogenide glass fibers made from chalcogen elements such as As, Ge, S, and Te contain no oxides or halides, making them a good choice for nonlaser power delivery applications.

HMFG Fibers

Poulain et al.[13] discovered HMFGs or fluoride glasses accidentally in 1975 at the University of Rennes. In general, the typical fluoride glass has a glass transition temperature T_g four times less than that of silica, is considerably less stable than silica, and has failure strains of only a few percent compared to greater than 5 percent for silica. While an enormous number of multicomponent fluoride glass compositions have been fabricated, comparably few have been drawn into fiber. This is because the temperature range for fiber drawing is normally too small in most HMFGs to permit fiberization of the glass. The most popular HMFGs for fabrication into fibers are the fluorozirconate and fluoroaluminate glasses, of which the most common are ZrF_4-BaF_2-LaF_3-AlF_3-NaF (ZBLAN) and AlF_3-ZrF_4-BaF_2-CaF_2-YF_3, respectively. The key physical properties of these glasses are summarized in Table 4. An important feature of the fluoroaluminate glass is its higher T_g, which largely accounts for the higher laser damage threshold for the fluoroaluminate glasses compared to ZBLAN at the Er:YAG laser wavelength of 2.94 μm.

The fabrication of HMFG fiber is similar to any glass fiber drawing technology except that the preforms are made using some type of melt-forming method rather than by a vapor deposition process as is common with silica fibers. Specifically, a casting method based on first forming a clad glass tube and then adding the molten core glass is used to form either multimode or single-mode fluorozirconate fiber preforms. The cladding tube is made either by a rotational casting technique in which the tube is spun in a metal mold or by merely inverting and pouring out most of the molten cladding glass contained in a metal mold to form a tube.[14] The cladding tube is then filled with a higher-index core glass. Other preform fabrication techniques include rod-in-tube and crucible techniques. The fluoroaluminate fiber preforms have been made using an unusual extrusion technique in which core and cladding glass plates are extruded into a core-clad preform.[15] All methods, however, involve fabrication from the melted glass rather than from the more pristine technique of vapor deposition used to form SiO_2-based fibers. This process creates inherent problems such as the formation of bubbles, core-cladding interface irregularities, and small preform sizes. Most HMFG fiber drawing is done using preforms rather than the crucible method. A ZBLAN preform is drawn at about 310°C in a controlled atmosphere (to minimize contamination by moisture or oxygen impurities, which can significantly weaken the fiber) using a narrow heat zone compared to silica. Either ultraviolet (UV) acrylate or Teflon coatings are applied to the fiber. In the case of Teflon, heat-shrink Teflon (FEP) is generally applied to the glass preform prior to the draw.

The attenuation in HMFG fibers is predicted to be about 10 times less than that for silica fibers.[16] Based on extrapolations of the intrinsic losses resulting from Rayleigh scattering and multiphonon

TABLE 4 Fluorozirconate vs. Fluoroaluminate Glasses

Property	Fluorozirconate (ZBLAN)	Fluoroaluminate (AlF_3-ZrF_4-BaF_2-CaF_2-YF_3)
Glass transition temperature, °C	265	400
Durability	Medium	Excellent
Loss at 2.94 μm, dB/m	0.01	0.1
Er:YAG laser peak output energy, mJ	300 (300-μm core)	850 (500-μm core)

Comparison between fluorozirconate and fluoroaluminate glasses of some key properties that relate to laser power transmission and durability of the two HMFG fibers. Other physical properties are relatively similar.

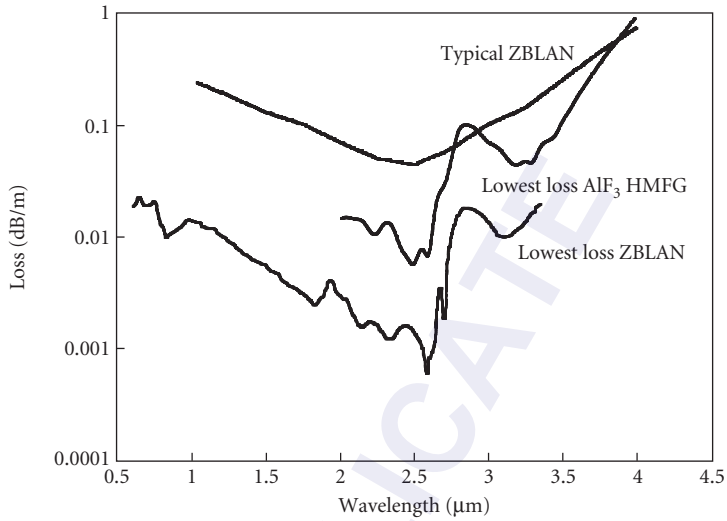

FIGURE 2 Losses in the best BTRL[7] and typical (Infrared Fiber Systems, Silver Spring, Maryland) ZBLAN fluoride glass fibers compared to those for fluoroaluminate glass fibers.[15]

absorption, the minimum in the loss curves or V-curves is projected to be about 0.01 dB/km at 2.55 μm. Recent refinements of the scattering loss have modified this value slightly to be 0.024 dB/km, or about 8 times less than that for silica fiber.[7] In practice, however, extrinsic loss mechanisms still dominate fiber loss. In Fig. 2, losses for two ZBLAN fibers are shown. The data from British Telecom (BTRL) represents state-of-the-art fiber 110 m in length.[7] The other curve is more typical of commercially available (Infrared Fiber Systems, Silver Spring, Maryland) ZBLAN fiber. More recently commercially available fiber (IRphotonics, Montreal, CA) has become available with a loss of 0.02 dB/m at 3 μm.[17] The lowest measured loss for a BTRL 60-m-long fiber is 0.45 dB/km at 2.3 μm. Some of the extrinsic absorption bands that contribute to the total loss shown in Fig. 2 for the BTRL fiber are Ho^{3+} (0.64 and 1.95 μm), Nd^{3+} (0.74 and 0.81 μm), Cu^{2+} (0.97 μm), and OH^- (2.87 μm). Scattering centers such as crystals, oxides, and bubbles have also been found in the HMFG fibers. In their analysis of the data in Fig. 2, the BTRL group separated the total minimum attenuation coefficient (0.65 dB/km at 2.59 μm) into an absorptive loss component equal to 0.3 dB/km and a scattering loss component equal to 0.35 dB/km. The losses for the fluoroaluminate glass fibers are also shown for comparison in Fig. 2.[15] Clearly, the losses are not as low as for the BTRL-ZBLAN fiber, but the $A1F_3$-based fluoride fibers do have the advantage of higher glass transition temperatures and therefore are better candidates for laser power delivery.

The reliability of HMFG fibers depends on protecting the fiber from attack by moisture and on pretreatment of the preform to reduce surface crystallization. In general, the HMFGs are much less durable than oxide glasses. The leach rates for ZBLAN glass range between 10^{-3} and 10^{-2} g/cm^2/day. This is about five orders of magnitude higher than the leach rate for Pyrex glass. The fluoroaluminate glasses are more durable, with leach rates that are more than three times lower than those for the fluorozirconate glasses. The strength of HMFG fibers is less than that of silica fibers. From Table 2 we see that Young's modulus E for fluoride glass is 51 GPa compared to 73 GPa for silica glass. Taking the theoretical strength to be about one-fifth that of Young's modulus gives a theoretical value of strength of 11 GPa for fluoride glass. The largest bending strength measured has been about 1.4 GPa, well below the theoretical value. To estimate the bending radius R, we may use the approximate expression $R = 1.198r(E/\sigma_{max})$, where σ_{max} is the maximum fracture stress and r is the fiber radius.[18]

Germanate Fibers

Heavy metal oxide glass fibers based on GeO_2 have recently shown great promise as an alternative to HMFG fibers for 3-μm laser power delivery.[19] Today, GeO_2-based glass fibers are composed of GeO_2 (30–76 percent)–RO (15–43 percent)-XO (3–20 percent), where R represents an alkaline earth metal and X represents an element of Group IIIA.[20] In addition, small amounts of heavy metal fluorides may be added to the oxide mixture.[21] The oxide-only germanate glasses have glass transition temperatures as high as 680°C, excellent durability, and a relatively high refractive index of 1.84. In Fig. 3, loss data is given for a typical germanate glass fiber. While the losses are not as low as they are for the fluoride glasses shown in Fig. 2, these fibers have an exceptionally high damage threshold at 3 μm. Specifically, over 20 W (2 J at 10 Hz) of Er:YAG laser power has been launched into these fibers.

Chalcogenide Fibers

Chalcogenide glass fibers were drawn into essentially the first IR fiber in the mid-1960s.[1] Chalcogenide fibers fall into three categories: sulfide, selenide, and telluride.[22] One or more chalcogen elements are mixed with one or more elements such as As, Ge, P, Sb, Ga, Al, Si, and so on to form a glass having two or more components. From the data in Table 2 we see that the glasses have low softening temperatures more comparable to those of fluoride glass than to those of oxide glasses. Chalcogenide glasses are very stable, durable, and insensitive to moisture. A distinctive difference between these glasses and the other IR fiber glasses is that they do not transmit well in the visible region and their refractive indices are quite high. Additionally, most of the chalcogenide glasses, except for As_2S_3, have a rather large value of dn/dT.[9] This fact limits the laser power handling capability of the fibers. In general, chalcogenide glass fibers have proven to be an excellent candidate for evanescent wave fiber sensors and for IR fiber image bundles.[23]

Chalcogenide glass is made by combining highly purified (>6 nines purity) raw elements in an ampoule that is heated in a rocking furnace for about 10 hours. After melting and mixing, the glass is quenched and a glass preform is fabricated using rod-in-tube or rotational casting methods. Preform

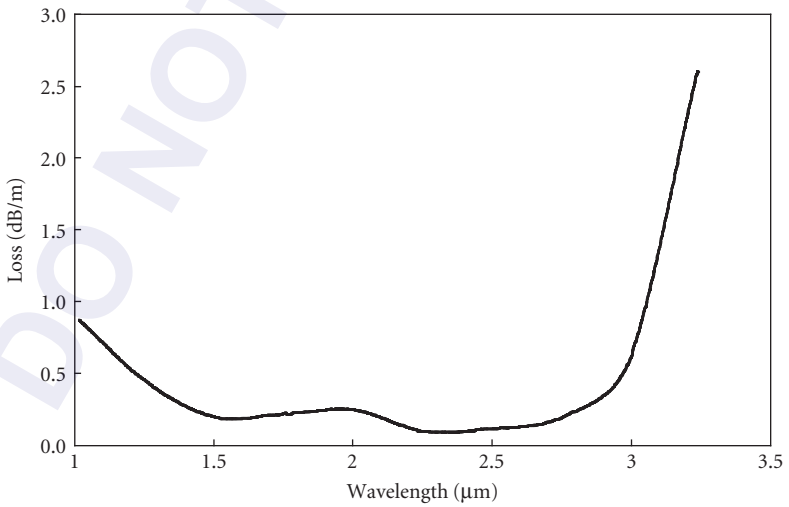

FIGURE 3 Germanate glass fiber manufactured by Infrared Fiber Systems, Silver Spring, Maryland.

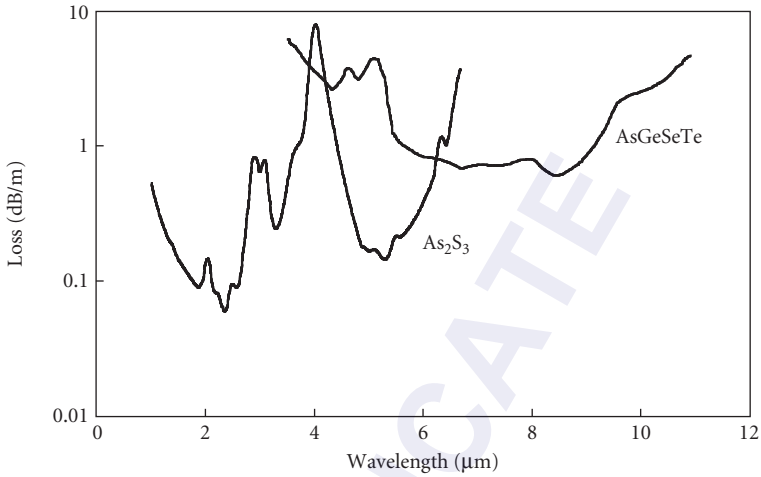

FIGURE 4 Two common chalcogenide glass fibers: As_2S_3 and an AsGeSeTe fiber.[9] Note the many impurity bands pervasive in these fiber systems.

fiber draws involve drawing a core-clad preform or a core-only preform. For the core-only preform draw, either a soft chalcogenide cladding can be extruded over the fiber as it is drawn or the preform can be Teflon clad. Crucible drawing is also possible.

The losses for the most important chalcogenide fibers are given in Fig. 4. Arsenic trisulfide (As_2S_3) fiber, one of the simplest and oldest chalcogenide fibers, has a transmission range from 0.7 to about 6 μm.[22] This fiber is red in color and therefore transmits furthest into the visible region but cuts off in the long-wavelength end well before the heavier chalcogenide fibers.[9] Longer wavelengths are transmitted through the addition of heavier elements like Te, Ge, and Se, as shown in Fig. 4. A key feature of essentially all chalcogenide glasses is the strong extrinsic absorption resulting from the bonding of contaminants such as hydrogen, H_2O, and OH^- to the elemental cations. In particular, absorption peaks between 4.0 and 4.6 μm are due to S-H or Se-H bonds, and those at 2.78 and 6.3 μm are due to OH^- (2.78 μm) and/or molecular water. The hydride impurities are often especially strong and can be deleterious when these fibers are used in chemical sensing applications where the desired chemical signature falls in the region of extrinsic absorption. Another important feature of most of the chalcogenide fibers is that their losses are in general much higher than those of the fluoride glasses. In fact, at the important CO_2 laser wavelength of 10.6 μm, the lowest loss is still above 1 dB/m for the Se-based fibers.[22] More recently single-mode chalcogenide fibers have been drawn from preforms made both using rotational casting and rod-in-tube methods.[24] It is also possible to form a chalcohalide glass which is composed of both chalcogen elements and a halide usually I^-. One example is the TeSeAsI glass which has been drawn into fiber by Lucas' group in Rennes, France.[25]

12.3 CRYSTALLINE FIBERS

Crystalline IR fibers are an attractive alternative to glass IR fibers because most nonoxide crystalline materials can transmit longer-wavelength radiation than IR glasses and, in the case of sapphire, exhibit some superior physical properties as well.[2] The disadvantage is that crystalline fibers are difficult to fabricate. There are two types of crystalline fiber: single-crystal (SC)[8] and polycrystalline (PC).[26,27] Historically, the first crystalline fiber made was hot-extruded KRS-5 fiber fabricated at Hughes Research Labs in 1975,[28] KRS-5 or TIBrI was chosen because it is very ductile and because

it can transmit beyond the 20-μm range required for the intended military surveillance satellite application. In fact, crystalline fibers such as KRS-5 and other halide crystals were initially thought to hold great potential as next-generation ultra-low-loss fibers because their intrinsic loss was predicted to be as low as 10^{-3} dB/m.[28] Unfortunately, this loss was not only never achieved but not even approached experimentally.

PC Fibers

There are many halide crystals that have excellent IR transmission, but only a few have been fabricated into fiber optics. The technique used to make PC fibers is hot extrusion. As a result, only the silver and thallium halides have the requisite physical properties (such as ductility, low melting point, and independent slip systems) to be successfully extruded into fiber. In the hot extrusion process, a single-crystal billet or preform is placed in a heated chamber and the fiber is extruded to net shape through a diamond or tungsten carbide die at a temperature equal to about half the melting point. The final PC fibers are usually from 500 to 900 μm in diameter with no buffer jacket. The polycrystalline structure of the fiber consists of grains on the order of 10 μm or larger in size. The billet may be clad using the rod-in-tube method. In this method, a mixed silver halide such as AgBrCl is used as the core and then a lower-index tube is formed using a Cl^--rich AgBrCl crystal. The extrusion of a core-clad fiber is not as easy to achieve as it is in glass drawing, but Artjushenko et al.[10] at the General Physics Institute (GPI) in Moscow have achieved clad Ag halide fibers with losses nearly as low as those for the core-only Ag halide fiber. Single-mode PC fibers have been extruded from a rod-in-tube preform by Katzir and his group at Tel Aviv University. These fibers have a core diameter of 50 to 60 μm and they are single-mode at 10.6 μm.[29] Today, the PC Ag halide fibers represent the best PC fibers. KRS-5 is no longer a viable candidate due largely to the toxicity of Tl and the greater flexibility of the Ag halide fibers.

The losses for the Ag halide fibers are shown in Fig. 5. Both the core-only and core-clad fibers are shown, and, as with the other IR fibers, we again see that there are several extrinsic absorption bands. Water is often present at 3 and 6.3 μm and there is sometimes an SO_4^- absorption near 9.6 μm. Furthermore, we note the decreasing attenuation as the wavelength increases. This is a result of λ^{-2}

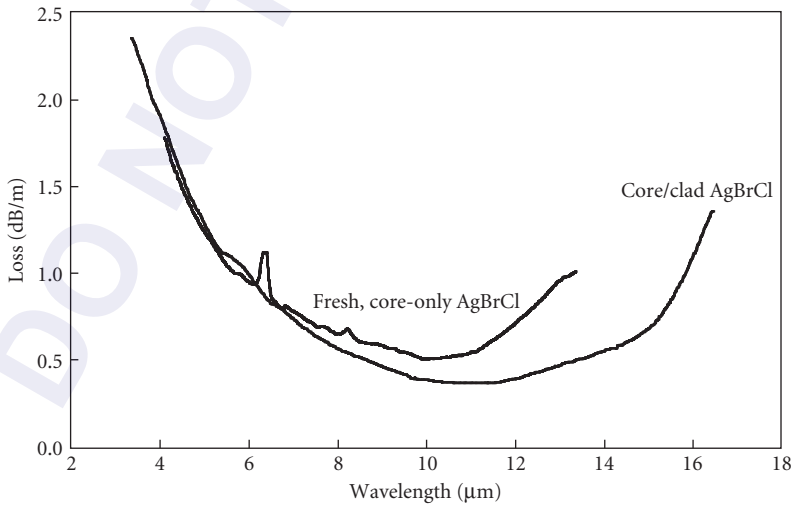

FIGURE 5 Losses in a typical PC silver halide fiber[26] compared to those in recently developed core-clad silver halide fiber.[10]

scattering from strain-induced defects in the extruded fiber. An important feature of the data is that the loss at 10.6 μm can be as low as 0.2 dB/m for the core-only fiber and these fibers will transmit to almost 20 μm. These fibers have been used to transmit about 100 W of CO_2 laser power, but the safe limit seems to be 20 to 25 W.[30] This is due to the low melting point of the fibers.

There are several difficulties in handling and working with PC fibers. One is an unfortunate aging effect in which the fiber transmission is observed to decrease over time.[31] Normally the aging loss, which increases uniformly over the entire IR region, is a result of strain relaxation and possible grain growth as the fiber is stored. Another problem is that Ag halides are photosensitive; exposure to visible or UV radiation creates colloidal Ag, which in turn leads to increased losses in the IR. Finally, AgBrCl is corrosive to many metals. Therefore, the fibers should be packaged in dark jackets and connectorized with materials such as Ti, Au, or ceramics.

The mechanical properties of these ductile fibers are quite different from those of glass fibers. The fibers are weak, with ultimate tensile strengths of about 80 MPa for a 50–50 mixture of AgBrCl. However, the main difference between the PC and glass fibers is that the PC fibers plastically deform well before fracture. This plastic deformation leads to increased loss as a result of increased scattering from separated grain boundaries. Therefore, in use, the fibers should not be bent beyond their yield point; too much bending can lead to permanent damage and a region of high loss in the fiber.

SC Fibers

Meter-long lengths of SC fibers have been made from only a small number of the over 80 IR transmissive crystalline materials. Initially some SC fibers were grown by zone-refining methods from the same metal halides used to extrude PC fibers. The idea was that removal of the grain boundaries in the PC fibers would improve the optical properties of the fiber. This did not occur, so most of the crystalline materials chosen today for SC fiber fabrication have been oxides. Compared to halides, oxide materials like $A1_2O_3$ (sapphire) have the advantage of high melting points, chemical inertness, and the ability to be conveniently melted and grown in air. Currently, sapphire is the most popular SC fiber.[8,32,33]

Sapphire is an insoluble, uniaxial crystal (trigonal structure) with a melting point of over 2000°C. It is an extremely hard and robust material with a usable fiber transmission from about 0.5 to 3.2 μm. Other important physical properties shown in Table 2 include a refractive index equal to 1.75 at 3 μm, a thermal expansion about 10 times higher than that of silica, and a Young's modulus approximately six times greater than that of silica. These properties make sapphire an almost ideal IR fiber candidate for applications less than about 3.2 μm. In particular, this fiber has been used to deliver over 10 W of average power from an Er:YAG laser operating at 2.94 μm.[34]

Sapphire fibers are fabricated using either the edge-defined, film-fed growth (EFG) or the laser-heated pedestal growth (LHPG) techniques.[35] In either method, some or all of the starting sapphire material is melted and an SC fiber is pulled from the melt. In the EFG method, a capillary tube is used to conduct the molten sapphire to a seed fiber, which is drawn slowly into a long fiber. Multiple capillary tubes, which also serve to define the shape and diameter of the fiber, may be placed in one crucible of molten sapphire so that many fibers can be drawn at one time. The LHPG process is a crucibleless technique in which a small molten zone at the tip of an SC sapphire source rod (< 2 mm diameter) is created using a CO_2 laser. A seed fiber slowly pulls the SC fiber as the source rod continuously moves into the molten zone to replenish the molten material. Both SC fiber growth methods are very slow (several millimeters per minute) compared to glass fiber drawing. The EFG method, however, has an advantage over LHPG methods because more than one fiber can be continuously pulled at a time. LHPG methods, however, have produced the cleanest and lowest-loss fibers owing to the fact that no crucible is used that can contaminate the fiber. The sapphire fibers grown by these techniques are unclad, pure $A1_2O_3$ with the *C* axis usually aligned along the fiber axis. Fiber diameters range from 100 to 300 μm and lengths are generally less than 2 m. Postcladding techniques mostly involve a Teflon coating using heat-shrink tubing.

The optical properties of the as-grown sapphire fibers are normally inferior to those of the bulk starting material. This is particularly evident in the visible region and is a result of color-center-type

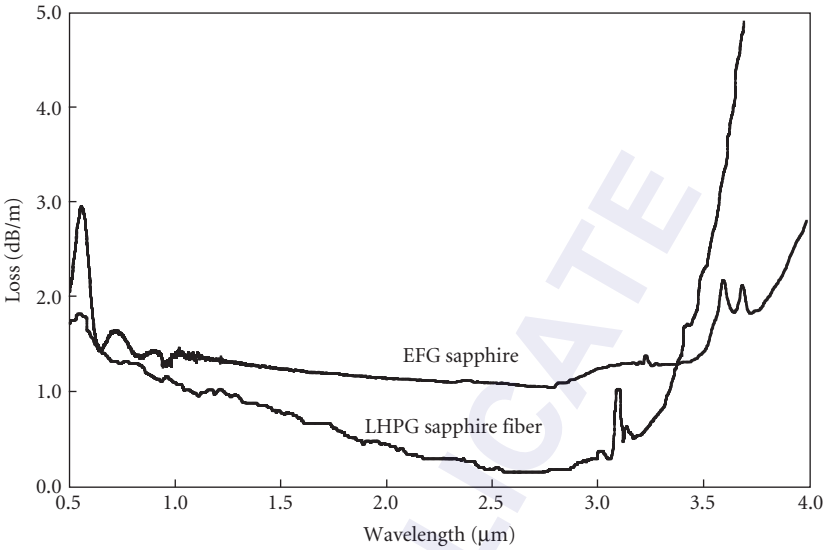

FIGURE 6 SC sapphire fibers grown by the EFG[35] (Saphikon, Inc., Milford, New Hampshire) and LHPG[34] methods.

defect formation during the fiber drawing. These defects and the resulting absorption can be greatly reduced if the fibers are postannealed in air or oxygen at about 1000°C. In Fig. 6, the losses for LHPG fiber grown at Rutgers University[8] and EFG fiber grown by Photran, Inc. (Milford, New Hampshire) are shown. Both fibers have been annealed at l000°C to reduce short-wavelength losses. We see that the LHPG fiber has the lowest overall loss. In particular, LHPG fiber loss at the important Er:YAG laser wavelength of 2.94 μm is less than 0.3 dB/m, compared to the intrinsic value of 0.15 dB/m. There are also several impurity absorptions beyond 3 μm that are believed to be due to transition metals like Ti or Fe. Sapphire fibers have been used at temperatures of up to 1400°C without any change in their transmission.

12.4 HOLLOW WAVEGUIDES

The first optical-frequency hollow waveguides were similar in design to microwave guides. Garmire et al.[36] made a simple rectangular waveguide using aluminum strips spaced 0.5 mm apart by bronze shim stock. Even when the aluminum was not well polished, these guides worked surprisingly well. Losses at 10.6 μm were well below 1 dB/m, and Garmire early demonstrated the high power handling capability of an air-core guide by delivering over 1 kW of CO_2 laser power through this simple structure. These rectangular waveguides, however, never gained much popularity, primarily because their overall dimensions (about 0.5 × 10 mm) were quite large in comparison to circular-cross-section guides and also because the rectangular guides cannot be bent uniformly in any direction. As a result, hollow circular waveguides with diameters of 1 mm or less fabricated using metal, glass, or plastic tubing are the most common guides today. In general, hollow waveguides are an attractive alternative to conventional solid-core IR fibers for laser power delivery because of the inherent advantage of their air core. Hollow waveguides not only enjoy the advantage of high laser power thresholds but also low insertion loss, no end reflection, ruggedness, and small beam divergence. A disadvantage, however, is a loss on bending, which varies as I/R where R is the bending radius.

In addition, the losses for these guides vary as $1/a^3$ where a is the radius of the bore; therefore the loss can be arbitrarily small for a sufficiently large core. The bore size and bending radius dependence of all hollow waveguides are characteristics of these guides not shared by solid-core fibers. Initially these waveguides were developed for medical and industrial applications involving the delivery of CO_2 laser radiation, but more recently they have been used to transmit incoherent light for broadband spectroscopic and radiometric applications.[37–39] Today they are one of the best alternatives for power delivery in IR laser surgery and industrial laser delivery systems, with losses as low as 0.1 dB/m and transmitted CW laser powers as high as 2.7 kW.[40]

Hollow core waveguides may be grouped into two categories: (1) those whose inner core materials have refractive indices greater than 1 (leaky guides) and (2) those whose inner wall materials have refractive indexes less than 1 [attenuated total reflectance (ATR) guides]. Leaky or $n > 1$ guides have metallic and dielectric films deposited on the inside of metallic,[41] plastic,[42] or glass[11] tubing. ATR guides are made from dielectric materials with refractive indices of less than 1 in the wavelength region of interest.[43] Therefore, $n < 1$ guides are fiber-like in that the core index ($n \approx 1$) is greater than the clad index. Hollow sapphire fibers operating at 10.6 μm ($n = 0.67$) are an example of this class of hollow guide.[44]

Hollow Metal and Plastic Waveguides

The earliest circular-cross-section hollow guides were formed using metallic and plastic tubing as the structural members. Miyagi and colleagues in Japan used sputtering methods to deposit Ge,[45] ZnSe, and ZnS[41] coatings on aluminum mandrels. Then a final layer of Ni was electroplated over these coatings before the aluminum mandrel was removed by chemical leaching. The final structure was then a flexible Ni tube with optically thick dielectric layers on the inner wall to enhance the reflectivity in the infrared. Croitoru and colleagues[46] at Tel Aviv University applied Ag followed by AgI coatings on the inside of polyethylene and Teflon tubing to make a very flexible waveguide. Similar Ag and Ag halide coatings were deposited inside Ag tubes by Morrow and colleagues.[47]

Hollow Glass Waveguides

The most popular structure today is the hollow glass waveguide (HGW) developed initially at Rutgers University.[48] The advantage of glass tubing is that it is much smoother than either metal and plastic tubing and, therefore, the scattering losses are less. HGWs are fabricated using wet chemistry methods to first deposit a layer of Ag on the inside of silica glass tubing and then to form a dielectric layer of AgI over the metallic film by converting some of the Ag to Agl. The silica tubing used has a polymer coating of UV acrylate or polyimide on the outside surface to preserve the mechanical strength. The thickness of the AgI is optimized to give high reflectivity at a particular laser wavelength or range of wavelengths. Using these techniques, HGWs have been fabricated with lengths as long as 13 m and bore sizes ranging from 250 to 1300 μm.

The spectral loss for an HGW with a 530-μm bore is given in Fig. 2. This HGW was designed for an optimal response at 10 μm. The peaks at about 3 and 5 μm are not absorption peaks but rather interference bands due to thin-film optical effects. For broadband applications and shorter-wavelength applications, a thinner AgI coating would be used to shift the interference peaks to shorter wavelengths. In fact, for the thinnest Agl films these HGWs not only transmit IR radiation but also shorter wavelengths down to nearly 0.5 μm.[49] For such HGWs the optical response will be nearly flat without interference bands in the far IR fiber region of the spectrum. The data in Fig. 7 shows the straight loss measured using a CO_2 and Er:YAG laser for different bore sizes. An important feature of this data is the $1/a^3$ dependence of loss on bore size predicted by the theory of Marcatili and Schmeltzer.[50] In general, the losses are less than 0.5 dB/m at 10 μm for bore sizes larger than ~400 μm. Furthermore, the data at 10.6 μm agrees well with the calculated values, but at 3 μm the measured losses are somewhat above those predicted by Marcatili and Schmeltzer. This is a result of increased scattering at the shorter wavelengths from the metallic and dielectric films. The bending loss depends

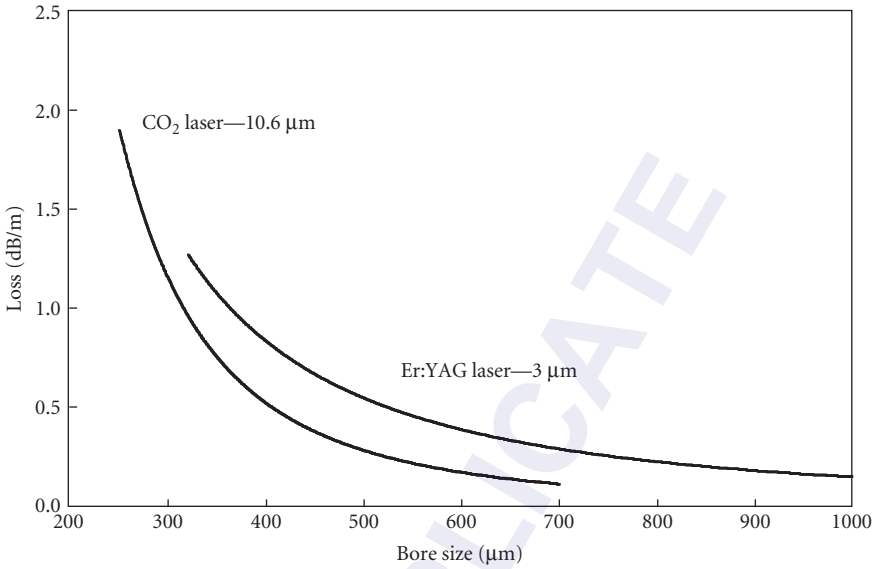

FIGURE 7 Straight losses measured in hollow glass waveguides with Ag/AgI films. The guide labeled "CO_2 laser" was designed for optimal transmission at 10.6 μm while that labeled "Er:YAG laser" was designed for optimal transmission at 3 μm. Note that the loss varies approximately as $1/a^3$.

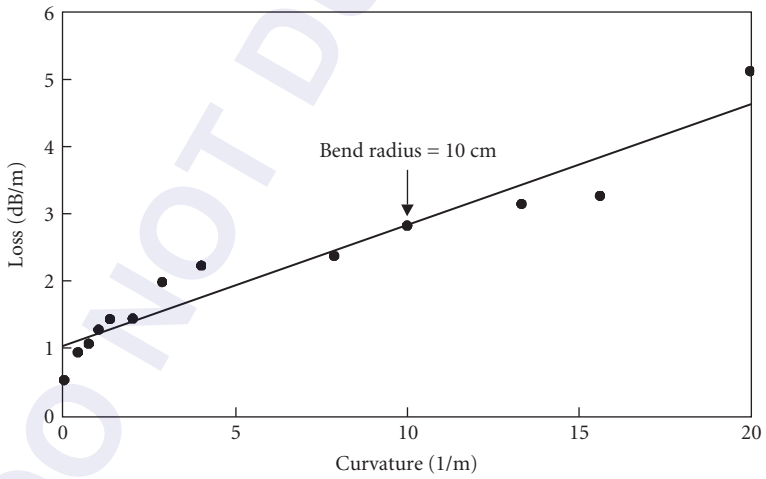

FIGURE 8 Additional loss on bending an HGW with a 530-μm bore, measured at 10.6 μm. The loss is seen to increase as the curvature increases.

on many factors such as the quality of the films, the bore size, and the uniformity of the silica tubing. A typical bending loss curve for an HGW with a 530-μm bore measured with a CO_2 laser is given in Fig. 8. The losses are seen to increase linearly with increasing curvature as predicted. It is important to note that while there is an additional loss on bending for any hollow guide, it does not necessarily mean that this restricts the use of hollow guides in power delivery or sensor applications. Normally

most fiber delivery systems have rather large bend radii and therefore a minimal amount of the guide is under tight bending conditions and the bending loss is low. From the data in Fig. 8 one can calculate the bending loss contribution for an HGW link by assuming some modest bends over a small section of guide length. An additional important feature of hollow waveguides is that they are nearly single mode. This is a result of the strong dependence of loss on the fiber mode parameter. That is, the loss of high-order modes increases as the square of the mode parameter, so even though the guides are very multimode, in practice only the lowest-order modes propagate. This is particularly true for the small-bore (<300 μm) guides, in which virtually only the lowest-order HE_{11} mode is propagated.

HGWs have been used quite successfully in IR laser power delivery and, more recently, in some sensor applications. Modest CO_2 and Er:YAG laser powers below about 80 W can be delivered without difficulty. At higher powers, water-cooling jackets have been placed around the guides to prevent laser damage. The highest CO_2 laser power delivered through a water-cooled hollow metallic waveguide with a bore of 1800 μm was 2700 W, and the highest power through a water-cooled HGW with a 700-μm bore was 1040 W.[51] Sensor applications include gas and temperature measurements. A coiled HGW filled with gas can be used in place of a more complex and costly White cell to provide an effective means for gas analysis. Unlike evanescent wave spectroscopy, in which light is coupled out of a solid-core-only fiber into media in contact with the core, all of the light is passing through the gas in the hollow guide cell, making this a sensitive, quick-response fiber sensor. Temperature measurements may be aided by using an HGW to transmit blackbody radiation from a remote site to an IR detector. Such an arrangement has been used to measure jet engine temperatures.

12.5 SUMMARY AND CONCLUSIONS

During the past 30 years of the development of IR fibers, there has been a great deal of fundamental research designed to produce a fiber with optical and mechanical properties close to those of silica. We can see that today we are still far from that Holy Grail, but some viable IR fibers have emerged that, as a class, can be used to address some of the needs for a fiber that can transmit greater than 2 μm. Yet we are still limited with the current IR fiber technology by high loss and low strength. Nevertheless, more applications are being found for IR fibers as users become aware of their limitations and, more importantly, how to design around their properties.

There are two near-term applications of IR fibers: laser power delivery and sensors. An important future application for these fibers, however, may be more in active fiber systems like the Er- and Pr-doped fluoride fibers and emerging doped chalcogenide fibers. In regards to power delivery fibers, the best choice seems to be hollow waveguides for CO_2 lasers and SC sapphire, germanate glass, or HGWs for Er:YAG laser delivery. Chemical, temperature, and imaging bundles make use mostly of solid-core fibers. Evanescent wave spectroscopy (EWS) using chalcogenide and fluoride fibers is quite successful. A distinct advantage of an IR-fiber EWS sensor is that the signature of the analyte is often very strong in the infrared or fingerprint region of the spectrum. Temperature sensing generally involves the transmission of blackbody radiation. IR fibers can be very advantageous at low temperatures, especially near room temperature, where the peak in the blackbody radiation is near 10 μm. Finally, there is an emerging interest in IR imaging using coherent bundles of IR fibers. Several thousand chalcogenide fibers have been bundled by Amorphous Materials (Garland, Texas) to make an image bundle for the 3- to 10-μm region.

SOURCES, MODULATORS, AND DETECTORS FOR FIBER OPTIC COMMUNICATION SYSTEMS

Elsa Garmire

Dartmouth College
Hanover, New Hampshire

13.1 INTRODUCTION

Optical communication systems utilize fiber optics to transmit the light that carries the signals. Such systems require optoelectronic devices as sources and detectors of such light, and they need modulators to impress the telecommunication signals onto the light. This chapter outlines the basics of these devices. Characteristics of devices designed for both high-performance, high-speed telecommunication systems (*telecom*) and low-cost, more modest performance local area networks (LAN) and data communication systems (*datacom*) are presented. Sources for telecom are edge-emitting laser diodes (LDs), including double heterostructure (DH), quantum well (QW), strained layer (SL), distributed feedback (DFB), and distributed Bragg reflector (DBR) laser diodes. Operating characteristics of these edge-emitting LDs include threshold, light-out versus current-in, spatial, and spectral characteristics. The transient response includes relaxation oscillations, turn-on delay, and modulation response. The noise characteristics are described by relative intensity noise (RIN), signal-to-noise ratio (SNR), mode partition noise (in multimode LDs), and phase noise (which determines linewidth). Frequency chirping broadens the linewidth, described in the small- and large-signal regime; external optical feedback may profoundly disturb the stability of the LDs and may lead to coherence collapse.

Semiconductor lasers usually have a laser cavity in the plane of the semiconductor device, with light emitted out through a cleaved edge in an elliptical output pattern. This output is not ideally suited to coupling into fibers, which have circular apertures. Low-cost systems, such as datacom, put a premium on simplicity in optical design. These systems typically use multimode fibers and surface-emitting, light-emitting diodes (LEDs). The LEDs are less temperature dependent than LDs and are more robust, but they typically are slower and less efficient. Those LEDs applicable to fiber optics are described here, along with their operating and transient response characteristics. Edge-emitting LEDs have some niche fiber-optic applications and are briefly described along with the latest advance in LEDs, which is to incorporate a resonant cavity to narrow both the linewidth and increase the output efficiency that can couple into a fiber.

Vertical cavity surface-emitting lasers (VCSELs) have vertical laser cavities that emit light vertically out of the plane of the semiconductor device. Fibers couple more easily to these surface-emitting sources, but VCSEL performance is usually degraded compared to that of the edge-emitting sources. This chapter outlines typical VCSEL designs (material, optical, and electrical); their spatial, spectral, and

polarization characteristics; and their light-out versus current-in characteristics. The most common VCSELs are based on gallium arsenide, operating from 750 to 980 nm, but longer wavelength VCSELs are becoming more practical with GalnNAs quantum wells on GaAs or five-component InAlGaAsP on indium phosphide (InP).

The most common modulators used in fiber-optic systems today are external lithium niobate modulators. These are usually used in *Y*-branch interferometers, creating intensity modulation as a result of phase modulation by the electro-optic effect. These modulators are introduced in this chapter along with a discussion of high-speed modulation, losses, and polarization dependence, as well as a brief description of optical damage and other modulator geometries. These devices provide chirpfree modulation that can be made very linear for applications such as cable TV.

A recent development in waveguide modulators is the multimode interference (MMI) modulator, based on interference between multiple in-plane spatial modes. This leads to ultra compact modulators, because of much reduced optical path length requirements.

Until recently, lithium niobate was the electro-optic material of choice. Recently polymers have become a viable option for some applications, particularly low-cost. These modulators can be ultra-high-speed and have less insertion loss because of their lower refractive index. Initial challenges of long-term reliability are being met with additional research.

An alternative modulator uses semiconductors, particularly QWs, which allow for more compact devices and monolithic integration. Typically, these are intensity modulators using electroabsorption. By careful design, the chirp in these modulators can be controlled and even used to counteract pulse spreading from chromatic dispersion in fibers. The quantum-confined Stark effect (QCSE) is described, along with the *pin* waveguides used as modulators and techniques for their integration with lasers. Their operating characteristics as intensity modulators, their chirp, and improvements available by using strained QWs are presented.

Some semiconductor modulators use phase change rather than absorption change. The electro-optic effect in III-V semiconductors is discussed, along with the enhanced refractive index change that comes from the QCSE, termed *electrorefraction*. Particularly large refractive index changes occur if available quantum well states are filled by electrons. Phase-change modulators based on this principle can be used in interferometers to yield intensity modulators.

Detectors used in fiber systems are primarily *pin* diodes, although short descriptions of avalanche photodetectors (APDs) and metal-semiconductor-metal (MSM) detectors are provided. The geometry, sensitivity, speed, dark current, and noise characteristics of the most important detectors used in fiber systems are described.

Most of the devices discussed in this chapter are based on semiconductors, and their production relies on the ability to tailor the material to design specifications through *epitaxial growth*. This technology starts with a bulk crystal substrate (usually the binary compounds GaAs or InP) and employs the multilayered growth upon this substrate of a few micrometers of material with a different composition, called a *heterostructure. Ternary* layers substitute a certain fraction x for one of the two binary components.

Thus, $Al_xGa_{1-x}As$ is a common ternary alloy used in laser diodes. Another common ternary is $In_xGa_{1-x}As$. Layers are *lattice-matched* when the ternary layers have the same size lattice as the binary; otherwise, the epitaxial layer will have *strain*. Lattice-matched epitaxial layers require the substituting atom to have approximately the same size as the atom it replaces. This is true of Al and Ga, so that $Al_xGa_{1-x}As$ ternary layers are lattice-matched to GaAs. The lowest-cost lasers are those based on GaAs substrates with $Al_xGa_{1-x}As$ ternary layers surrounding the active layer. These lasers operate at wavelengths near the bandgap of GaAs, about 850 nm, and are typically used in low-cost data communications (as well as in CD players).

The wavelengths required for laser sources in telecommunications applications are those at which the fiber has the lowest loss and/or dispersion, traditionally 1.55 and 1.3 μm. There is no binary semiconductor with a bandgap at these wavelengths, nor is there a lattice-matched ternary. The $In_xGa_{1-x}As$ ternary will be strained under compression when it is grown on either GaAs or InP, because indium is a much bigger atom than gallium, and arsenic is much bigger than phosphorous. The way to eliminate this strain is to use a fourth small atom to reduce the size of the lattice back to that of the binary. This forms a *quaternary*. The heterostructure most useful for fiber optics applications is based on InP substrates.

The quaternary $In_xGa_{1-x}As_yP_{1-y}$ is commonly used, with the compositions x and y chosen to simultaneously provide the desired wavelength and lattice match. These quaternary heterostructures are the basis for much of the long-wavelength technology: sources, modulators, and detectors.

Earlier volumes of this *Handbook* discuss the basics of lasers (Chap. 16, "Lasers," Vol. II), LEDs (Chap. 17, "Light-Emitting Diodes," Vol. II), modulators (Pt. 3, "Modulators," Vol. V), and detectors (Pt. 5, "Detectors," Vol. II). The reader is referred there for general information. This chapter is specific to characteristics that are important for fiber communication systems.

13.2 DOUBLE HETEROSTRUCTURE LASER DIODES

Telecommunication sources are usually edge-emitting lasers, grown with an active laser layer that has a bandgap near either 1.55 or 1.3 μm. The active layer has a quaternary composition consisting of $In_xGa_{1-x}As_yP_{1-y}$, grown lattice-matched to InP. The materials growth and fabrication technology had to be developed specifically for telecommunication applications and is now mature. These LDs are more temperature sensitive than GaAs lasers, and this fact has to be incorporated into their use. For telecom applications they are often attached to a thermoelectric cooler and typically provided with a monitoring photodiode in the laser package in order to provide a signal for temperature and/or current control.

Today's telecom systems use single-mode fibers, which require lasers with a single spatial mode. In order to avoid dispersion over long distances, a single frequency mode is necessary. These requirements constrain the geometry of laser diodes used for telecom applications, as discussed in the next section. Following sections discuss the operating characteristics of these LDs and their transient response and noise characteristics, both as isolated diodes and when subject to small reflections from fiber facets. The modulation characteristics of these diodes are discussed, along with frequency chirping. Advanced laser concepts, such as quantum well lasers, strained layer lasers, and lasers with distributed reflection (DFB and DBR lasers) are also introduced.

A typical geometry of an edge-emitting InGaAsP/InP laser is shown in Fig. 1. The active quaternary laser region is shown cross-hatched. It is from this region that light will be emitted. Light travels back and forth between cleaved mirror facets, confined to the active InGaAsP region by the buried heterostructure, and is emitted out of the cross-hatched region, where it diffracts to the far field. The current is confined to the stripe region by the current-blocking *npn* structure on either side. Traditionally, the active regions have uniform composition and are lattice-matched to the substrate. More advanced laser diodes, often used for telecom applications, have active regions containing one or more quantum wells and may be grown to incorporate internal strain in the active region. Both these characteristics are described in Sec. 13.6.

The design of a double heterostructure laser diode requires optimization of the issues discussed in the following subsections.

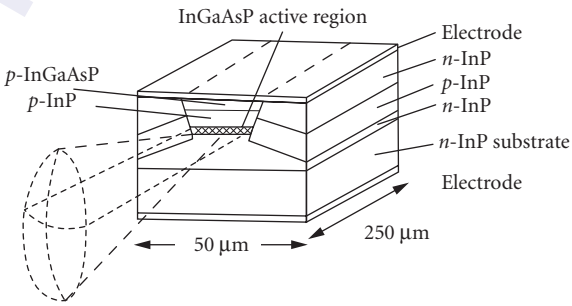

FIGURE 1 Typical geometry for an edge-emitting long-wavelength laser diode, as used in telecommunication systems.

Injection of a Population Inversion into the Active Region

Stimulated emission requires a forward-biased diode, created by sandwiching the active region between *p* and *n* layers. Electrons are injected into the active region from the *n* side and holes are injected from the *p* side; they become *free carriers*. Efficient electrical injection requires high-quality ohmic contacts attached to the *n* and *p* layers; electrical current through the junction then drives the laser.

Confinement of Carriers within the Plane of the Active Layer

Confinement is achieved by growing the *n* and *p* layers on either side of the active region with a larger bandgap, as shown in Fig. 2*a*. In quaternary lasers, wider bandgap material is provided by decreasing *x* and *y* relative to their values in the active region. Stimulated emission during electron-hole recombination in the narrow bandgap active layer provides the laser light. The thinner the active layer, the higher its gain. When the active layer thickness is as small as a few 10s of nanometers, the free electron and hole energy levels become quantized in the growth direction, and the active layer becomes a *quantum well*. Quantum wells have higher gain than bulk semiconductor active layers, and thus one or more QWs are often used as the active layers (see Sec. 13.6).

Confinement of Light Near the Active Layer

Stimulated emission gain is proportional to the product of the carrier and photon densities, so that edge-emitting lasers require the highest possible light intensity. This is done by containing the light in an optical waveguide, with a typical near-field light profile, as shown in Fig. 2*b*. To achieve optical confinement, the layers surrounding the waveguide must have lower refractive indices. It is fortunate that higher-bandgap materials that confine carriers also have smaller refractive index, and so the active layer automatically becomes a waveguide.

Proper optical confinement requires a single waveguide mode. This means that the waveguide layer must be thinner than the cutoff value for higher-order modes. The waveguide thickness d_g must be small enough that

$$d_g k_o \sqrt{n_g^2 - n_c^2} \equiv V < \pi \tag{1}$$

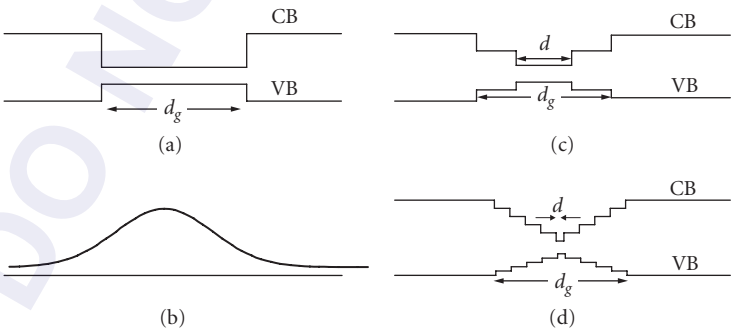

FIGURE 2 Typical diode laser energy band structures and guided mode profile: (*a*) conduction band (CB) and valence band (VB) of double heterostructure; (*b*) corresponding near-field spatial profile for light guided in layer of width d_g; (*c*) separate confinement heterostructure (SCH); and (*d*) graded index separate confinement heterostructure (GRINSCH).

where n_g is the refractive index of the waveguide layer (usually the active layer), n_c is the refractive index of the surrounding cladding (usually the p and n layers), and $k_o = 2\pi/\lambda$, where λ is the free-space wavelength of the laser light. Typically, $n_g - n_c \sim 0.2$ and $d_g < 0.56$ μm for $\lambda = 1.3$ μm. The parameter V is usually introduced to characterize a waveguide.

If the waveguide is too thin, however, the waveguided optical mode spreads out beyond the waveguide layer. The fraction of optical power Γ_g (called the *waveguide confinement factor*) that remains in the waveguide layer of thickness d_g is given approximately by[1]

$$\Gamma_g = \frac{V^2}{V^2 + 2} \tag{2}$$

As d_g becomes small, the confinement factor becomes small. When the carriers are confined in very thin layers, such as in quantum wells, the electrical carrier confinement layer cannot serve as an effective optical waveguide because the confinement factor is too small. Then a thicker waveguide region is used to confine the photons, and the carriers are separately confined in a thinner active region, a geometry called a *separate confinement heterostructure* (SCH), as shown in Fig. 2*c*. In this case the optical confinement factor, defined by the fraction of photons in the active layer of thickness d, is $\Gamma = \Gamma_g(d/d_g)$.

The light can be more effectively focused into a thin active layer by grading the refractive index in the separate confinement region, called a *graded index SCH* (GRINSCH) laser, shown in Fig. 2*d*. This graded refractive index is produced by growing material with varying bandgaps within the waveguide layer. Grading can be achieved by several discrete layers, as shown, or by grading many ultrathin layers with slight compositional differences. In either case, the focusing property of a GRINSCH structure can be approximated by fitting the graded refractive index to a parabolic refractive index profile $n(x)$ such that $n(x)^2 = n_g^2(1 - x^2/x_0^2)$, where x_0 is related to the curvature of the refractive index near $x = 0$: $x_0 = (n_g/n'')^{1/2}$, where $n'' \equiv \partial^2 n/\partial x^2$ near $x = 0$. The mode guided by this profile has a gaussian beam-intensity profile $I(x) = I_o \exp(-x^2/w^2)$, where $w^2 = x_o/k_g$ and $k_g = 2\pi n_g/\lambda$.

Limiting Carrier Injection to Stripe Geometry

Lasers are most efficient when the drive current is limited to the width of the optically active laser area. This requires defining a narrow stripe geometry electrode by means of a window etched in an isolating oxide layer or by ion implantation to render either side of the stripe resistive. More complex laser structures, such as those used in telecommunication applications, often define the conductive stripe electrode by using current-blocking *npn* layers grown on either side of the electrode, as shown in Fig. 1. The *npn* layers, consisting of back-to-back diodes, do not conduct current.

Injected carriers do not usually need lateral confinement, except to achieve the highest possible efficiency. Lateral free-carrier confinement may occur as a by-product of lateral optical confinement, which is discussed next.

Lateral Confinement of Light

The simplest laser diode structures do not specifically confine light laterally, except as the result of the stripe geometry carrier injection. These are called *gain-guided* because high gain in the stripe region, due to the presence of free carriers, introduces a complex refractive index that guides the light laterally. Gain-guided LDs tend to be multimode (both lateral spatial modes and longitudinal frequency modes) unless the stripe is very narrow (<10 μm). In this case, the spatial far-field pattern has "rabbit ears," a double-lobed far-field pattern that is typically not very useful for coupling into single-mode fibers. Thus, gain-guided LDs are not usually used for telecommunications.

High-quality single-mode LDs for telecom applications typically require a real refractive index difference laterally across the laser. The lowest threshold lasers use *buried heterostructure* (BH) lasers, the geometry shown in Fig. 1. After most of the layers are grown, the sample is taken out of the

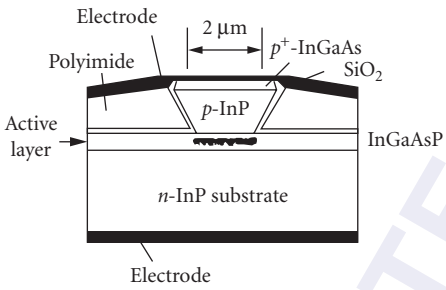

FIGURE 3 Geometry for a ridge waveguide (RWG) laser.

growth chamber and a stripe geometry mesa is etched. Then the sample is returned to the growth chamber, and one or more cladding layers with lower refractive index (higher bandgap) are grown, typically InP, as shown in Fig. 1. When the regrowth is planar, these are called *planar buried heterostructure* (PBH) lasers. The result is a real refractive index guide in the lateral dimension. The width of these *index-guided* laser stripes may be anything from 1 μm to more than 10 μm, depending on the refractive index difference between the active stripe and the lateral cladding material. Equation (1), which specifies the condition for single-mode, applies here, with d_g as the width of the lateral index guide and n_c defined by the regrown material. A typical lateral width for low-threshold BH lasers is 3 μm.

A laser geometry that is much simpler to fabricate and has a higher reliability in production than that of BH lasers is the *ridge waveguide* (RWG) laser, shown in Fig. 3. Light is confined to the region under the *p*-InP etched mesa by strip loading, which increases the effective refractive index in the waveguide region under the etched mesa. The fabrication starts with the growth of a separate confinement heterostructure (sometimes with the addition of a thin etch-stop layer just after the top waveguide layer), followed by a stripe mesa etch down to the waveguide layer, finishing with planarization and contacting to the stripe. The etch leaves a ridge of *p*-cladding material above the waveguide layer, which causes *strip loading*, raising the effective refractive index locally in the stripe region, thereby creating lateral confinement of the light. Although the RWG laser is attractive because it requires only a single epitaxial growth, its threshold current is relatively high.

Retroreflection of Guided Light Along the Stripe

Light is usually reflected back and forth inside the laser cavity by Fresnel reflection from cleaved end facets. Since the waveguide refractive index is $n_g \sim 3.5$, the natural Fresnel reflectivity at an air interface, $R = [(n_g - 1)/(n_g + 1)]^2$, is ~ 0.3. This rather low reflectivity means that LDs are high gain, requiring enough amplification that 70 percent of the light is regenerated on each pass through the active medium.

Relying on Fresnel reflection means that both facets emit light. The light emitted out the back facet may be recovered by depositing a high-reflectivity multilayer coating on the back facet, as is typically done in most telecom lasers. Sometimes a coating is also provided on the front facet to alter its reflectivity, typically to lower it, which increases the output power (as long as the gain is high enough to overcome the large loss upon reflection). The reflectivities must be such that the laser can obey the laser operating condition, which states that in a single round-trip through a laser of length L, the increase in optical power from gain must balance the reduction from finite reflectivity, so that their product is unity. That is,

$$R_1 R_2 \exp(2g_L L) = 1 \tag{3}$$

where R_1 and R_2 are the reflectivities of the two facets and g_L is the *modal gain per unit length* (as experienced by the waveguided laser mode), with a subscript L to represent that the gain is measured with respect to length. If $R_1 = R_2 = 0.3$, then $g_L L = 1.2$. Typical laser diodes have lengths of 400 μm, so $g_L \sim 30\ \text{cm}^{-1}$.

In-plane retroreflection can also be achieved by using distributed feedback created from a grating fabricated on top of the active layer. This method enables the construction of *distributed feedback* (DFB) lasers and *distributed Bragg reflector* (DBR) lasers, which are discussed in Sec. 13.5.

Mounting so that Light Is Edge-Emitted

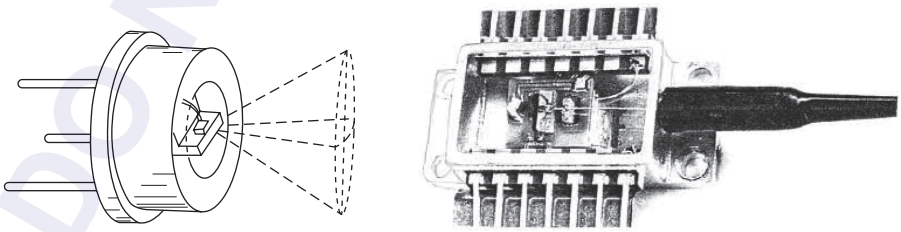
Because the light is emitted out of the facet laterally, there must be a clear optical path for the light as it exits the laser. In many cases, the light is mounted with the active layer down, very close to its copper (or diamond) heat sink, in order to maximize cooling.[2] In this case, the laser chip must be placed at the very edge of the heat-sink block, as shown in Fig. 4*a*.

In some cases, the laser is mounted with its active region up with its substrate next to the heat sink. The edge alignment is not so critical in this case, but of course the laser light will still be emitted in a direction parallel to the plane of the heat sink. Because the thermal conductivity of the heat sink is much higher than that of the substrate, only the lowest threshold lasers, operating at moderate power levels, are operated with the active region up.

Suitable Packaging in Hermetic Enclosure

Water vapor can degrade bare facets of a semiconductor laser when it is operating; therefore, LDs are usually passivated (i.e., their facets are coated with protective layers) and/or they are placed in sealed packages. The LD may be placed in a standard three-pin semiconductor device package, such as a TO-46 can with an optical window replacing the top of the can, as shown in Fig. 4*a*. The LD will be situated near the package window because the light diverges rapidly after it is emitted from the laser facet. The package window should be antireflection coated because any light reflected back into the laser can have serious consequences on the stability of the output (see Sec. 13.5).

Many high-end applications require an on-chip power monitor and/or a controllable thermoelectric cooler. In this case a more complex package will be used, typically a 14-pin "butterfly" package, often aligned to a fiber pigtail, such as shown in Fig. 4*b.* In the less expensive datacom applications, nonhermetic packages may be acceptable with proper capping and passivation of the laser surfaces.



(a) (b)

FIGURE 4 Packaging laser diodes: (*a*) typical hermetically sealed package showing heat sink and emission pattern for a laser diode with its active region placed down on a copper (or diamond) heat sink and (*b*) typical butterfly package, showing laser in the middle, monitoring photodiode (behind), and fiber alignment chuck in front, all mounted on a thermoelectric cooler. (*Photo provided by Spectra-Diode Laboratories.*)

Fiber Pigtail Connection

Because light diverges at a rather large angle as it comes out of an edge-emitting laser (as discussed later), it is often desirable to use a laser provided with a *fiber pigtail*, which is a prealigned length of fiber that can be spliced or connected to the telecom fiber in the field. There will be an inevitable reduction in output power (compared to that of a laser with no pigtail) because of finite coupling efficiency into the pigtail, but the output will be immediately useful in a telecom system. The alternative to a fiber pigtail is the use of a microlens, often a graded index (GRIN) lens, discussed in Chap. 18 in this volume.

Long Life

Early lasers showed degradation with running time, but those problems have been solved, and the LDs used in telecom systems should last hundreds of thousands of hours. However, long life requires that care be taken in their use because large reverse-bias static voltages can break down the *pn* diode. Thus, protection from electrostatic shock while handling and from reflected reverse-bias electrical currents during operation should be maintained. In addition, if LDs are driven with too much forward-bias current, the optical output can be so large that the light may damage the facet out of which it is emitted. Since the threshold is strongly temperature dependent, a laser driven at constant current that becomes too cold can emit too much light, with resulting optical damage. Thus, many telecom lasers have monitoring photodiodes to control the laser output and ensure that it stays within acceptable bounds.

13.3 OPERATING CHARACTERISTICS OF LASER DIODES

The principles of semiconductor laser operation are shown in Chap. 19 in Vol. II of this *Handbook*. A forward-biased *pn* junction injects carriers into the active region. As the drive current increases, the carrier density in the active region increases. This reduces the absorption from an initially high value (at thermal equilibrium the absorption coefficient $\alpha \approx 500$ cm^{-1}) to zero, at which point the active layer becomes transparent at the prospective laser wavelengths. An active layer is characterized by its carrier density at transparency, N_{tr}. Typically, $N_{tr} \approx 10^{18}$ cm^{-3}. Above this carrier density, stimulated emission occurs, with a gain proportional to the diode carrier density above transparency. The gain depends on the detailed device design, taking into account the issues enumerated in the preceding section and the materials involved. The gain is sizeable only in direct-band semiconductors (semiconductors based on the III-V or II-VI columns of the periodic table).

Laser Threshold

Threshold is given by the requirement that the round-trip optical gain due to stimulated emission must equal the round-trip optical loss due to the sum of the transmission out the end facets and any residual distributed loss. Gain occurs only for light that is actually in the active region, and not for the fraction of waveguided light that extends outside the active region. Typically, the *local* gain per unit length G_L is defined as that experienced locally by light inside the active region. (The *modal* gain per unit length is $g_L = \Gamma\, G_L$.) Near transparency, the local gain depends linearly on carrier density N: $G_L = a_L (N - N_{tr})/N_{tr}$, where a_L is the proportionality constant in units of length ($a_L \equiv N\, \partial G_L/\partial N$ near N_{tr}). Assuming G_L is linear in N, an unpumped region ($N = 0$) has $G_L = -a_L$, which is its loss per unit length. Typically, $a_L \sim 250$ cm^{-1}.

The current density (J) is related to the carrier density through $J = eNd/\tau$, where τ is the lifetime of the electron-hole pairs. The transparency current density is 1200 A/cm^2 when $d = 0.15$ μm,

$N_{tr} = 10^{18}$ cm^{-3}, and $\tau = 2$ ns. The threshold condition on gain can be found by taking the natural logarithm of Eq. (3) to obtain $g_{L,th} = G_{L,th}\,\Gamma = \alpha_i + \alpha_m$, where α_m is the mirror reflectivity amortized over length, such that $2\alpha_m L = \ln(1/R_1R_2)$; and α_i represents any internal losses for the laser mode, also amortized over length. Combining these relations, along with the fact that the current I in a LD with stripe width w and length L is $I = JwL$, gives

$$I_{th} = I_{tr} + \frac{ewN_{tr}}{\tau a_L}\left[\frac{1}{2}\ln\left(\frac{1}{R_1R_2}\right) + \alpha_i L\right]d\left(1 + \frac{2}{V^2}\right) \tag{4}$$

where the waveguide V parameter is from Eq. (1) with $d_g = d$. Note that the threshold current is independent of device length L when the internal losses are small. The longer the spontaneous lifetime, the lower the threshold current density (although this may lengthen the turn-on time, as discussed in Sec. 13.4). Finally, as expected by the relation between current and current density, a thinner stripe width w will lower the threshold current (consistent with appropriate spatial output, as discussed later). The current density at transparency N_{tr} is a basic property of the gain curve of the active region. It is smaller for QW lasers (Sec. 13.6) than for thicker active regions.

Because V is linearly proportional to d, there is an optimal active layer thickness, a trade-off between increasing the carrier density as much as possible, but not so much as to lose optical confinement. The optimum thickness for $\lambda = 1.3$-μm LDs is ~0.15 μm, and comparable for $\lambda = 1.55$-μm LDs (0.15 to 0.18 μm). Threshold currents for broad-area DH lasers can be under 500 A/cm^2 at $\lambda = 1.3$ μm and ~1000 A/cm^2 at $\lambda = 1.55$ μm. Confining carriers and light separately can beat this requirement, a trick used in designing QW lasers.

Light Out versus Current In (the L-I Curve)

Below laser threshold only spontaneous emission is observed, which is the regime of the LED, as discussed in Sec. 13.8. In the spontaneous regime, the output varies linearly with input current and is emitted in all directions within the active region. As a result, a negligible amount of light is captured by the single-mode fiber of telecom below threshold.

Above threshold, the electrical power is converted to optical power. In general, the light will come out of both facets, so the amount of light reflected out the front facet depends on the rear facet reflectivity. When a 100 percent reflective mirror is deposited on the back facet, the optical power at photon energy $h\nu$ (wavelength $\lambda = c/\nu$) emitted out the front facet is

$$P_{out} = \frac{h\nu}{e}\frac{\alpha_m}{\alpha_m + \alpha_i}(I - I_{th} - I_L)\,\eta_i \tag{5}$$

where η_i is the *internal quantum efficiency,* which is the fraction of injected carriers that recombine by radiative recombination (usually close to unity in a well-designed semiconductor laser), and I_L is any leakage current. This equation indicates a linear dependence between light out and current above threshold (for constant quantum efficiency). The power out will drop by a factor of 2 if the back facet has a reflectivity equal to that of the front facet, since half the light will leave out the back.

From Eq. (5) can be calculated the *external slope efficiency* of the LD, given by $\partial P_{out}/\partial I$. This allows the *differential quantum efficiency* η_D to be calculated in terms of the power out (both facets):

$$\eta_D \equiv \frac{e}{h\nu}\frac{\partial P_{out}}{\partial I} = \eta_i\frac{\alpha_m}{\alpha_m + \alpha_i} \tag{6}$$

The quantity η_D is also called the *external quantum efficiency*. This efficiency depends on intrinsic loss, possibly due to scattering from roughness in the edges of the waveguide. In long-wavelength lasers, this loss is primarily due to intervalence band absorption.

The *internal* quantum efficiency η_i depends on the way carriers recombine. The rate of carrier loss is the sum of spontaneous processes, expressed in terms of carrier density divided by a lifetime τ_e, and stimulated emission, expressed in terms of local gain per unit time G_T and local photon density P:

$$R(N) = \frac{N}{\tau_e} + G_T(N)P \tag{7}$$

The spontaneous carrier lifetime is given by

$$\frac{1}{\tau_e} = A_{\text{nr}} + BN + CN^2 \tag{8}$$

The term BN is due to spontaneous radiative recombination; its dependence on N results from needing the simultaneous presence of both an electron and hole (which have the same charge densities because of charge neutrality in undoped active regions). The nonradiative recombination terms that decrease the quantum efficiency below unity are a constant term A_{nr} (accounting for all background nonradiative recombination) and an Auger recombination term (with coefficient C) that depends on the square of the carrier density (Auger processes involve several carriers simultaneously). This term is particularly important in long-wavelength lasers where the Auger coefficient C is large.

Stimulated emission is accounted for by gain in the time domain G_T, which depends on N (approximately linearly near threshold). The group velocity v_g converts gain per unit length G_L into a rate G_T (gain per unit time), $G_T \equiv v_g G_L$. We can define a_T in the time domain by $a_T = v_g a_L$ so that $G_T = a_T (N - N_{\text{tr}})/N_{\text{tr}}$.

The *internal* quantum efficiency in a laser is the fraction of the recombination processes that emit light:

$$\eta_i = \frac{BN^2 + G_T(N)P}{A_{\text{nr}}N + BN^2 + CN^3 + G_T(N)P} \tag{9}$$

At high powers in well-designed lasers, the internal quantum efficiency approaches 1.

Figure 5 shows a typical experimental result[3] for the light out of a LD as a function of applied current (the so-called *L-I* curve). It can be seen that the linear relation between light out and current

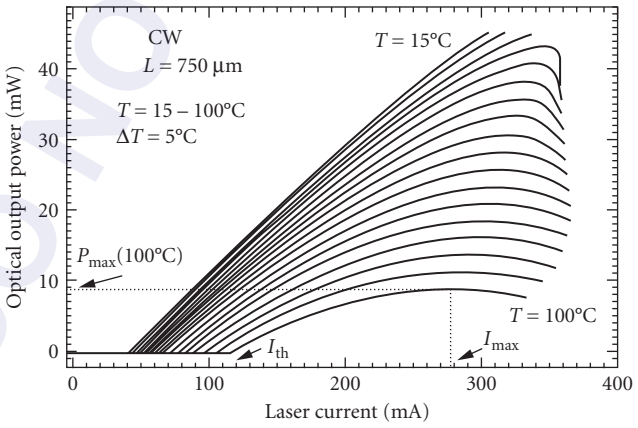


FIGURE 5 Typical experimental result for light out versus current in (the *L-I* curve). These results are for diodes operating at 1.3 μm, consisting of strained layer multiple quantum well InGaAsP lasers measured at a series of elevated temperatures.[3]

saturates as the current becomes large enough, particularly at high temperatures. The decrease in external slope efficiency with increasing current has contributions from the increase in leakage current with injection current, from junction heating that reduces recombination lifetime and increases threshold current, and because the internal absorption increases with injection current.

When there is more than one mode (longitudinal or transverse) in the LD, the *L-I* curve has *kinks* at certain current levels. These are slight abrupt reductions in light out as the current increases. After a kink the external slope efficiency may be different, along with different spatial and spectral features of the laser. These multimode lasers may be acceptable for low-cost communication systems, but high-quality systems require singlemode lasers that do not exhibit such kinks in their *L-I* curves.

Temperature Dependence of Laser Properties

Long-wavelength lasers are typically more sensitive to temperature than are GaAs lasers. This sensitivity is usually expressed as an experimentally measured exponential dependence of threshold on temperature T through $I_{\text{th}}(T) = I_o \exp(T/T_o)$, where T_o is a characteristic temperature (in kelvin) that expresses the measured thermal sensitivity. This formula is valid only over a limited temperature range, because it has no real physical derivation, but it has proved convenient and is often quoted. The data in Fig. 5 correspond to $T_o \approx 80$ K.

The mechanisms for LD sensitivity to temperature depend on the material system. In InP-based long-wavelength DH lasers, T_o is dominated by Auger recombination. However, in short-wavelength GaAs lasers and in strained layer QWs, Auger recombination is suppressed, T_o is higher and is attributed to intervalence band absorption and/or carrier leakage over the heterostructure barrier, depending on the geometry. Typical long-wavelength DH lasers have T_o in the range of 50 to 70 K. Typical strained layer QW lasers have T_o in the range of 70 to 90 K, although higher T_o can be achieved by incorporating aluminum in the barriers, with as high as 143 K reported.[4] This temperature dependence limits the maximum optical power that can be obtained because of the phenomenon of *thermal runaway*, as shown at the highest temperatures in Fig. 5. While increasing the current usually increases the power, the junction temperature also increases (due to ohmic losses), so the threshold may increase and the output power may tend to decrease.

Various means for increasing T_o have been explored; the most effective solution is an active layer of tensile strained QWs (discussed in Sec. 13.6). This has increased T_o from approximately 50 K to as high as 140 K, comparable to that measured in GaAs. In double heterostructures, losses by carrier leakage can be reduced with a dual active region for double carrier confinement, which was demonstrated to achieve T_o values as high as 180 K in 1.3-μm InP lasers.[5]

The temperature dependence of long-wavelength lasers may limit their performance at high temperatures, which in turn limits where they can be used in the field. In practice, many long-wavelength lasers require thermoelectric coolers, particularly at higher power levels.

Spatial Characteristics of Emitted Light

Light is emitted out the facet of the laser diode after it has been waveguided in both directions. It will diverge by diffraction, more strongly in the out-of-plane dimension, where it has been more strongly guided. The diffracting output is sketched in Fig. 1. The spatial characteristics of the output can be estimated by fitting the guided light to a gaussian profile and then calculating the far-field pattern. The *out-of-plane* near-field profile for the lowest-order mode in an optical confinement layer of width d_g has been fit to a gaussian distribution $\exp(-x^2/w^2)$ with[6]

$$w = d_g\left(0.321 + \frac{2.1}{V^{3/2}} + \frac{4}{V^6}\right) \qquad \text{for } 1.8 < V < 6 \tag{10}$$

where V is from Eq. (1). The far-field diffraction angle θ_{ff} has a slightly different gaussian fit, with a half-angle given by $\tan \theta_{ff} = \lambda/\pi w_o$, with[6]

$$w_o = d_g\left(0.31 + \frac{3.15}{V^{3/2}} + \frac{2}{V^6}\right) \qquad \text{for } 1.5 < V < 6 \tag{11}$$

Experimental data can be compared to the gaussian beam formulation by remembering that the full-width half-maximum power FWHM $= w(2 \ln 2)^{1/2}$. For a typical strongly index-guided buried heterostructure laser, the far-field FWHM angle out-of-plane is approximately 1 rad and in-plane is approximately 1/2 rad. These angles are independent of current for index-guided lasers. Separate confinement heterostructure (SCH) lasers can have smaller out-of-plane beam divergences, more typically approximately 30°.

Single-mode lasers that are index-guided in the lateral direction (buried heterostructure and ridge waveguide) will obey the preceding equations, with lateral divergence angles varying from 30° to 10°, depending on design. This beam width will also be independent of current. When LDs are gain-guided laterally, the spatial variation of the gain leads to a complex refractive index and a curved wavefront. The result is that the equivalent gaussian lateral beam appears to have been emitted from somewhere inside the laser facet. The out-of-plane beam, however, is still index-guided and will appear to be emitted from the end facet. This means that the output of a gain-guided laser has *astigmatism*, which must be compensated for by a suitably designed external lens if the laser is to be focused effectively into a fiber (as discussed elsewhere in this *Handbook*).

If the laser emits a diverging gaussian beam with waist w, a lens can be used to focus it into a fiber. An effective thin lens of focal length f placed a distance d_1 after the laser facet will focus to a new waist w' given by

$$w'^2 = w^2 \frac{f^2}{b^2 + X_1^2} \tag{12}$$

where $b \equiv \pi w^2/\lambda$ and $X_1 \equiv d_1 - f$.

The new waist will be located a distance d_2 from the lens, where

$$X_2 = X_1 \frac{f^2}{X_1^2 + b^2} \tag{13}$$

and $X_2 \equiv d_2 - f$.

This new waist must be matched to the spatial mode of the fiber. Because of the large numerical aperture of LD emission, simple lenses may exhibit severe spherical aberration and typical coupling efficiencies may be only a few percent. Fiber systems usually utilize pigtailed fiber, butt-coupled as close as possible to the laser, without any intervening lens. Alternatively, a ball lens may be melted directly onto a fiber tip and placed near the laser facet. Sometimes *graded index* (GRIN) lenses are used to improve coupling into fibers.

Gain-guided LDs with electrode stripe widths of more than 5 μm usually emit multiple in-plane spatial modes that interfere laterally, producing a spatial output with multiple maxima and nulls. Such spatial profiles are suitable for multimode fiber applications, but cannot be efficiently coupled into single-mode fibers. They will diffract at an angle given by setting w equal to the minimum near-field feature size. If the stripe is narrow enough, gain-guided LDs are always single-mode, but these devices have a double-lobed far-field spatial profile (from the complex refractive index in the gain medium) that cannot be conveniently coupled into single-mode fibers.

Spectral Characteristics of Laser Light

In principle, a Fabry-Perot laser has many frequency modes with frequencies ν_m, given by requiring standing waves within the laser cavity. Since the mth mode obeys $m\lambda/2n = L$, where n is the refractive index experienced by the guided laser mode, then $\nu_m = mc/2nL$. Taking the differential, the frequency

difference between modes is $\Delta\nu = c/2n_{\text{eff}}L$, where the *effective group refractive index* $n_{\text{eff}} = n + \nu(\partial n/\partial\nu)$. For typical semiconductor lasers, $n = 3.5$ and $n_{\text{eff}} = 4$, so that when $L = 250$ μm, the frequency difference between modes is $\Delta\nu = 150$ GHz, and since $\Delta\lambda = (\lambda^2/c)\Delta\nu$, when $\lambda = 1.5$ μm, the wavelength spacing is $\Delta\lambda \approx 1$ nm.

At any given instant in time, a single spatial mode emits only one spectral mode. However, in multimode lasers, considerable *mode hopping* occurs, in which the LD jumps from one spectral mode to another very rapidly. Most spectral measurements are time averages and do not resolve this mode hopping, which can occur in nanoseconds or less. Explanations for the mode hopping typically involve *spatial hole burning* or *spectral hole burning*. Hole burning occurs when the available carrier density is momentarily depleted, either spatially or spectrally. At that time an adjacent mode with a different (longitudinal or lateral) spatial profile providing a different resonance wavelength may be more advantageous for laser action. Thus, the laser jumps to this new mode. The competition for available gain between different modes often induces semiconductor lasers to emit light at several frequencies.

One way to provide a single spectral mode is to ensure a single (lateral) spatial mode. It has been found that single spatial mode lasers usually have single spectral modes, at least at moderate power levels. However, this may change upon modulation. The only way to *ensure* a single-frequency LD is to ensure a single longitudinal mode by using distributed feedback, as discussed in Sec. 13.7.

Polarization

The light emitted from a typical LD is usually linearly polarized in the plane of the heterostructure. While gain in the semiconductor medium has no favored polarization dependence, the *transverse electric* (TE) *waveguide mode* (polarized in-plane) is favored for two reasons. First, the TE mode is slightly more confined than the *transverse magnetic* (TM) mode (polarized out-of-plane). Second, the Fresnel reflectivity off the cleaved end facets is strongly polarization sensitive. As waveguided light travels along the active stripe region, it can be considered to follow a zig-zag path, being totally internally reflected by the cladding layers. The total internal reflection angle for these waves is about 10° off the normal to the cleaved facets of the laser. This is enough to cause the TM waveguide mode to experience less reflectivity, while the TE-polarized mode experiences higher reflectivity and has a lower threshold. Thus, laser light from LDs is traditionally polarized in the plane of the junction.

The introduction of strain (Sec. 13.6) in the active layer changes the polarization properties, and the particular polarization will depend on the details of device geometry. In addition, DFB and DBR lasers (Sec. 13.7) do not have strong polarization preferences, and they must be carefully designed and fabricated if well-defined single polarization is required.

13.4 TRANSIENT RESPONSE OF LASER DIODES

When laser diodes are operated by direct current, the output is constant and follows the *L-I* curve discussed previously. When the LD is rapidly switched, however, there are transient phenomena that must be taken into account. Such considerations are important for any high-speed communication system, especially digital systems. The study of these phenomena comes from solving the semiconductor rate equations.[7]

Turn-On Delay

When a semiconductor laser is turned on abruptly by applying forward-biased current to the diode, it takes time for the carrier density to reach its threshold value and for the photon density to build up, as shown in the experimental data of Fig. 6.[8] This means that a laser has an unavoidable turn-on time. The delay time depends on applied current and on carrier lifetime, which depends on carrier density

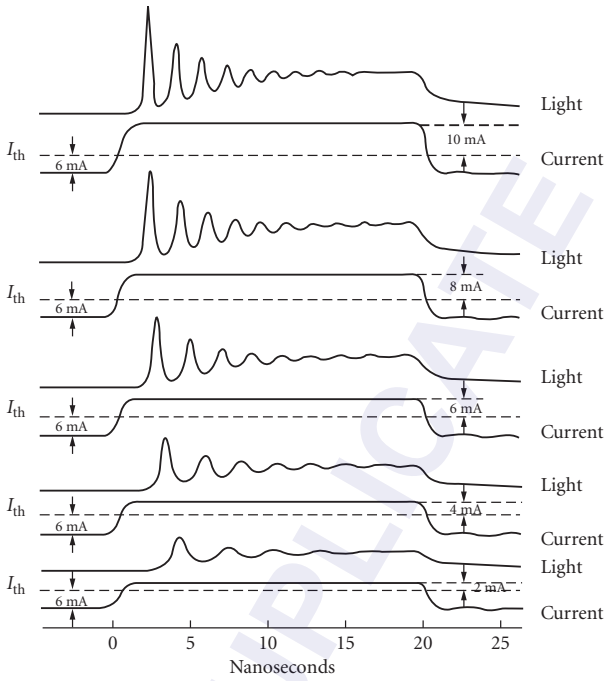

FIGURE 6 Experimental example of turn-on delay and relaxation oscillations in a laser diode when the operating current is suddenly switched from 6 mA below the threshold current of 177 mA to varying levels above threshold (from 2 to 10 mA). The GaAs laser diode was 50 μm long, with a SiO_2-defined stripe 20 μm wide. Light output and current pulse are shown for each case.[8]

N, as shown in Eq. (8). Using a differential analysis, the turn-on time for a laser that is switched from an initial current I_i just below threshold to I just above threshold is

$$\tau_d = \tau'(N_{\text{th}})\frac{I_{\text{th}} - I_i}{I - I_{\text{th}}} \tag{14}$$

where $\tau'(N)$ is a differential carrier recombination given by $1/\tau' = A_{\text{nr}} + 2BN + 3CN^2$. When the LD is initially off ($I_i = 0$) and $I >> I_{\text{th}}$, the turn-on delay has an inverse current dependence: $\tau_d = \tau_e(N_{\text{th}})\, I_{\text{th}}/I$.

When radiative recombination dominates, then $1/\tau_e \approx BN$ and $1/\tau' \approx 2BN \approx 2/\tau_e$, as seen by comparing the middle terms of Eqs. (11) and (22). For a 1.3-μm laser, $A_{\text{nr}} = 10^8$/s, $B = 10^{-10}$ cm^3/s, $C = 3 \times 10^{-29}$ cm^6/s, and $N_{\text{th}} \approx N_{\text{tr}} = 10^{18}$ cm^{-3}. Thus, $\tau_e = 5$ ns and a typical turn-on time at 1.5 times threshold current is 3 ns. The increase in delay time as the current approaches threshold is clearly seen in the data of Fig. 6. To switch a laser rapidly, it is necessary to switch it from just below threshold to far above threshold. However, Fig. 6 shows that under these conditions there are large transient oscillations, discussed in the following section.

Relaxation Oscillations

An important characteristic of the output of any rapidly switched laser (not just LDs) is the *relaxation oscillations* that can be observed in Fig. 6. These overshoots and undershoots occur as the photon and

carrier dynamics are coming into equilibrium. Such oscillations are characteristic of the nonlinear coupled laser rate equations and can be found by simple perturbation theory. These relaxation oscillations have a radian frequency Ω_R given, to first order, by[9]

$$\Omega_R^2 = \frac{1+\chi}{\tau_e \tau_p} \frac{I - I_{\text{th}}}{I_{\text{th}}} \tag{15}$$

where I is the current, I_{th} is the current at threshold, τ_p is the photon lifetime in the cavity, given by $v_g \tau_p = (\alpha_i + \alpha_m)^{-1}$, and $\chi = \Gamma a_L v_g \tau_p = \Gamma a_T \tau_p = \Gamma\,[a_L/(\alpha_i + \alpha_m)]$, where a_L was previously defined and is approximately the unpumped absorption loss in the active medium. The factor χ is then the ratio of the unpumped absorption loss to the cavity loss, typically 1 to 3 for semiconductor lasers. It can also be shown that $\chi = I_{\text{tr}}/(I_{\text{th}} - I_{\text{tr}})$, where I_{tr} is the current at transparency.

At 50 percent above threshold, and when $\chi \approx 1$, the time between successive relaxation oscillation maxima is approximately the geometric mean of the carrier and photon lifetimes: $\Omega_R^2 \approx 1/\tau_e \tau_p$. Typical LD numbers are $\tau_e = 10$ ns and $\tau_p = 3$ ps, so at 1.5 times threshold current, the relaxation oscillation frequency is $f_R = \Omega_R/2\pi = 1$ GHz, and the time between relaxation oscillation peaks is 1 ns.

The decay rate of these relaxation oscillations γ_R is given by

$$2\tau_e \gamma_R = 1 + \chi \frac{I - I_{\text{th}}}{I_{\text{tr}}} = 1 + (1+\chi)\frac{I - I_{\text{th}}}{I_{\text{th}}} = 1 + \Omega_R^2 \tau_e \tau_p \tag{16}$$

and is roughly 2 ns at twice threshold for typical heterostructure lasers. At 1.5 times threshold and when $\chi \approx 1$, Eq. (16) gives $\gamma_R \approx 1/\tau_e$. The relaxation oscillations last approximately as long as the spontaneous emission lifetime of the carriers.

This first-order analysis has several assumptions that do not seriously affect the relaxation oscillation frequency, but will overestimate the time that relaxation oscillations are present. The analysis ignores *gain saturation*, which reduces gain with increased photon density P and is important at high optical powers. It also ignores the rate of spontaneous emission in the cavity, R_{sp}, which is important at small optical powers. Finally, it ignores the impact of changing carrier density on spontaneous emission lifetime. A more typical experimental decay rate for lasers at 1.3 μm wavelength is $\gamma \approx 3/\tau_e$. A more exact theoretical formulation can be found in Ref. 10.

The number of relaxation oscillations (before they die out) in an LD at 1.5 times threshold is roughly $\Omega_R/\gamma_R \propto (\tau_e/\tau_p)^{1/2}$. Shorter carrier lifetimes mean fewer relaxation oscillations, because carriers reach steady state more rapidly. Shorter carrier lifetimes also mean faster turn-on times. Carrier lifetimes are shortened by high carrier densities, an important regime for high-speed semiconductor lasers; high carrier densities can be achieved by using as small an active region as possible (such as QWs) and by reducing the reflectivity of the laser facets to raise the threshold carrier density.

The relaxation oscillations disappear if the current is just at threshold. However, we've also seen that under this situation the turn-on time becomes very long. It is more advantageous to turn the laser on fast, suffering the relaxation oscillations and using LDs designed to achieve a high decay rate, which means using LDs with the highest possible relaxation oscillation frequency.

The relaxation oscillation can also be expressed in terms of the photon density P inside the laser cavity, or in terms of the power out, P_{out}:

$$\Omega_R^2 = g_T g_T' P = \frac{g_T' P}{\tau_m} = g_T' \left(\frac{P_{\text{out}}}{h\nu V_a} \frac{\alpha_m + \alpha_i}{\alpha_m} \right) \tag{17}$$

where g_T is the modal gain per unit time and $g_T' \equiv \partial g_T/\partial N = \Gamma a_T/N_{\text{tr}}$. This formulation makes use of the relationship between output power and internal photon density in a cavity of volume V_a:

$$P_{\text{out}} = h\nu \left(\frac{P}{\tau_m} \right) V_a \tag{18}$$

where $\tau_m = (v_g \alpha_m)^{-1}$ is the time it takes light to bleed out the mirror. Note that the relaxation oscillation frequency increases as the photon density increases, confirming that smaller laser dimensions are better for high-speed modulation.

Relaxation oscillations can be avoided by biasing the laser just below threshold (letting the laser "simmer"). Fiber optic systems are designed to reduce the impact of these relaxation oscillators, whether they are digital telecommunication systems, or high-speed analog CATV systems. Many communication applications avoid these issues by operating the LD at steady state with DC current applied and use external modulators.

Modulation Response and Gain Saturation

The *modulation response* describes the amplitude of the modulated optical output as a function of frequency under small-signal current modulation. Laser diodes have a resonance in the modulation response at the relaxation oscillation frequency, as indicated by the experimental data in Fig. 7.[11] It is more difficult to modulate the laser above the relaxation oscillation frequency. Carrying out a small-signal expansion of the rate equations around photon density P, the modulation response (in terms of current density J) is[12]

$$\frac{\partial P}{\partial J} = \frac{(1/ed)(g_T' P + \beta_{sp}/\tau_e)}{(g_T' P/\tau_p + \beta_{sp}/\tau_e \tau_p - \omega^2) + j\omega(g_T' P + 1/\tau_e)} \tag{19}$$

where β_{sp} is the fraction of spontaneous emission that radiates into the mode. This modulation response has the form of a second-order low-pass filter. Resonance occurs when $\omega^2 \approx g_T' P/\tau_p = \Omega_R^2$ (from Eq. (17), with negligible internal loss); that is, at the relaxation oscillation frequency.

The modulation response at a frequency well below the relaxation oscillation frequency can be expressed as $\partial P_{out}/\partial I$ using Eq. (19) in the limit when $\omega \to 0$. From $\partial P/\partial J = \tau_p/ed$ and using Eq. (18), the low frequency modulation response is

$$\frac{\partial P_{out}}{\partial I} = \frac{h\nu}{\tau_m} V_a \frac{\partial P}{\partial J} \cdot \frac{1}{wL} = \frac{h\nu}{e} \cdot \frac{\tau_p}{\tau_m} = \frac{h\nu}{e} \cdot \frac{\alpha_m}{\alpha_m + \alpha_i} \tag{20}$$

which is expected from Eq. (5) for $\eta_i \to 1$.

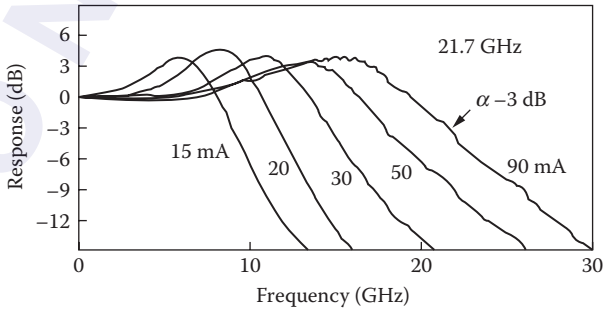

FIGURE 7 Measured small-signal modulation response of a high-speed DFB laser at several bias levels. Zero-dB modulation response is defined in terms of the low-frequency modulation response, Eq. (32).[11]

The 3-dB modulation radian frequency bandwidth ω_B can be expressed in terms of the relaxation oscillation parameters by[13]

$$\omega_B^2 = \Omega_R^2 - \gamma_R^2 + 2\sqrt{\Omega_R^2(\Omega_R^2 + \gamma_R^2 + \gamma_R^4}} \tag{21}$$

The parameters are strongly power dependent and ω_B increases with optical power. When $\gamma_R << \Omega_R$, which means the time carriers remain in the active region is longer than the time photons remain in the cavity, the 3-dB bandwidth $\omega_B \approx \sqrt{3\Omega_R} \propto \sqrt{P}$. At high optical powers the presence of gain saturation (reduced gain at high optical power densities) must be included; the modulation bandwidth saturates, and the limiting value depends on the way that the gain saturates with photon density.

Using a heuristic expression for modal gain saturation of the form $g_T(N,P) = g_T'(N - N_o)/(1 + P/P_s)^{1/2}$, the limiting value of the modulation bandwidth at high optical powers is $\omega_B^2 = 3g_T'P_s/2\tau_p$, where P_s is the saturation photon density. A typical modulation bandwidth for an InGaAsP laser operating at 1.55-μm wavelength is ω_B = 20 to 40 GHz.

Frequency Chirping

When the carrier density in the active region is rapidly changed, the refractive index n also changes rapidly, causing a frequency shift proportional to $\partial n/\partial t$. This broadens the laser linewidth from its original width of approximately 100 MHz into a double-peaked profile with a gigahertz linewidth, as shown in the experimental results of Fig. 8.[14] The frequency spread is directly proportional to the dependence of the refractive index n on carrier density N. This is a complex function that depends on wavelength and degree of excitation, but for simplicity a Taylor expansion around the steady-state carrier density N_o can be assumed: $n = n_o + n_1(N - N_o)$, where $n_1 \equiv \partial n/\partial N$. The (normalized) ratio of this slope to that of the modal gain per unit length g_L is called the cavity *linewidth enhancement factor* β_c:

$$\beta_c \equiv -2k_o \frac{\partial n/\partial N}{\partial g_L/\partial N} = -2k_o \frac{n_1}{g_L'} \tag{22}$$

Sometimes the linewidth enhancement factor is called the *α-factor*. Typical values lie between 2 and 6.

The magnitude of the frequency spread between the double lobes of a chirped pulse, $2\delta\omega_{CH}$, can be estimated in the small-signal and large-signal regimes from analyzing the time dependence of a modulated pulse in terms of the sum of all frequency components, shown next.[15]

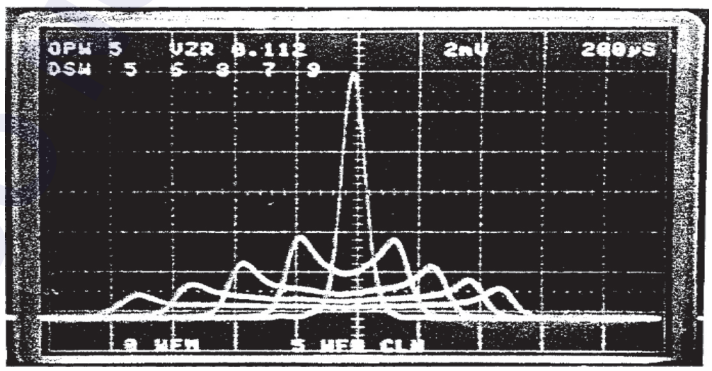

FIGURE 8 Time-averaged power spectra of 1.3-μm InGaAsP laser under sinusoidal modulation at 100 MHz. Horizontal scale is 0.05 nm per division. Spectrum broadens with increase in modulation current due to frequency chirping.[14]

Small Signal Modulation For a modulation frequency ω_m that is less than the relaxation oscillation frequency, and assuming that the carrier lifetime is longer than the photon lifetime, $\gamma_R << \Omega_R$, a small modulation current I_m will cause a frequency chirp of magnitude

$$\delta\omega_{\text{CH}} = \frac{\beta_c I_m h_\nu}{2eP_{\text{out}}}\left(\frac{\alpha_m}{\alpha_m + \alpha_i}\right)\sqrt{\omega_m^2 + \gamma_p^2} \tag{23}$$

where $\gamma_p = N/P(\beta_{\text{sp}}/\tau_e) - (\partial g_T/\partial P)P$ (remembering that $\partial g_T/\partial P$ is negative). The origin of chirp is the linewidth enhancement factor β_c. It will be largest for gain-guided devices where β_c is the maximum. The chirp will be smaller in lasers with $\alpha_m << \alpha_i$, such as will occur for long lasers, where mirror loss is amortized over a longer length, but such lasers will have a smaller differential quantum efficiency and smaller relaxation oscillation frequency. Typical chirp bandwidths (using $\delta\lambda_{\text{CH}} = \lambda^2\delta\omega_{\text{CH}}/2\pi c$) at 25-mA modulation current can vary from $\delta\lambda_{\text{CH}} = 0.2$ nm for gain-guided lasers to $\delta\lambda_{\text{CH}} = 0.03$ nm for ridge waveguide lasers. At a wavelength of 1 micrometer in frequency units this would be 60 GHz for gain-guided lasers and 9 GHz for ridge waveguide lasers.

Large Signal Modulation There is a transient frequency shift during large-signal modulation given by

$$\delta\omega_{\text{CH}} = \frac{\beta_c}{2}\left(\frac{1}{P}\frac{\partial P}{\partial t}\right) \tag{24}$$

When a gaussian shape pulse is assumed as exp $(-t^2/T^2)$, the chirp becomes $\delta\omega_{\text{CH}} \approx \beta_c/T$.

The importance of the linewidth enhancement factor β_c is evident from this section; its existence will inevitably broaden modulated laser linewidths. Because it is a basic characteristic of the laser medium itself, there are no design freedoms to reduce chirp under large signal modulation.

13.5 NOISE CHARACTERISTICS OF LASER DIODES

Noise in LDs results from fluctuations in spontaneous emission and from the carrier generation-recombination process (shot noise). To analyze the response of LDs to noise, one starts with rate equations, introduces Langevin noise sources as small perturbations, and linearizes (performs a small-signal analysis). Finally, one solves in the frequency domain using Fourier analysis.[16,17] Only the results are given here.

Relative Intensity Noise

Noise at a given frequency is described in terms of *relative intensity noise* (RIN), defined by

$$\text{RIN} = \frac{\Delta \times \text{P0}^2}{P_T^2} \tag{25}$$

where ΔP0^2 is the photon noise spectral density (noise per unit frequency interval), and P_T is the total photon number, $P_T = PV_a$. The solution to the analysis for RIN in an LD is

$$\text{RIN} = \frac{2\beta_{\text{sp}} I_{\text{th}}}{ePV_a} \cdot \frac{1/\tau'^2 + \omega^2 + (\partial g_T/\partial N)^2 P/(\beta_{\text{sp}} V_a)}{[(\Omega_R - \omega)^2 + \gamma_R^2][(\Omega_R + \omega)^2 + \gamma_R^2]} \tag{26}$$

where β_{sp} is the fraction of spontaneous emission emitted into the laser cavity. As before, the photon density P can be related to the optical power out both facets by $P_{\text{out}} = (h\nu)\, PV_a/\tau_m$. Note the significant enhancement of noise near the relaxation oscillation frequency $\omega = \Omega_R$, where the noise has

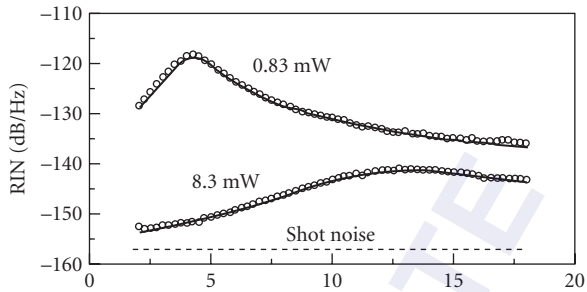

FIGURE 9 Measured relative intensity noise as a function of frequency in a multiple quantum well 1.5-μm laser diode, for optical power near threshold and high above threshold. The shot noise level for the higher power measurement is also shown.[18]

its maximum value. An example of RIN as a function of frequency ω is shown in Fig. 9,[18] for both low power and high power, showing that the RIN goes up as the total optical power decreases.

At low frequencies, and for $\gamma_R << \Omega_R$, the noise is proportional to the inverse fourth power of the relaxation oscillation frequency. Clearly, it is advantageous to use as high a relaxation oscillation frequency as possible to reduce RIN. Since the relaxation oscillation frequency is proportional to the square root of the power P, the RIN increases as $1/P^3$ as the power decreases. Inserting the expression for Ω_R into Eq. (26) gives

$$\mathrm{RIN}_{\mathrm{lf}} = \frac{2\beta_{\mathrm{sp}} I_{\mathrm{th}} \tau_m^2 V_a^2}{e P_T^3 (\partial g_T/\partial N)^2}\left[\frac{1}{\tau'^2} + \left(\frac{\partial g_T}{\partial N}\right)^2 \frac{P}{\beta_{\mathrm{sp}} V_a}\right] \tag{27}$$

where τ' is the differential carrier recombination time and P_T is the total photon number. Usually, the first term dominates. It can be seen that the volume of the active laser region V_a should be as small as possible, consistent with maintaining a significant power out.

Signal-to-Noise Ratio

The *signal-to-noise ratio* (SNR) can be found in terms of the relaxation oscillation parameters using the simplified expression for RIN (which assumes $\tau_e \Omega_R >> \gamma_R \Omega_R >> 1$) and the total photon number:

$$\mathrm{SNR}^2 = \frac{2\gamma_R e}{\beta_{\mathrm{sp}} I_{\mathrm{th}}} P_T = \frac{2\gamma_R e \tau_m}{\beta_{\mathrm{sp}} I_{\mathrm{tr}} h\nu} P_{\mathrm{out}} \tag{28}$$

As expected, the SHR ratio increases linearly with output power and increases as the amount of spontaneous emission decreases. This expression can be simplified further by recalling that $\gamma_R \approx \tau_e/3$.

Gain saturation at high optical powers eventually limits the SNR to about 30 dB; while at powers of a few milliwatts it is 20 dB, with intensity fluctuations typically close to 1 percent.

Mode Partition Noise in Multimode Laser Diodes

The preceding discussion of noise holds qualitatively for multimode lasers as long as all the laser modes are included. However, measurements made on any one mode show much more noise, particularly at low frequencies. This is due to the mode-hopping discussed previously, and is referred

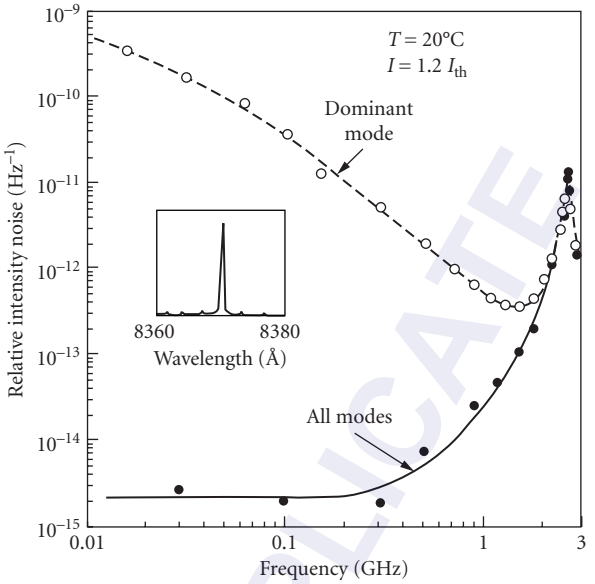

FIGURE 10 Effect of mode partition noise on relative intensity noise in multimode lasers. Experimentally observed intensity-noise spectra in all modes (solid curve) or in dominant mode (dashed curve). Inset shows spectrum of average mode power.[19]

to as *mode partition noise*. That is, the power partitions itself between different laser modes in a way that keeps the overall intensity relatively constant, as shown by the solid line in Fig. 10. The power in each mode is not a steady function of time, because the power distribution among the modes changes with time. Whenever the distribution changes, the power output undergoes fluctuation, leading to a noise term on a nominally stable output. This leads to the enhanced RIN on the dominant mode in Fig. 10.[19] Even an output whose spectrum looks nominally single-mode, as shown in the inset of Fig. 10, can have a large RIN on the dominant mode. This is because the spectrum is time averaged. A sidemode does not contain 5 percent of the power all the time; for example, it contains 100 percent of the power for 5 percent of the time. This causes the very large RIN observed. The solution to avoiding this noise is to insist on a single longitudinal mode by using distributed feedback. Since lasers for telecommunication applications are typically single mode, we will not consider mode partition noise further. It becomes important for data communications based on multimode lasers, however.

Phase Noise—Linewidth

The fundamental linewidth of a laser is given by the stochastic process of spontaneous emission, as first derived by Schawlow and Townes in the very early days of lasers. In a laser diode, additional noise enters from the stochastic process of carrier injection. Because the refractive index is a function of the carrier density, changes in carrier density cause changes in refractive index, which in turn create phase noise.

The formula for the radian frequency linewidth of a LD includes the *linewidth enhancement factor* β_c:

$$\delta\omega = (1 + \beta_c^2)\delta\omega_o \tag{29}$$

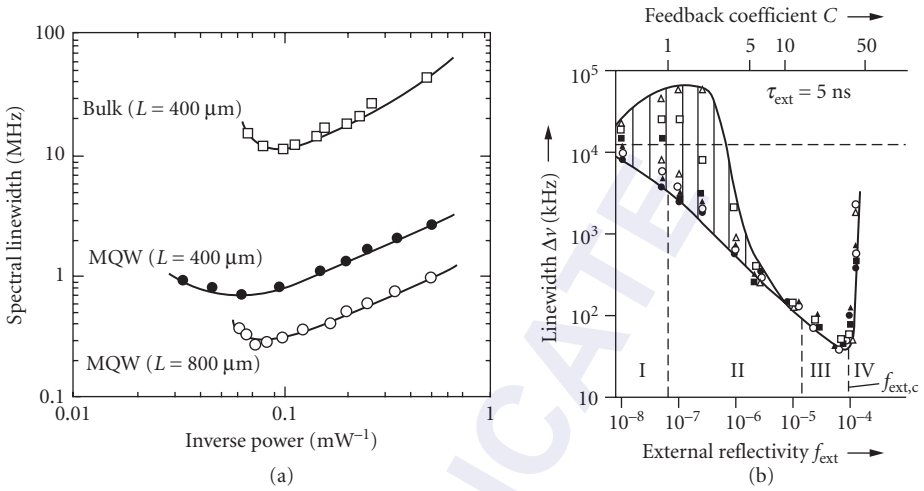

FIGURE 11 Linewidth of a laser diode: (*a*) DFB lasers as a function of inverse power, comparing bulk active regions and multiple quantum well active regions[20] and (*b*) Fabry-Perot laser as a function of feedback parameter, with corresponding feedback regimes.[21]

where $\delta\omega_o$ the original Schawlow-Townes linewidth is given by

$$\delta\omega_o = \frac{\beta_{sp} I_{th} h\nu \tau_m}{2eP_{out}} \tag{30}$$

Typical value of the linewidth enhancement factor is $\beta_c = 5$. The linewidth decreases inversely as the laser power increases. However, as shown in the experimental data in Fig. 11*a*,[20] at high enough power (above 10 mW) the linewidth narrowing saturates at approximately 1 to 10 MHz and then begins to broaden again at even higher power levels. It is also possible to reduce the linewidth by using QWs and increasing the cavity length (to decrease N_{th} and increase P).

External Optical Feedback and Coherence Collapse

Laser diodes are extremely sensitive to weak time-delayed feedback, such as from reflections off the front ends of fiber pigtails. These fed-back signals can result in mode hopping, strong excess noise, and chaotic behavior in the *coherence collapse* regime. Some of the features of feedback-induced noise are outlined here.

Various regimes of feedback can be characterized by a *feedback parameter C*:

$$C = \sqrt{f_{ext}}\, C_e \frac{\tau_{ext}}{\tau_L} \sqrt{1 + \beta_c^2} \tag{31}$$

where f_{ext} is the fraction of the emitted power that is externally reflected back into the laser. The external coupling factor $C_e = (1 - R)/\sqrt{R}$, where R is the reflectivity of the laser facet and β_c is the linewidth enhancement factor. The external round-trip time delay is τ_{ext} and the laser round-trip time is τ_L. Figure 11*b*[21] gives an example of the linewidth of a semiconductor laser versus the external coupling factor C in which various feedback regimes are indicated.

Regimes of Feedback The following provides a useful classification scheme:[22]

Regime I ($C < 1$): At the lowest levels of feedback, narrowing or broadening of the emission line is observed, depending on the phase of the feedback.

Regime II ($C > 1$): At higher levels of feedback, mode hopping between different external cavity modes may appear.

Regime III ($C >> 1$): Further increasing the levels of feedback, the laser is observed to operate in a mode with the smallest linewidth.

Regime IV (*coherence collapse*): At yet higher feedback levels, satellite modes appear, separated from the main mode by the relaxation oscillation frequency. These grow as the feedback increases and the laser line eventually broadens, due to the collapse of the coherence of the laser. This regime does not depend on distance from the laser to the reflector.

Regime V (*external cavity laser*): This regime of stable operation can be reached only with an antireflection-coated laser output facet to ensure a two-mirror cavity with the largest possible coupling back into the laser, and is not of concern here.

A quantitative discussion of these regimes follows.[21] Assume that the coupling efficiency from the laser into the fiber is η. Because feedback requires a double pass, the fraction of emitted light fed back into the laser is $f_{ext} = \eta^2 R_e$, where R_e is the reflectivity from the end of the fiber. The external reflection changes the overall cavity reflectivity and therefore the threshold gain, depending on its phase relative to the phase inside the cavity. Possible modes are defined by the threshold gain and the requirement that an effective round-trip phase = $m\pi$. But a change in the threshold gain also changes the refractive index and the phase through the linewidth enhancement factor β_c.

Regime I For very weak feedback, there is only one solution when the laser phase is set equal to $m\pi$, so that the laser frequency ω is at most slightly changed and its linewidth $\Delta\omega_o$ will be narrowed or broadened, as the external reflection adds to or subtracts from the output of the laser. The linewidth lies between extremes:

$$\frac{\Delta\omega_o}{(1+C)^2} << \Delta\omega << \frac{\Delta\omega_o}{(1-C)^2} \tag{32}$$

The system performance moves toward regime II as $C \rightarrow 1$. Note that at $C = 1$ the maximum value predicts an infinite linewidth. This indicates that even very small feedback can cause wide spectral response, as long as $C \sim 1$.

Regime II For higher feedback with C > 1, several solutions with the round-trip laser phase = $m\pi$ may exist. Linewidth broadening occurs because the single external cavity mode now has split into a dual mode, accompanied by considerable phase noise. Mode hopping gives linewidth broadening and intensity noise. This is a low-frequency noise with a cutoff frequency of about 10 MHz.

Regime III With increasing feedback, the mode splitting increases up to a frequency $\Delta\omega = 1/\tau_{ext}$ and the cutoff frequency for mode hopping noise decreases until only one of the split modes survives. To understand which mode survives, it is important to realize that in regime III, stable and unstable modes alternate with increasing phase. Because $\beta_c \neq 0$, the mode with the best phase stability (corresponding to the minimum linewidth mode) does not coincide with the mode with minimum threshold gain. The minimum linewidth mode predominates, due to its phase stability. This mode remains relatively stable and has the same emission frequency as the laser without feedback. This mode predominates as long as the inverse of the linewidth of the solitary laser is larger than the external cavity round-trip time. In this regime, the laser is stably phase locked by the feedback.

Regime IV The stable linewidth of regime III collapses as the fraction of power fed back f_{ext} increases to a critical value. There is considerable discussion of the physical mechanism that leads to

this coherence collapse. The existence of this regime has been demonstrated by simulation, through numerical solution of the rate equations. Fitting theoretical analyses to experimental results indicates that the onset of coherence collapse occurs when the feedback factor is larger than a critical value given by[23]

$$C \geq C_{\text{crit}} = 2\gamma_R \tau_{\text{ext}} \frac{1+\beta_c^2}{\beta_c^2} \tag{33}$$

where γ_R is the damping rate of the relaxation oscillations. As the feedback level approaches the critical value C, undamped relaxation oscillations appear and oscillations of carrier density through the linewidth enhancement factor β_c induce the phase of the field to oscillate. This analytical result assumes that $\tau_{\text{ext}} >> 1/\gamma_R$. An approximate solution for γ_R gives $C_{\text{crit}} = \tau_{\text{ext}}/\tau_e \times (1 + \beta_c{}^2)/\beta_c{}^2$.

Cavity Length Dependence and RIN In some regimes the stable regions depend on the length of the external cavity, that is, the distance from the extra reflection to the laser diode. These regions have been mapped out for two different laser diodes, as shown in Fig. 12.[24] The qualitative dependence on the distance of the laser to the reflection should be similar for all LDs.

The RIN is low for weak to moderate levels of feedback but increases tremendously in regime IV. The RIN and the linewidth are strongly related (see Fig. 11); the RIN is suppressed in regimes III and V.

Low-Frequency Fluctuations When a laser operating near threshold is subject to a moderate amount of feedback, chaotic behavior evolves into *low-frequency fluctuations* (LFF). During LFF the average laser intensity shows sudden dropouts, from which it gradually recovers, only to drop out again after some variable time, typically on the order of tens of external cavity round-trips. This occurs in regimes of parameter space where at least one stable external cavity mode exists, typically at the transition between regimes IV and V. Explanations differ as to the cause of LFF, but they appear to originate in strong-intensity pulses that occur during the build-up of average intensity, as a form of mode locking, being frustrated by the drive toward maximum gain. Typical frequencies for LFF are 20 to 100 MHz, although feedback from reflectors very close to the laser has caused LFF at frequencies as high as 1.6 GHz.

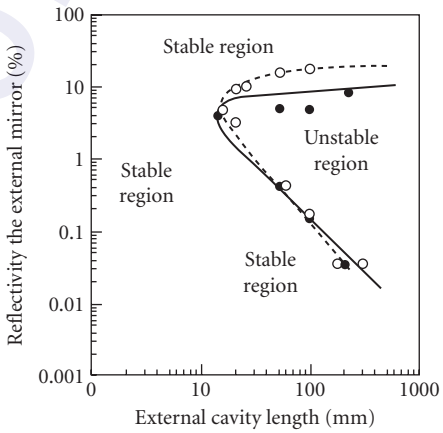

FIGURE 12 Regimes of stable and unstable operation for two laser diodes (○ and •) when subject to external feedback at varying distances and of varying amounts.[24]

Conclusions A laser diode subject to optical feedback exhibits a rich and complex dynamic behavior that can enhance or degrade the laser's performance significantly. Feedback can occur through unwanted back reflections—for instance, from a fiber facet—and can lead to a severe degradation of the spectral and temporal characteristics, such as in the coherence collapse or in the LFF regime. In both regimes, the laser intensity fluctuates erratically and the optical spectrum broadens, showing large sidebands. Because these unstable regimes can occur for even minute levels of feedback, optical isolators or some other means of reflection prevention are often used in systems applications.

13.6 QUANTUM WELL AND STRAINED LASERS

Introducing quantum wells and strain into the active region of diode lasers has been shown to provide higher gain, greater efficiency, and lower threshold. Essentially all high-quality lasers for optical communications use one or both of these means to improve performance over bulk heterostructure lasers.

Quantum Well Lasers

We have seen that the optimum design for low-threshold LDs uses the thinnest possible active region to confine free carriers, as long as the laser light is waveguided. When the active layer has a thickness less than a few tens of nanometers (hundreds of angstroms), it becomes a *quantum well*. That is, the layer is so thin that the confined carriers have energies that are quantized in the growth direction z, as described in Chap. 19 in Vol. II of this *Handbook*. This changes the density of states and the gain (and absorption) spectrum. While bulk semiconductors have an absorption spectrum near the band edge that increases with photon energy above the bandgap energy E_g as $(h\nu - E_g)^{1/2}$, quantum wells have an absorption spectrum that is steplike in photon energy at each of the allowed quantum states. Riding on this steplike absorption is a series of exciton resonances at the absorption steps that occur because of the Coulomb interaction between free electrons and holes, which can be seen in the spectra of Fig. 13.[25] These abrupt absorption features result in much higher gain for QW lasers than for bulk semiconductor lasers. The multiple spectra in Fig. 13 record the reduction in absorption as the QW states are filled with carriers. When the absorption goes to zero, transparency is reached. Figure 13 also shows that narrower wells push the bandgap to higher energies, a result of quantum confinement. The QW thickness is another design parameter in optimizing lasers for telecommunications.

Because a single quantum well (SQW) is so thin, its optical confinement factor is small. It is necessary to use either multiple QWs (separated by heterostructure barriers that contain the electron wave functions within individual wells) or to use a guided wave structure that focuses the light into a SQW. The latter is usually a GRIN structure, as shown in Fig. 2*d*. Band diagrams as a function of distance in the growth direction for typical QW separate confinement heterostructures are shown in Fig. 14. The challenge is to properly confine carriers and light using materials that can be reliably grown and processed by common crystal growth methods.

Quantum wells have provided significant improvement over bulk active regions, as originally observed in GaAs lasers. In InP lasers, Auger recombination and other losses come into play at the high carrier densities that occur in quantum-confined structures. However, it has been found that strain in the active region can improve the performance of quaternary QW lasers to a level comparable with GaAs lasers. Strained QW lasers are described in the following section.

The LD characteristics described in Secs. 13.2 to 13.5 hold for QW lasers as well as for bulk lasers. While the local gain is larger, the optical confinement factor will be much smaller. Equation (1) shows that the parameter V becomes very small when d_g is small, and Eq. (2) shows Γ_g is likewise small. With multiple quantum wells (MQWs), d_g can be the thickness of the entire region containing the MQWs and their barriers, but Γ must now be multiplied by the filling factor Γ_f of the QWs within the MQW region. If there are N_w wells, each of thickness d_w, then $\Gamma_f = N_w d_w / d_g$. With a GRINSCH structure, the optical confinement factor depends on the curvature of its refractive gradient near the center of the guide.

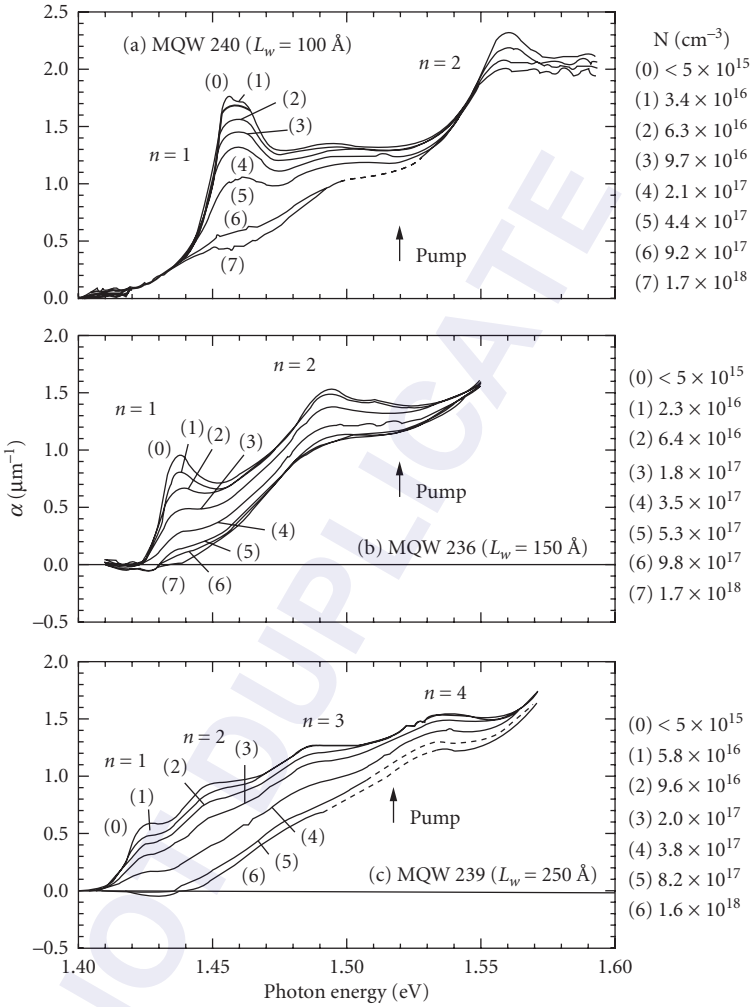

FIGURE 13 Absorption spectrum for multiple quantum wells of three different well sizes, for varying levels of optically induced carrier density, showing the decrease in absorption toward transparency. Note the stronger excitonic resonances and increased bandgap with smaller well size.[25]

Different geometries have subtle differences in performance, depending on how many QWs are used and the extent to which a GRINSCH structure is dominant. The lowest threshold current densities have been reported for the highest *Q* cavities (longest lengths or highest reflectivities) using SQWs. However, for lower *Q* cavities the lowest threshold current densities are achieved with MQWs, even though they require higher carrier densities to achieve threshold. This is presumably because Auger recombination depends on the cube of the carrier density, so that SQW lasers will have excess losses, due to their higher carrier densities. In general, MQWs are a better choice in long-wavelength lasers, while SQWs have the advantage in GaAs lasers. However, with MQW lasers it is important to realize that the transport of carriers moving from one well to the next during high-speed modulation must be taken into account. In addition, improved characteristics of strained layer QWs make SQW devices more attractive.

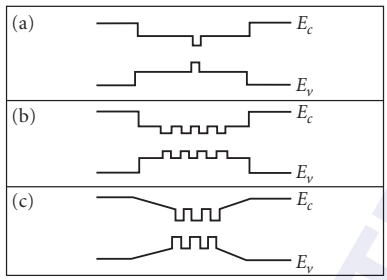

FIGURE 14 Typical band diagrams (energy of conduction band E_c and valence band E_v versus growth direction) for quantum wells in separate confinement laser heterostructures: (*a*) single quantum well; (*b*) multiple quantum wells; and (*c*) graded index separate confinement heterostructure (GRINSCH) and multiple quantum wells.

Strained Layer Quantum Well Lasers

Active layers containing *strained quantum wells* have proven to be an extremely valuable advance in high-performance long-wavelength InP lasers. They have lower thresholds, enhanced differential quantum efficiency η_D, larger characteristic temperature T_o, reduced linewidth enhancement factor β_c (less chirp), and enhanced high-speed characteristics (larger relaxation oscillation frequency Ω_R), compared to unstrained QW and bulk devices. This results from the effect of strain on the energy-versus-momentum band diagram. Bulk semiconductors have two valence bands that are degenerate at the potential well minimum (at momentum $k_x = 0$;), as shown in Fig. 15*a*. They are called

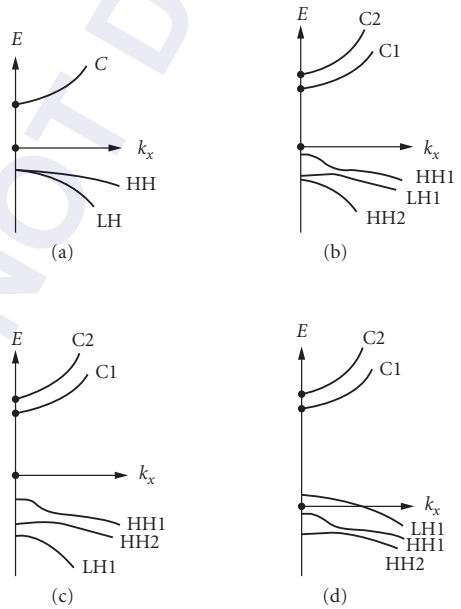

FIGURE 15 The effect of strain on the band diagram (energy E versus in-plane momentum k_x) of III-V semiconductors: (*a*) no strain; (*b*) quantum wells; (*c*) compressive strain; and (*d*) tensile strain.

heavy-hole (HH) and *light-hole* (LH) bands, since the smaller curvature means a heavier effective mass. Quantum wells lift this degeneracy, and interaction between the two bands near momentum $k = 0$ causes a local distortion in the formerly parabolic bands, also shown in Fig. 15*b*. There are now separately quantized conduction bands (C_1 and C_2) and a removal of the valence band degeneracy, with the lowest energy heavy holes HH_1 no longer having the same energy as the lowest energy light holes LH_1 at $k = 0$. The heavy hole effective mass becomes smaller, more nearly approaching that of the conduction band. This allows population inversion to become more efficient, increasing the differential gain; this is one factor in the reduced threshold of QW lasers.[26]

Strain additionally alters this structure in a way that can improve performance even more. Compressive strain in the QW moves the heavy-hole and light-hole valence bands further apart and further reduces the hole effective mass (Fig. 15*c*). Strain also decreases the heavy-hole effective mass by a factor of 2 or more, further increasing the differential gain and reducing the threshold carrier density. Higher differential gain also results in a smaller linewidth enhancement factor. Tensile strain moves the heavy-hole and light-hole valence bands closer together (Fig. 15*d*). In fact, at one particular tensile strain value these bands become degenerate at $k = 0$. Further tensile strain results in the light hole having the lowest energy at $k = 0$. These lasers will be polarized TM, because of the angular momentum properties of the light-hole band. This polarization has a larger optical matrix element, which can enhance the gain within some wavelength regions.

In addition to the heavy- and light-hole bands, there is an additional, higher-energy valence band (called the *split-off band*, not shown in Fig. 15) which participates in Auger recombination and intervalence band absorption, both of which reduce quantum efficiency. In unstrained material there is a near-resonance between the bandgap energy and the difference in energy between the heavy-hole and split-off valence bands, which enhances these mechanisms for nonradiative recombination. Strain removes this near-resonance and reduces those losses that are caused by Auger recombination and intervalence band absorption. This means that incorporating strain is essential in long-wavelength laser diodes intended to be operated at high carrier densities. The reliability of strained layer QW lasers is excellent, when properly designed. However, strain does increase the intraband relaxation time, making the gain compression factor worse, so strained lasers tend to be more difficult to modulate at high-speed.

Specific performance parameters depend strongly on the specific material, amount of strain, size and number of QWs, and device geometry, as well as the quality of crystal growth. Calculations show that compressive strain provides the lowest transparency current density, but tensile strain provides the largest gain (at sufficiently high carrier densities), as shown in Fig. 16.[27] The lowest threshold lasers, then, will typically be compressively strained. Nonetheless, calculations show that, far enough above the band edge, the differential gain is 4 times higher in tensile strain compared to compressive strain. This results in a smaller linewidth enhancement factor, even if the refractive index changes per carrier density are larger. It has also been found that tensile strain in the active region reduces

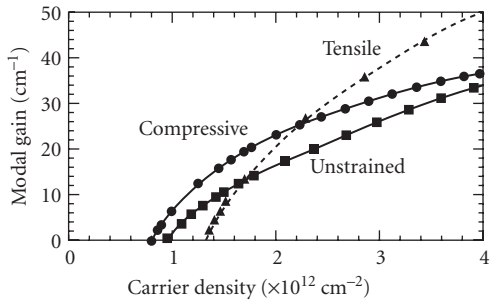

FIGURE 16 Modal gain at 1.55 μm in InGaAs QW lasers calculated as a function of the carrier density per unit area contained in the quantum well. Well widths were determined by specifying wavelength.[27]

the Auger recombination, decreasing the losses introduced at higher temperatures. This means that T_o can increase with strain, particularly tensile strain. Strained QWs enable performance at 1.55 μm comparable with that of GaAs lasers. Deciding between compressively and tensilely strained QWs will be a matter of desired performance for specific applications.

Threshold current densities under 200 A/cm^2 have been reported at 1.55 μm; T_o values on the order of 140 K have been reported—3 times better than bulk lasers. Strained QW lasers have improved modulation properties compared with bulk DH lasers. Because the gain coefficient can be almost double, the relaxation oscillation frequency is expected to be almost 50 percent higher, enhancing the modulation bandwidth and decreasing the relative intensity noise for the same output power. Even the frequency chirp under modulation will be less, because the linewidth enhancement factor is less. The typical laser geometry, operating characteristics, transient response, noise, frequency chirping, and the effects of external optical feedback are all similar in the strained QW lasers to what has been described previously for bulk lasers. Only the experimentally derived numerical parameters will be somewhat different; strained long-wavelength InP-based semiconductor lasers have performance parameters comparable to those of GaAs lasers. One difference is that the polarization of the light emitted from strained lasers may differ from that emitted from bulk lasers. As explained in Sec. 13.3, the gain in bulk semiconductors is independent of polarization, but lasers tend to be polarized in-plane because of higher facet reflectivity for that polarization. The use of QWs causes the gain for the TE polarization to be slightly (~10 percent) higher than for the TM polarization, so lattice-matched QW lasers operate with in-plane polarization. Compressive strain causes the TE polarization to have significantly more gain than the TM polarization (typically 50 to 100 percent more), so these lasers are also polarized in-plane. However, tensile strain severely depresses the TE gain, and these lasers have the potential to operate in TM polarization.

Typical 1.3- and 1.5-μm InP lasers today use from 5 to 15 wells that are grown with internal strain. By providing strain-compensating compressive barriers, there is no net buildup of strain. Typical threshold current densities today are ~1000 A/cm^2, threshold currents ~10 mA, T_o ~ 50 to 70 K, maximum powers ~40 mW, differential efficiencies ~0.3 W/A, and maximum operating temperatures ~70°C before the maximum power drops by 50 percent. There are trade-offs on all these parameters; some can be made better at the expense of some of the others.

13.7 DISTRIBUTED FEEDBACK AND DISTRIBUTED BRAGG REFLECTOR LASERS

Rather than cleaved facets, some lasers use distributed reflection from corrugated waveguide surfaces. Each groove provides some slight reflectivity, which adds up coherently along the waveguide at the wavelength given by the corrugation. This has two advantages. First, it defines the wavelength (by choice of grating spacing) and can be used to fabricate single-mode lasers. Second, it is an in-plane technology (no cleaves) and is therefore compatible with monolithic integration with modulators and/or other devices.

Distributed Bragg Reflector Lasers

The *distributed Bragg reflector* (DBR) *laser* replaces one or both laser facet reflectors with a waveguide diffraction grating located outside the active region, as shown in Fig. 17.[28] The reflectivity of a Bragg mirror is the square of the reflection coefficient (given here for the assumption of lossless mirrors):[29]

$$r = \frac{\kappa}{\delta - iS\coth(SL)} \tag{34}$$

where κ is the *coupling coefficient* due to the corrugation (which is real for corrugations that modify the effective refractive index in the waveguide, but would be imaginary for periodic modulations in the gain

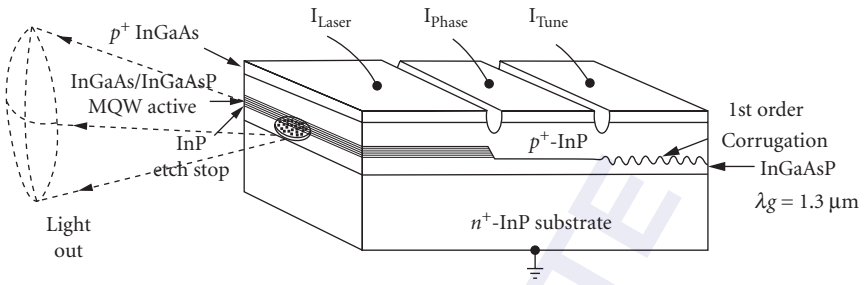

FIGURE 17 Schematic for DBR laser configuration in a geometry that includes a phase portion for phase tuning and a tunable DBR grating. Fixed-wavelength DBR lasers do not require this tuning region. Designed for 1.55-μm output, light is waveguided in the transparent layer below the MQW that has a bandgap at a wavelength of 1.3 μm. The guided wave reflects from the rear grating, sees gain in the MQW active region, and is partially emitted and partially reflected from the cleaved front facet. Fully planar integration is possible if the front cleave is replaced by another DBR grating.[28]

and could, indeed, be complex). Also, δ is a *detuning parameter* that measures the offset of the optical wavelength λ from the grating periodicity Λ. When the grating is used in the mth order, the detuning δ relates to the optical wavelength λ by

$$\delta = \frac{2\pi n_g}{\lambda} - \frac{m\pi}{\Lambda} \tag{35}$$

where n_g is the effective group refractive index of the waveguide mode, and m is any integer. Also, S is given by $S^2 = \kappa^2 - \delta^2$. When detuning $\delta > \kappa$, Eq. (34) is still valid, and is analytically evaluated with S as imaginary.

The Bragg mirror has its maximum reflectivity on resonance when $\delta \to 0$ and the wavelength on resonance λ_m is determined by the mth order of the grating spacing through $\Lambda = m\lambda_m/2n_g$. The reflection coefficient on resonance is $r_{max} = -i \tanh(KL)$, and the Bragg reflectivity on resonance is

$$R_{max} = \tanh^2(KL) \tag{36}$$

where K is the coupling per unit length, $K = |\kappa|$, and is larger for deeper corrugations or when the refractive index difference between the waveguide and the cladding is larger. The reflectivity falls off as the wavelength moves away from resonance and the detuning increases. Typical resonant reflectivities are $R_{max} = 0.93$ for $KL = 2$ and $R_{max} = 0.9987$ for $KL = 4$.

A convenient formula for the shape of the reflectivity as a function of detuning near resonance is given by the reflection loss:

$$1 - R = \frac{1 - (\delta L)^2/(\kappa L)^2}{\cosh^2(SL) - (\delta L)^2/(\kappa L)^2} \tag{37}$$

The reflection loss doubles when off resonance by an amount $\delta L = 1.6$ for $\kappa L = 2$ and when $\delta L = 2$ for $\kappa L = 4$. The wavelength half-bandwidth is related to the detuning δL by $\Delta\lambda = \lambda_o^2(\delta L/2\pi)/n_g L$. The calculated FWHM of the resonance is 0.6 nm (when $L = 500$ μm, $\lambda = 1.3$ μm) for a 99.9 percent reflective mirror. The wavelength of this narrow resonance is fixable by choosing the grating spacing and can be modulated by varying the refractive index (with, for example, carrier injection), properties that make the DBR laser very favorable for use in optical communication systems.

The characteristics of Fabry-Perot lasers described previously still hold for DBR lasers, except that the narrow resonance can ensure that these lasers are single-mode, even at high excitation levels.

Distributed Feedback Lasers

When the corrugation is put directly on the active region or its cladding, this is called *distributed feedback* (DFB). One typical BH example is shown in Fig. 18, with a buried grating waveguide that was grown on top of a grating-etched substrate, which forms the separate confinement heterostructure laser. The cross-hatched region contains the MQW active layer. A stripe mesa was etched and regrown to bury the heterostructure. Reflection from the cleaved facets must be suppressed by means of an antireflection coating. As before, the grating spacing is chosen such that, for a desired wavelength near λ_o, $\Lambda = m\lambda_o/2n_{ge}$, where n_{ge} is the effective group refractive index of the laser mode inside its waveguiding active region, and m is any integer. A laser operating under the action of this grating has feedback that is distributed throughout the laser gain medium. In this case, Eq. (34) is generalized to allow for the gain: $\delta = \delta_o + ig_L$, where g_L is the laser gain and $\delta_o = 2\pi n_{ge}/\lambda - 2\pi n_{ge}/\lambda_o$. Equations (34) to (37) remain valid, understanding that now δ is complex.

The laser oscillation condition requires that after a round-trip inside the laser cavity, a wave must have the same phase that it started out with, so that successive reflections add in phase. Thus, the phase of the product of the complex reflection coefficients (which now include gain) must be an integral number of 2π. This forces r^2 to be a positive real number. So, laser oscillation requires $r^2 > 0$.

On resonance $\delta_o = 0$ and $S_o^2 = \kappa^2 + g_L^2$, so that S_o is pure real for simple corrugations (κ real). Since the denominator in Eq. (34) is now pure imaginary, r^2 is negative and the round-trip laser oscillation condition cannot be met. Thus, there is no on-resonance solution to a simple DFB laser with a corrugated waveguide and/or a periodic refractive index. The DFB laser oscillates slightly off-resonance.

DFB Threshold We look for an off-resonance solution to the DFB. A laser requires sufficient gain that the reflection coefficient becomes infinite. That is, $\delta_{th} = iS_{th} \coth (S_{th}L)$, where $S_{th}^2 = \kappa^2 - \delta_{th}^2$. By simple algebraic manipulation, the expression for δ_{th} can be inverted. For large gain, $\delta_{th}^2 >> K^2$, so that $S_{th} = i\delta_{th} = i\delta_o - g_L$, and the inverted equation becomes[30]

$$\exp(2S_{th})\frac{4(g_L - i\delta_o)^2}{K^2} = -1 \tag{38}$$

This is a complex eigenvalue equation that has both a real and an imaginary part, which give both the detuning δ_o and the required gain g_L.

The required laser gain is found from the magnitude of Eq. (38) through

$$2\tan^{-1}\left(\frac{\delta_o}{g_L}\right) - 2\delta_o L + \delta_o L\frac{K^2}{g_L^2 + \delta_o^2} = (2m+1)\pi \tag{39}$$

There is a series of solutions, depending on the value of m.

For the largest possible gains, $\delta_o L = -(m + 1/2)\pi$. There are two solutions, $m = -1$ and $m = 0$, giving $\delta_o L = -\pi/2$ and $\delta_o L = +\pi/2$. These are two modes equally spaced around the Bragg resonance.

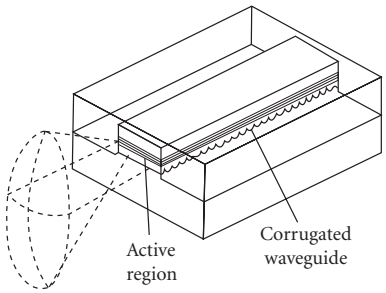

FIGURE 18 Geometry for a buried grating heterostructure DFB laser.

Converting to wavelength units, the mode detuning becomes $\delta_o L = -2\pi n_g L\,(\delta\lambda/\lambda^2)$, where $\delta\lambda$ is the deviation from the Bragg wavelength. Considering $\delta_o L = \pi/2$, for $L = 500$ μm, $n_g = 3.5$, and $\lambda = 1.55$ μm, this corresponds to $\delta\lambda = 0.34$ nm. The mode spacing is twice this, or 0.7 nm.

The required laser gain is found from the magnitude of Eq. (38) through

$$\frac{K^2}{4} = (g_L^2 L^2 + \delta_o^2 L^2)\exp(-2g_L L) \tag{40}$$

For the required detuning $\delta_o L = -\pi/2$, the gain can be found by plotting Eq. (40) as a function of gain g_L, which gives $K(g_L)$, which can be inverted to give $g_L(K)$.

These results show that there is a symmetry around $\delta_o = 0$, so that there will tend to be *two* modes, equally spaced around λ_o. Such a multimode laser is not useful for communication systems so something must be done about this. The first reality is that there are usually cleaved facets, at least at the output end of the DFB laser. This changes the analysis from that given here, requiring additional Fresnel reflection to be added to the analysis. The additional reflection will usually favor one mode over the other, and the DFB will end up as a single-mode. However, there is very little control over the exact positioning of these additional cleaved facets with respect to the grating, and this has not proven to be a reliable way to achieve single-mode operation. The most common solution to this multimode problem is to use a *quarter-wavelength-shifted grating*, as shown in Fig. 19. Midway along the grating, the phase is made to change by $\pi/2$ and the two-mode degeneracy is lifted. This is the way DFB lasers are made today.

Quarter-Wavelength-Shifted Grating Introducing an additional phase shift of π to the round-trip optical wave enables an on-resonance DFB laser. This is done by interjecting an additional phase region of length $\Lambda/2$, or $\lambda/4n_g$, as shown in Fig. 19. This provides an additional $\pi/2$ phase each way, so that the high-gain oscillation condition becomes $\delta_o L = -m\pi$. Now there is a unique solution at $m = 0$, given by Eq. (40) with $\delta_o = 0$:

$$KL = g_L L \exp(-g_L L) \tag{41}$$

Given a value for the DFB coupling parameter KL, the gain can be calculated. Alternatively, the gain can be varied, and the coupling coefficient that must be used with that gain can be calculated. It can be seen that if there are internal losses α_i, the laser must have sufficient gain to overcome them as well: $g_L \to g_L + \alpha_i$.

Quarter-wavelength-shifted DFB lasers are commonly used in telecommunication applications. DFB corrugations can be placed in a variety of ways with respect to the active layer. Most common is to place the corrugations laterally on either side of the active region, where the evanescent wave of the guided mode experiences sufficient distributed feedback for threshold to be achieved. Alternative methods place the corrugations on a thin cladding above the active layer. Because the process of corrugation may introduce defects, it is traditional to avoid corrugating the active layer directly. Once a

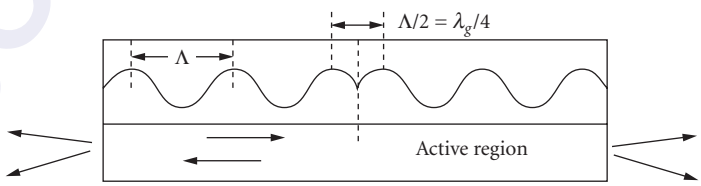

FIGURE 19 Side view of a quarter-wavelength-shifted grating, etched into a separate confinement waveguide above the active laser region. Light with wavelength in the medium λ_g sees a $\pi/4$ phase shift, resulting in a single-mode DFB laser operating on line-center.

DFB laser has been properly designed, it will be single-mode at essentially all power levels and under all modulation conditions. Then the single-mode laser characteristics described in the early part of this chapter will be well satisfied. However, it is crucial to avoid reflections from fibers back into the laser, because instabilities may arise, and the output may cease to be single-mode.

A different technique that is sometimes used is to spatially modulate the gain. This renders κ complex and enables an on-resonance solution for the DFB laser, since S will then be complex on-resonance. Corrugation directly on the active region makes this possible, but care must be taken to avoid introducing centers for nonradiative recombination.

More than 35 years of research and development have gone into semiconductor lasers for telecommunications. Today it appears that the optimal sources for these applications are strained QW distributed feedback lasers operating at 1.3 or 1.55 μm wavelength.

13.8 TUNABLE LASERS

The motivation to use tunable lasers in optical communication systems comes from wavelength division multiplexing (WDM), in which a number of independent signals are transmitted simultaneously, each at a different wavelength. The first WDM systems used wavelengths far apart (so-called *coarse* WDM) and settled on a standard of 20-nm wavelength spacing (~2500 GHz). But interest grew rapidly toward *dense* wavelength division multiplication (DWDM), with much closer wavelength spacing. The International Telecommunications Union (ITU) defined a standard for a grid of optical frequencies, each referring to a reference frequency which has been fixed at 193.10 THz (1552.5 nm). The grid separation can be as narrow as 12.5 GHz or as wide as 100 GHz. Tuning range can extend across the conventional erbium amplifier window C band (1530 to 1565 nm) and ideally extends to either side. Tuning to longer wavelengths will extend through the L band out to 1625 nm or even farther through the ultra-long U band to 1675 nm. On the short wavelength side, the S band goes to 1460 nm, after which the extended E band transmits only in fibers without water absorption. The original O band lies between 1260 and 1360 nm. An ideal tuning range would extend throughout all these optical fiber transmission bands.

Two kinds of tunable lasers have application to fiber optical communications. The first is a laser with a set of fixed wavelengths at the ITU frequencies that can be tuned to any wavelength on the grid and operated permanently at that frequency. This approach may be cost-effective because network operators do not have to stock-pile lasers at each of the ITU frequencies; they can purchase a few identical tunable lasers and set them to the required frequency when replacements are needed. The other kind of tunable laser is agile in frequency; it can be tuned in real time to whatever frequency is open to use within the system. These agile tunable lasers offer the greatest systems potential, perhaps someday enabling wavelength switching even at high-speed packet rates. These agile lasers also tend to be more expensive, and at the present time somewhat less reliable.

Most tunable laser diodes in fiber optics communications can be divided into three categories: an array of different frequency lasers with a moveable external mirror, a tunable external cavity laser (ECL), and a monolithic tunable laser. Each of these will be discussed in the following sections.

Array with External Mirror

Many applications do not require rapid change in frequency, such as for replacement lasers. In this case it is sufficient to have an array of DFB lasers, each operating at a different frequency on the ITU grid, and to move an external mirror to align the desired laser to the output fiber. Fujitsu, NTT, Furukawa, and Santur have all presented this approach at various conferences. A typical system might contain a collimating lens, a tilting mirror [often a MEMS (micro-electromechanical structure)] and a lens that focuses into the fiber. The challenge is to develop a miniature device that is cost-effective. A MEMS mirror may be fast enough to enable agile wavelength switching at the circuit level; speeds are typically milliseconds but may advance to a few tenths of a millisecond.

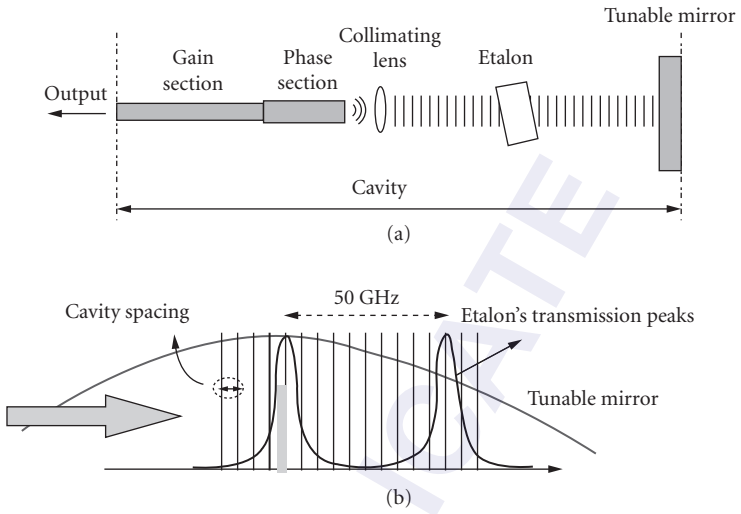

FIGURE 20 Tunable external cavity laser: (*a*) geometry, showing etalon set at the ITU spacing of 50 GHz and a tunable mirror and (*b*) spectrum of mirror reflectivity. Spectral maximum can be tuned to pick the desired etalon transmission maximum. The cavity spacing must match the two other maxima, which is done with the phase section. *(Adapted from Ref. 31.)*

External Cavity Laser

Tunable lasers may consist of a single laser diode in a tiny, wavelength-tunable external cavity, as shown in Fig 20*a*. A tunable single-mode is achieved by inserting two etalons inside the cavity. One is set at the 50-GHz spacing of the ITU standard; the other provides tuning across the etalon grid, as shown in Fig. 20*b*. A tunable phase section is also required to ensure that the mode selected by the overall laser cavity length adds constructively to the mode selection from the etalon and mirror. The mechanism for tuning has varied from a liquid crystal mirror,[31] to thermal tuning of two Fabry-Perot filters within the cavity, reported by researchers at Intel. Pirelli is another company that uses an ECL; they have not reported their method of tuning, but previous work from their laboratory suggests that a polished fiber coupler with variable core separation could be used to tune a laser wavelength.

An alternative tunable filter is acousto-optic, fabricated in lithium niobate, which has been shown to have a tuning range of 132 nm, covering the entire L, C, and S bands.[32] Stable oscillation was achieved for 167 channels, each separated by 100 GHz, although there is no evidence that this has become a commercial device.

The speed of tuning external cavity lasers to date is on the order of milliseconds, perhaps fast enough to enable circuit switching to different wavelengths; additional research is underway to achieve faster switching times.

Monolithic Tunable Lasers

Integration of all elements on one substrate offers the greatest potential for compact, inexpensive devices that can switch rapidly from one wavelength to another. The aim is to tune across the entire ITU frequency grid, as far as the laser gain spectrum will allow. All monolithic tunable lasers reported to date involve some sort of grating vernier so that a small amount of tuning can result in a large spectral shift. When the periods of two reflection spectra are slightly mismatched, lasing will occur at that pair of reflectivity maxima that are aligned. Inducing a small index change in one mirror

relative to the other causes adjacent reflectivity maxima to come into alignment, shifting the lasing wavelength a large amount for a small index change. However, to achieve continuous tuning between ITU grid frequencies, the phase within the two-mirror cavity must be adjusted so that its mode also matches the chosen ITU frequency.

The refractive index in the gratings is usually changed by current injection, since changing the free-carrier density in a semiconductor alters its refractive index. Free-carrier injection also introduces loss, which is made up for by the semiconductor optical amplifier (SOA). In principle this modulation speed can be as fast as carriers can be injected and removed. Thermal tuning of the refractive index is an important alternative, because of the low thermal conductivity of InP-based materials. Local resistive heating is enough to create the 0.2 percent change in refractive index needed for effective tuning. The electro-optic effect under reverse bias is not used at present, because the effect does not create large-enough index change at moderate voltages.

In order for the grating to be retroreflective, its periodicity must be half the wavelength of light in the medium (or an odd integral of that); this spacing was discussed in the section on DBR gratings (Sec. 13.7). The other requirement is that there be a periodicity Λ at a scale that provides a comb of possible frequencies at the ITU-T grid (like the etalon in the ECL). This is done in monolithic grating devices by installing an overall periodicity to the grating at the grid spacing. One way to do this is with a *sampled grating* (SG), as shown in Fig. 21*a*. Only samples of the grating are provided, periodically at frequency Λ; this is usually done by removing periodic regions of a continuous grating. A laser with DBR mirrors containing sampled gratings is called a *sampled grating DBR* (SG-DBR) laser. If the sampling is abrupt, the reflectance spectrum of the overall comb of frequencies will have the conventional sinc function. The comb reflectance spectrum can be made flat by adding a semiconductor optical amplifier in-line with the DBR laser, or inserting an electroabsorption modulator (EAM) (which will be described in Sec. 13.12), or both, as shown in Fig. 21*b*.[33] The EAM can be used to modulate the laser output, rather than using direct modulation of the laser. JDS Uniphase tunable diode lasers apparently have this geometry.

An alternative approach to achieving a flat spectrum over the tuning range has been to divide the grating into identical elements, each Λ long, and each containing its own structure.[34] This concept has been titled the *superstructure grating* (SSG). The periodicity Λ provides the ITU grid frequencies. When the structure of each element is a phase grating that is chirped quadratically (Fig. 22*a*), the overall reflectance spectrum is roughly constant and the number of frequencies can be very large. Without the quadratic phase grating structure, the amplitude of the overall reflectance spectrum would have the typical sinc function. Figure 22*b* shows how the desired quadratic phase shift can be achieved with uneven spacing of the grating teeth, and Fig. 22*c* shows the resulting measured flat reflectance spectrum.[34]

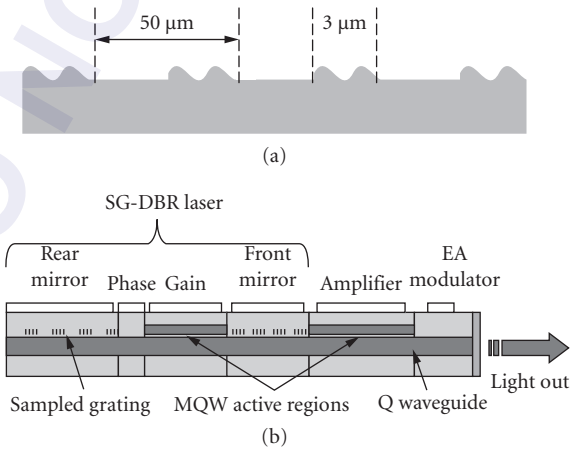

FIGURE 21 Sampled grating: (*a*) the geometry and (*b*) sampled grating DBR laser integrated with SOA and EAM.[33]

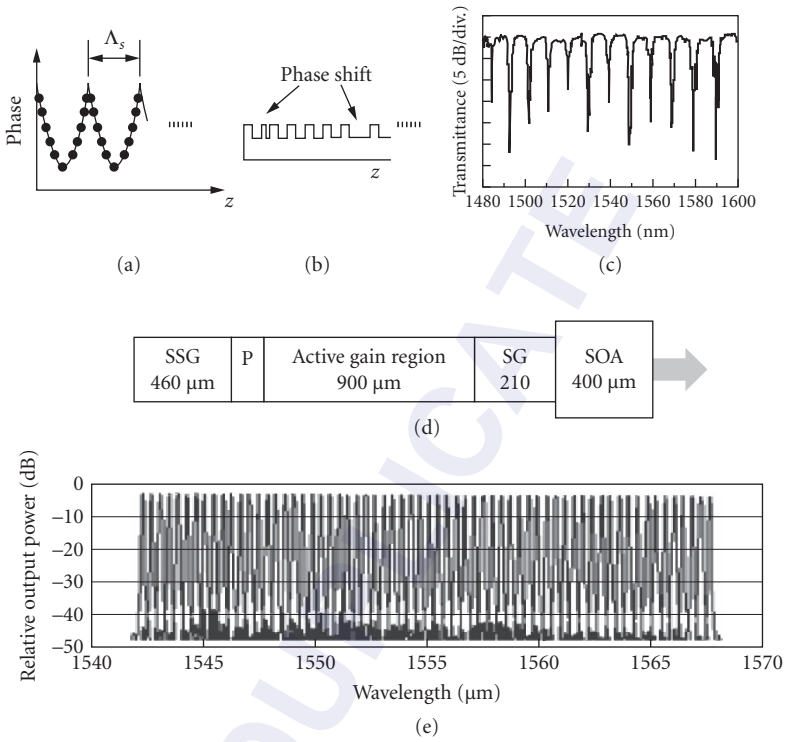

FIGURE 22 Sampled superstructure grating: One period of (*a*) quadratic phase shift and (*b*) quadratic phase superstructure; (*c*) SSG reflectance spectrum;[34] (*d*) geometry for wide-bandwidth integrated tunable laser; and (*e*) measured tuning output spectrum.[35]

A relatively new tunable laser diode that can be tuned for DWDM throughout most of the C band contains a front SG-DBR and a rear SSG-DBR.[35] Figure 22*d* shows the design of this device, with lengths given in micrometers (P represents a phase shift region 150 μm long). At the bottom is the spectral output of such a monolithic laser, tuned successively across each wavelength of the ITU grid. A short, low-reflectivity front mirror enables high output power, while keeping the minimum reflectivity that enables wavelength selection based on the Vernier mechanism. A long SSG-DBR was adopted as the rear mirror along with phase control inside the laser cavity, to provide a uniform reflectivity spectrum envelope with a high peak reflectivity (greater than 90%). This monolithic tunable laser includes an integrated SOA for high output power.

A laser tunable for coarse WDM uses a rear reflector comprising a number of equal lengths of uniform phase grating separated by π-phase shifts and a single continuously chirped grating at the front.[36] By the correct choice of the number and positions of the phase shifts, the response of the grating can be tailored to produce flat comb of reflection peaks throughout the gain bandwidth. The phase grating was designed to provide seven reflection peaks, each with a 6.8-nm spacing. Over the 300-μm-long front grating is placed a series of short contacts for injecting current into different parts of the grating in a controlled way (Fig. 23). This enables the enhancement of the reflection at a desired wavelength simply by injecting current into a localized part of the chirped grating. The chirp rate was chosen to yield a total reflector bandwidth of around 70 nm. As with other devices, the monolithic chip includes a phase control region and a SOA. As seen in Fig. 23, the waveguide path through the SOA is curved to avoid retroreflection back into the laser cavity—a standard technique.

A different approach is to use a multimode interferometer (MMI) as a Y branch (which will be explained in Sec. 13.11 on modulators).[37] This separates backward-going light into two branches, each

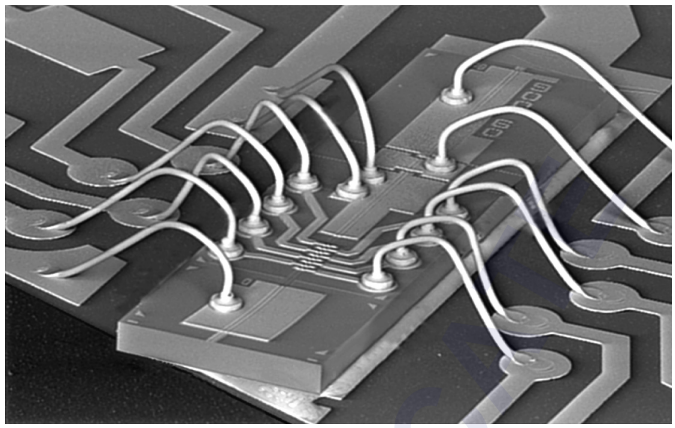

FIGURE 23 Scanning electron microscope image of a monolithically integrated tunable laser for coarse WDM.[36]

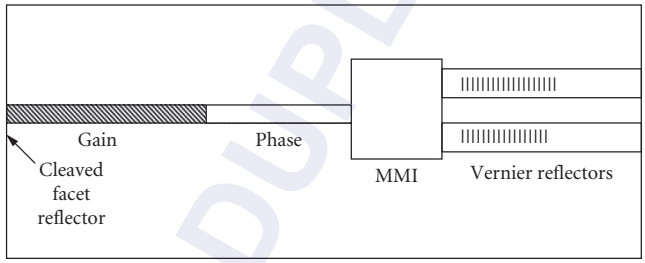

FIGURE 24 Conceptual design of tunable modulated grating DBR laser, including multimode interferometric beam splitter as a Vernier.

reflecting from a grating of a different periodicity, as shown in Fig. 24. The Vernier effect extends the tuning range through parallel coupling of these two *modulated grating* (MG) reflectors with slightly different periods; both reflections are combined at the MMI. The aggregate reflection seen from the input port of the MMI coupler gives a large reflection only when the reflectivity peaks of both gratings align. A large tuning range (40 nm) is obtained for relatively small tuning of a single reflector (by an amount equal to the difference in peak separation). A phase section aligns a longitudinal cavity mode with the overlapping reflectivity peaks. Tunable high-speed direct modulation at 10 Gb/s has been demonstrated with low injection current, with low power consumption and little heat dissipation.

Commercial tunable laser diodes for optical communications are still in their infancy; it is still unclear which of these technologies will be optimum for practical systems. The ultimate question is whether for any given application it is worth the added cost and complexity of tunability.

13.9 LIGHT-EMITTING DIODES

Sources for low-cost fiber communication systems, such as used for communicating data, have traditionally used light-emitting diodes (LEDs). These may be *edge-emitting LEDs* (E-LEDs), which resemble laser diodes, or *surface-emitting LEDs* (S-LEDs), which emit light from the surface of the diode and can be butt-coupled to multimode fibers. The S-LEDs resemble today's VCSELs, discussed

in the following section. The LED can be considered a laser diode operated below threshold, but it must be specially designed to maximize its output.

When a *pn* junction is forward biased, electrons are injected from the *n* region and holes are injected from the *p* region into the active region. When free electrons and free holes coexist with comparable momentum, they will combine and may emit photons of energy near that of the bandgap, resulting in an LED. The process is called *injection-* or *electroluminescence*, since injected carriers recombine and emit light by spontaneous emission. A semiconductor laser diode below threshold acts as an LED. Indeed, a laser diode without mirrors *is* an LED. Because LEDs have no threshold, they usually are not as critical to operate and are often much less expensive because they do not require the fabrication step to provide optical feedback (in the form of cleaved facets or DFB). Because the LED operates by spontaneous emission, it is an incoherent light source, typically emitted from a larger aperture (out the top surface) with a wider far-field angle and a much wider wavelength range (30 to 50 nm). In addition, LEDs are slower to modulate than laser diodes because stimulated emission does not remove carriers. Nonetheless, they can be excellent sources for inexpensive multimode fiber communication systems, as they use simpler drive circuitry. They are longer lived, exhibit more linear input-output characteristics, are less temperature sensitive, and are essentially noise-free electrical-to-optical converters. The disadvantages are lower power output, smaller modulation bandwidths, and pulse distortion in fiber systems because of the wide wavelength band emitted. Some general characteristics of LEDs are discussed in Chap. 17 in Vol. II of this *Handbook*.

In fiber communication systems, LEDs are used for low-cost, high-reliability sources typically operating with graded index multimode fibers (core diameters approximately 62 μm) at data rates up to 622 Mb/s. For short fiber lengths they may be used with step-index plastic fibers. The emission wavelength will be at the bandgap of the active region in the LED; different alloys and materials have different bandgaps. For medium-range distances up to ~10 km (limited by modal dispersion), LEDs of $In_xGa_yAs_{1-x}P_{1-y}$ grown on InP and operating at $\lambda = 1.3$ μm offer low-cost, high-reliability transmitters. For short-distance systems, up to 2 km, GaAs LEDs operating near $\lambda = 850$ nm are used, because they have the lowest cost, both to fabricate and to operate, and the least temperature dependence. The link length is limited to ~2 km because of chromatic dispersion in the fiber and the finite linewidth of the LED. For lower data rates (a few megabits per second) and short distances (a few tens of meters), very inexpensive systems consisting of red-emitting LEDs with $Al_xGa_{1-x}As$ or $GaIn_yP_{1-y}$ active regions emitting at 650 nm can be used with plastic fibers and standard silicon detectors. The 650-nm wavelength is a window in the absorption in acrylic plastic fiber, where the loss is ~0.3 dB/m; a number of companies now offer 650-nm LEDs.

A typical GaAs LED heterostructure is shown in Fig. 25, with (*a*) showing the device geometry and (*b*) showing the heterostructure bandgap under forward bias. The forward-biased *pn* junction injects electrons and holes into the narrowband GaAs active region. The $Al_xG_{1-x}As$ cladding layers confine the carriers in the active region. High-speed operation requires high levels of injection (and/or doping) so that the spontaneous recombination rate of electrons and holes is very high. This means that the active region should be very thin. However, nonradiative recombination increases at high carrier concentrations, so there is a trade-off between internal quantum efficiency and speed. Under some conditions, LED performance is improved by using QWs or strained layers. The improvement is not as marked as with lasers, however.

Spontaneous emission causes light to be emitted in all directions inside the active layer, with an internal quantum efficiency that may approach 100 percent in these direct band semiconductors. However, only the light that gets out of the LED and into the fiber is useful in a communication system, as illustrated in Fig. 25*a*. The challenge, then, is to collect as much light as possible into the fiber end. The simplest approach is to butt-couple a multimode fiber to the S-LED surface as shown. Light emitted at too large an angle will not be guided in the fiber core, or will miss the core altogether. Light from the edge-emitting E-LED (in the geometry of Fig. 1, with antireflection-coated cleaved facets) is more directional and can be focused into a single-mode fiber. Its inexpensive fabrication and integration process makes the S-LED common for inexpensive data communication. The E-LED has a niche in its ability to couple with reasonable efficiency into single-mode fibers. Both LED types can be modulated at bit rates up to 622 Mbps, an asynchronous transfer mode (ATM) standard, but many commercial LEDs have considerably smaller modulation bandwidths.

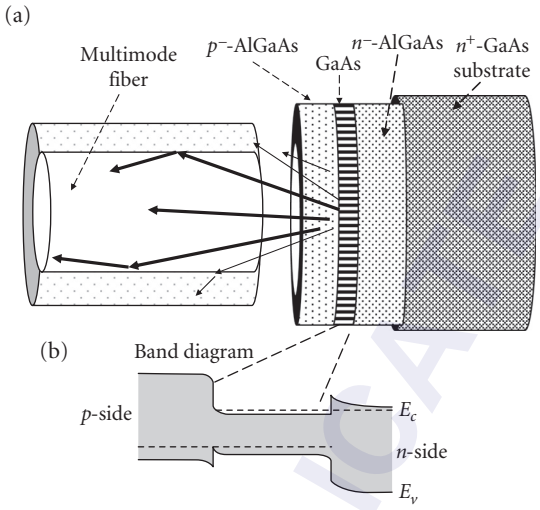

FIGURE 25 GaAs light-emitting diode (LED) structure: (*a*) cross-section of surface-emitting LED aligned to a multimode fiber, showing rays that are guided by the fiber core and rays that cannot be captured by the fiber and (*b*) conduction band E_c and valence band E_v as a function of distance through the LED.

Surface-Emitting LEDs

The coupling efficiency of an S-LED butt-coupled to a multimode fiber (shown in Fig. 26*a*) is typically small, unless methods are employed to optimize it. Because light is spontaneously emitted in all internal directions, only half is emitted toward the top surface. In addition, light emitted at too great an angle to the surface normal is totally internally reflected back down and is lost (although it may be reabsorbed, creating more electron-hole pairs). The critical angle for total internal reflection between the semiconductor of refractive index n_s and the output medium (air or plastic encapsulant) of refractive index n_o is given by $\sin \theta_c = n_o/n_s$. The refractive index of GaAs is $n_s \sim 3.3$, when the output medium is air, the critical angle $\theta_c \sim 18°$. Because this angle is so small, less than 2 percent of the total internal spontaneous emission can come out the top surface, at any angle. A butt-coupled fiber can accept only spontaneous emission at those external angles that are smaller than its numerical aperture. For a typical fiber NA ≈ 0.25, this corresponds to an external angle (in air) of 14°, which corresponds to only 4.4° inside the GaAs. This means

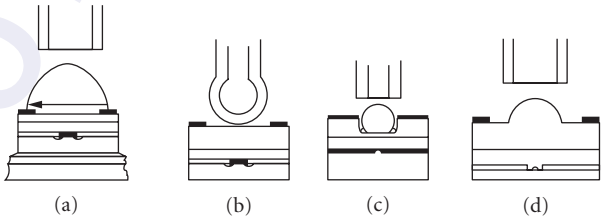

FIGURE 26 Typical geometries for coupling from LEDs into fibers: (*a*) hemispherical lens attached with encapsulating plastic; (*b*) lensed fiber tip; (*c*) microlens aligned through use of an etched well; and (*d*) spherical semiconductor surface formed on the substrate side of the LED.

that the cone of spontaneous emission that can be accepted by the fiber in this simple geometry is only ~0.2 percent of the entire spontaneous emission! Fresnel reflection losses make this number even smaller.

For InP-based LEDs, operating in the 1.3- or 1.55-μm wavelength region, the substrate is transparent and LED light can be emitted out the substrate. In this geometry the top contact to the *p*-type material no longer need be a ring; it can be solid and reflective, so light emitted backward can be reflected toward the substrate, increasing the efficiency by a factor of 2.

The coupling efficiency can be increased in a variety of other ways, as shown in Fig. 26. The LED source is incoherent, a lambertian emitter, and follows the law of imaging optics: A lens can be used to reduce the angle of divergence of LED light, but this will enlarge the apparent source. The image of the LED source must be smaller than the fiber into which it is to be coupled. Unlike a laser, the LED has no modal interference and the output of a well-designed LED has a smooth intensity distribution that lends itself to imaging.

The LED can be encapsulated in materials such as plastic or epoxy, with direct attachment to a focusing lens (Fig. 26*a*). The output cone angle will depend on the design of this encapsulating lens. Even with a parabolic surface, the finite size of the emitting aperture and resulting aberrations will be the limiting consideration. In general, the user must know both the area of the emitting aperture and the angular divergence in order to optimize coupling efficiency into a fiber. Typical commercially available LEDs at $\lambda = 850$ nm for fiber optic applications have external half-angles of ~25° without a lens and ~10° with a lens, suitable for butt-coupling to multimode fiber.

Improvement can also be achieved by lensing the pigtailed fiber to increase its acceptance angle (Fig. 26*b*); this example shows the light emitted through and out the substrate. Another alternative is to place a microlens between the LED and the fiber (Fig. 26*c*), possibly within an etched well. Substrate-side emission enables a very effective geometry for capturing light by means of a domed surface fabricated directly on the substrate, as shown in in Fig. 26*d*. Because the refractive index of encapsulating plastic is <1.5, compared to 3.3 of the semiconductor, only a dome etched within the semiconductor can entirely eliminate total internal reflection. Integrated semiconductor domes require advanced semiconductor fabrication technology, but have proven effective. In GaAs diodes the substrate is absorptive, but etching a well in the substrate and inserting a fiber can serve to collect backside emission. For any of these geometries, improvement in efficiency by as much as a factor of 2 can be obtained if a mirror is provided to reflect backward-emitted light. This mirror can be either metal or a dielecric stack deposited at the air-semiconductor interface, or even a DBR mirror grown within the semiconductor structure.

Current must be confined to the surface area of emission, which is typically 25 to 75 μm in diameter. This is done by constricting the flow of injection current by mesa etching or by using an oxide-defined electrode. Regrowth using *npn* blocking layers or semi-insulating material in the surrounding areas (as in lasers) has the advantage of reducing thermal heating. Surface-emitting LEDs require that light be emitted out of the surface in a gaussian-like pattern; it must not be obscured by the contacting electrode. Typically, a highly conductive cap layer brings the current in from a ring electrode. In InP-based devices, when light is collected out of the substrate side, a solid top electrode can be reflective and electrical contact may be made to the substrate surrounding an optical output aperture.

A typical S-LED at 1310-nm wavelength might couple 35 μW of light into a pigtailed multimode fiber of 62.5 μm diameter, if driven with 62-mA input current at ~1-V forward bias, for an efficiency of less than 0.06 percent. The spectral width is 160 nm, and the rise or fall time of 3 ns means 200-MHz modulation capability. By contrast, a similar S-LED at 850-nm wavelength under similar drive conditions has comparable power at half the modulation speed and a fifth the bandwidth.[38]

Improved performance has been obtained by sandwiching the active layer between DBR mirrors to form a resonant cavity (RC-LED). This reduces the spontaneous emission linewidth, thereby increasing the modulation bandwidth that can be transmitted through dispersive fibers. The RC-LEDs look very much like VCSELs operated below threshold (see the following section). The resonant cavity promotes emission into resonances supported by the cavity while suppressing off-resonance emission. The cavity narrows the emission angles and increases the external quantum efficiency to greater than 20 percent. By controlling reflectivities and drive current, the output can be tailored anywhere from a wide spectrum LED to a narrow spectrum laser. Below threshold the RC-LED will have the operating characteristics of a spontaneous LED, as described in this section. Above threshold, the resonant structure becomes a VCSEL. The more exacting fabrication of these devices increases their cost, however.

A typical GaAs LED has a spectral width of 50 nm, while an RC-LED has a spectral width of 6.7 nm and 5 times the output power when coupled into a multimode fiber. The narrower spectrum also means much less pulse-broadening in fiber communication systems. The RC-LED, with a spot size of 20 μm, will have an output power typically a quarter that of a VCSEL laser. In comparison, a typical VCSEL has a spot side of 8 μm and a spectral width of 3.2 nm.

RC-LEDs have enhanced modulation bandwidth compared to conventional LEDs, due to a higher carrier density for a given current, which leads to a reduction in the spontaneous lifetime. However, the RC-LEDs bandwidth is current dependent. The fastest modulation speed is obtained by lasers, of course, but they have a highly nonlinear light-current relationship, unlike LEDs.

Edge-Emitting LEDs

Edge-emitting LEDs (E-LEDs or EELEDs) have a geometry that is similar to that of a conventional LD (Fig. 1), but without a feedback cavity. That is, light travels back and forth in the plane of the active region of an E-LED and is emitted out of one antireflection-coated cleaved end. As in a laser, the active layer is 0.1 to 0.2 μm thick. Because the light in an E-LED is waveguided in the out-of-plane dimension and is lambertian in-plane, the output radiation pattern will be elliptical, with the largest divergence in-plane with full width at half-maximum (FWHM) angle of 120°. The out-of-plane guided direction typically radiates with a 30° half-angle. An elliptical collimating lens will be needed to optimally couple light into a fiber. The efficiency can be doubled by depositing a reflector on the back facet of the E-LED, just as in the case of a laser.

Edge-emitting LEDs can be coupled into fibers with greater efficiency because their source area is smaller than that of a S-LED. However, the alignment and packaging is more cumbersome than with S-LEDs. Typically, E-LEDs can be obtained already pigtailed to fibers. Edge-emitting diodes can be coupled into *single-mode* fiber with modest efficiency. A single-mode fiber pigtailed to an E-LED can typically transmit 30 μW at 150-mA drive at 1 V, for an overall efficiency of 0.04 percent.[39] This efficiency is comparable to the emission of surface-emitting lasers into *multimode* fiber (with an area 50 times larger than single-mode fibers). Because of their wide emission wavelength bandwidth, E-LEDs are typically used as low-coherence sources for fiber sensor applications, rather than in communications applications.

Operating Characteristics of LEDs

In an LED, the output optical power P_{opt} is linearly proportional to the drive current I; the relation defines the output efficiency η:

$$P_{out} = \frac{\eta h \nu I}{e} \tag{42}$$

This efficiency is affected by the geometry of the LED. The power coupled into a fiber is further reduced by the coupling efficiency between the LED emitter and the fiber, which depends on the location, size, and numerical aperture of the fiber as well as on the spatial distribution of the LED output light and the optics of any intervening lens. The *internal* quantum efficiency (ratio of emitted photons to incident electrons) is usually close to 100 percent.

Figure 27 shows a typical result for power coupled into a graded index multimode fiber as a function of current for various temperatures. The nonlinearity in the light out versus current, which is much less than in a laser diode, nevertheless causes some nonlinearity in the modulation of LEDs. This LED nonlinearity arises from both material properties and device configuration; it may be made worse by ohmic heating at high drive currents. The residual nonlinearity is an important characteristic of any LED used in communication systems. Edge emitters are typically less linear because they operate nearer the amplified spontaneous limit.

The InP-based S-LED shows approximately 10 percent reduction in output power for a 25°C increase in temperature (compared to ~50 percent reduction for a typical laser). Unlike a laser, there is no temperature-dependent threshold. Also, the geometric factors that determine the fraction of light

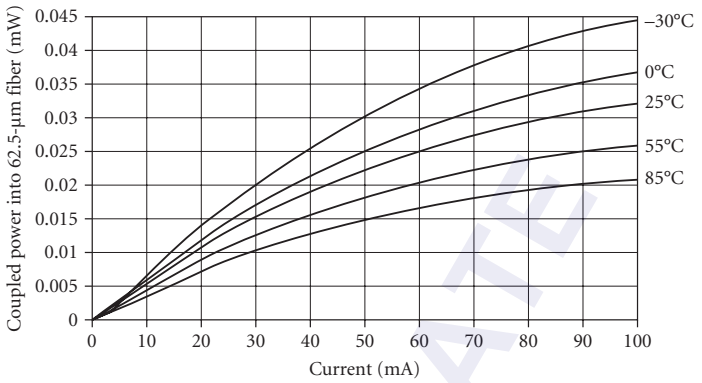

FIGURE 27 Optical power coupled from an *InGaAsP S*-LED into graded index fiber at 1.3-μm wavelength as a function of drive current, for several temperatures.[40]

emitted from the LED are not temperature dependent. Nonetheless, InP-based LEDs have a stronger temperature dependence than GaAs-based LEDs, because of more nonradiative recombination, particularly at the high injection levels required by high-speed LEDs.

The spectrum of the incoherent light emitted from an LED has a roughly gaussian shape with an FWHM around 40 nm in the case of a typical GaAs/AlGaAs LED operating near $\lambda = 0.8$ μm. This bandwidth, along with chromatic dispersion in graded index fibers, limits the distance over which these LEDs can be used in fiber systems. InGaAsP/InP LEDs have wider linewidths (due to alloy scattering, heavy doping, and temperature fluctuations), which depend on the details of their design. As temperature increases, the peak of the spectrum shifts to longer wavelength and the spectrum widens. The variation of the central wavelength with temperature at $\lambda = 1.3$ μm, is approximately 5 meV/°C. However, graded index fibers have negligible chromatic dispersion at this wavelength, so this is not usually a problem; if it is, heat sinking and/or cooling can be provided. Resonant cavity LEDs can provide narrower linewidths.

LEDs do not suffer from the catastrophic optical damage that lasers do, because of their lower optical power densities. However, they do degrade with time; 10^6 to 10^9 hours can be expected. Because degradation processes have an exponential dependence on temperature, LED life can be shortened by operating at excessive temperatures. Experiments with thermally accelerated life testing suggest that the power out P varies with time t as

$$P(t) = P(0) \exp(-qt) \tag{43}$$

where $q = q_o \exp(-W_a/k_B T)$, with W_a as the activation energy, k_B as Boltzman's constant, and T as temperature. In GaAs LEDs, W_a is 0.6 to 1 eV. Of course this assumes that the LEDs are placed in a proper electrical circuit.

LED light is typically unpolarized, since there is no preferred polarization for spontaneous emission.

Transient Response *M*ost LEDs respond in times faster than 1 μs; with optimization, they can reach the nanosecond response times needed for optical communication systems. To achieve the 125 Mb/s rate of the fiber distributed data interface (FDDI) standard requires maximum rise and fall times of 3.5 ns; to achieve the 622 Mb/s rate of the asynchronous transfer mode standard, the necessary times drop to 0.7 ns.

The speed of an LED is limited by the recombination time of injected carriers; it does not have the turn-on delay of lasers, nor any relaxation oscillations, but it also does not have the fast decay of stimulated emission. The LED intrinsic frequency response (defined as the ratio of the AC components of the emitted light to the DC value) is[41]

$$r(\omega) = (1 + \omega^2\tau^2)^{-1/2} \tag{44}$$

where τ is the minority carrier lifetime in the injected region. This shows that high-speed LEDs require small minority carrier lifetimes. The square-root dependence comes out of the rate equation solution.

When the active region is doped higher than the injected carrier density, the lifetime τ_L decreases as the background doping density N_o increases:

$$\frac{1}{\tau_L} = BN_o \tag{45}$$

The challenge is to provide high levels of doping without increasing the nonradiative recombination. Typical high-speed response is about 1 ns, although doping with beryllium (or carbon) at levels as high as 7×10^{19} cm^{-3} has allowed speeds to increase to as much as 0.1 ns, resulting in a cutoff frequency of 1.7 GHz (at the sacrifice of some efficiency).[42]

When operating in the high-injection regime, the injected carrier density N can be much larger than the doping density, and $1/\tau_H = BN$, where N is created by a current density J such that $N = J\tau/ed$. Combining these two equations

$$\frac{1}{\tau_H} = \left(\frac{BJ}{ed}\right)^{1/2} \tag{46}$$

The recombination time may be reduced by thinning the active region and by increasing the drive current. However, too much injection may lead to thermal problems, which in turn may cause modulation nonlinearity. LEDs with thin active layers operated in the high-injection regime will have the fastest response. Bandwidths in excess of 1 GHz have been achieved in practical LEDs.

Because LEDs have such wide wavelength spectra, frequency chirping is negligible. Because LEDs do not have optical cavities, as do lasers, they will not have modal interference and noise. Also, there will not be strong feedback effects coming from external fiber facets, such as the coherence collapse. Because of their inherent light-current linearity at moderate drive levels, the modulation response of LEDs should be a direct measure of their frequency response. They add no noise to the circuit, and they add distortion only at the highest drive levels.

Drive Circuitry and Packaging The LED is operated under sufficient forward bias to flatten the bands of the *pn* junction. This voltage depends on the bandgap and doping and is typically between 1 and 2 V. The current will be converted directly to light; typically a hundred milliamperes is required to produce a few milliwatts of output into a fiber, with a series resistor used to limit the current.

The LED is modulated by varying the drive current. A typical circuit might apply the signal to the base circuit of a transistor connected in series with the LED and a current-limiting resistor. The variation in current flowing through the LED (and therefore in the light out) is proportional to the input voltage in the base circuit. LEDs are typically mounted on standard headers such as TO-18 or TO-46 cans; SMA and ST connectors are also used. The header is covered by a metal cap with a clear glass top through which light can pass.

13.10 VERTICAL CAVITY SURFACE-EMITTING LASERS

The *vertical cavity surface-emitting laser* (VCSEL) has advantages for low-cost data transmission. The use of a laser means that multi-gigahertz modulation is possible, and the stimulated emission is directional, rather than the isotropic spontaneous emission of LEDs, leading to much higher efficiencies. Because the light is emitted directly from the surface, a single or multimode fiber can be directly butt-coupled with an inexpensive mounting technology, and the coupling efficiency can be very high. VCSELs can be fabricated in linear arrays that can be coupled inexpensively to linear arrays of fibers for parallel fiber interconnects with aggregate bit rates of several gigabits per second,

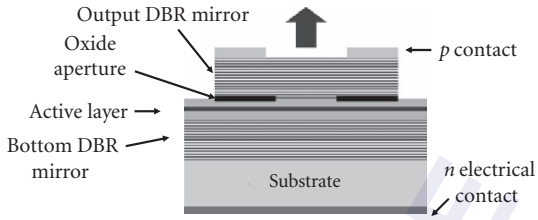

FIGURE 28 Cross-sectional view of an oxidized GaAs VCSEL. The oxidized AlAs layer aperture is shown in black, as is the active layer.[43]

amortizing the alignment cost over the number of elements in the array. VCSELs lend themselves to two-dimensional arrays as well, which makes them attractive to use with smart modulating pixels. The planar fabrication of VCSELs allows for wafer-scale testing, another cost saving.

Advantages of VCSELs include single longitudinal-mode operation and a circular emission pattern that allows for better coupling into optical fiber without the need for beam-shaping optics. The planar structure also allows much easier fabrication and testing, resulting in higher device yield. VCSELs can also be fabricated in two-dimensional laser arrays with each laser operating at a slightly different frequency, for WDM.

The VCSEL requires mirrors on the top and bottom of the active layer, forming a vertical cavity, as shown in Fig. 28. These lasers use the fact that a DBR (or a multilayer quarter-wavelength dielectric stack) can achieve very high reflectance. Thus, the very short path length through a few QWs (at normal incidence to the plane) is sufficient to reach threshold.

The first VCSELs were based on GaAs: either GaAs active regions that emitted at $\lambda = 850$ nm, or strained InGaAs active regions that emitted at $\lambda = 980$ nm. The former are of greater interest in low-cost communication systems because they are compatible with inexpensive silicon detectors. This section explains VCSEL concepts in terms of GaAs-based devices operating in the 850-nm region. With an active region of $Al_xIn_yGa_{1-x-y}P$, GaAs-based devices can be fabricated in the 650-nm wavelength regime that is optimum for use with plastic fiber. Highly strained InGaAs QWs enable GaAs-based devices to operate near the 1.3-μm wavelength zero-dispersion regime. The addition of a small amount of nitrogen in the active region extends GaAs-based devices to even longer wavelengths. The development of GaAs-based VCSELs has been relatively straightforward because of the existence of epitaxial GaAs/AlGaAs high-reflectivity DBR mirrors.

VCSELs based on InP technology have been more challenging because the reflectivity of InP-based DBR mirrors is quite low. Also, InP-based QWs have lower gain and significant free carrier absorption, especially in the *p* layers, Also, the quaternaries have poor thermal conductivity, so the active layer has a relatively high temperature. Several novel technologies have been developed that look like they might overcome these challenges, which will be described in subsequent sections.

Number of Quantum Wells

A single quantum well of GaAs requires input current densities of approximately 100 A/cm^2 to achieve transparency; *N* wells require *N* times this current. To keep the threshold current less than 1 kA/cm^2, then, means active regions with less than 10 QWs. The VCSEL requires an optical standing wave that has a period of a half-wavelength, which is approximately 120 nm in GaAs. The gain region should be confined to the quarter-wavelength region at the peak of the optical standing wave, a region of about 60 nm. Thus, a typical active region might consist of 3 QWs of 8 μm thickness, each separated by approximately 10 nm. Strained QWs have higher gain than unstrained QWs, and can be grown by adding indium or phosphorous into the composition.

InP-based QWs for 1.3 μm and 1.55 μm operation have somewhat lower gain, but typical geometries still use 3 to 5 QWs; higher reflectivity mirrors compensate for lower gain.

Mirror Reflectivity

When the mirror reflectivity R in a laser is close to 1, a simple expression for the threshold gain-length product, $G_L L$ is

$$G_L L = (1 - R_1)(1 - R_2) \tag{47}$$

Typical GaAs lasers have gains $G_L \sim 1000$ cm^{-1}. For a quantum well thickness of 10 nm, the gain per quantum well is 10^{-3}, so that with 3 QW, reflectivities of ~98 percent for each mirror should be sufficient to achieve threshold. Very often, however, in order to lower the threshold much higher reflectivities are used, particularly on the back mirror.

The on-resonance Bragg mirror reflectivity is the square of the reflection coefficient r, given by

$$r = \frac{1 - (n_f/n_i)(n_l/n_h)^{2N}}{1 + (n_f/n_i)(n_l/n_h)^{2N}} \tag{48}$$

where there are N pairs of quarter-wavelength layers that alternate high-index and low-index (n_h and n_l, respectively), and n_f and n_i are the refractive index of the final and initial media, respectively.[44]

For high-reflectance Bragg mirrors, the second term in the numerator and denominator is small, and the reflectivity can be simplified to

$$\varepsilon = 1 - R = 1 - r^2 = 4\left(\frac{n_f}{n_i}\right)\left(\frac{n_l}{n_h}\right)^{2N} \tag{49}$$

Higher reflectivity (smaller ε) is provided by either more layer pairs or a larger refractive index difference between the two compositions in the layer pairs. Also, Eq. (49) shows that internal mirrors ($n_f = n_i$) will have a smaller reflectivity than external mirrors ($n_f = 1$), for the same number of layer pairs. If the layer pair consists of GaAs ($n \sim 3.6$) and AlAs ($n \sim 3.0$), a mirror of 15 layer pairs will have an internal reflectivity R = 98 percent and an external reflectivity R = 99.5 percent. Thirty layer pairs are required to increase the internal reflectivity to 99.96 percent. Bragg mirrors with a smaller fraction of AlAs in the low-index layers will require even more layer pairs to achieve the same reflectivity.

In long-wavelength InP-based VCSELs, the $In_xGa_{1-x}As_yP_{1-y}$/InP refractive index difference is small and many layers are required to achieve sufficiently high reflectivity. Often the top DBR layer is replaced by a deposited mirror, such as alternating quarter-wave layers of ZnSe and MgF, or amorphous silicon and aluminum oxide. Hybrid mirrors use fewer dielectric layers and can terminate with a gold layer. Because the substrate is transparent, these devices are mounted upside-down, with the gold layer attaching to a thermal heat sink.

Another option has been to replace epitaxial InP-based DBR mirrors with fusion-bonded traditional GaAs-AlAs DBR mirrors that have been grown on GaAs substrates. Some commercial VCSELs have used this approach. Wafer fusion occurs when pressing the two wafers together (after removing oxide off their surfaces) at 15 atm and heating to 630°C under hydrogen for 20 min. Mirrors can be wafer-fused on both sides of the VCSEL by etching away the InP substrate and one of the GaAs substrates.

Finally, new multicomponent compositions show promise of alternative mirrors, especially by adding aluminum. Forty lattice-matched pairs of $Al_xGa_yIn_{1-x-y}As$ and InP quarter-wave layers have been shown to yield a reflectivity of 99.9 percent.[45] Some commercial VCSEL manufacturers have favored this all-epitaxial fabrication process.

An entirely different approach, which is not yet commercial, is to push GaAs-based devices out to longer wavelength. Adding dilute amounts of nitrogen yields an active layer of $Ga_xIn_{1-x}N_yAs_{1-y}$, which has been shown to produce VCSELs near the 1.3-μm wavelength range. It turns out that adding a small amount of antimony produces QWs of higher quality. This has suggested that the five-component material $Ga_xIn_{1-x}N_yAs_zSb_{1-y-z}$ has the potential to achieve even lower bandgaps; VCSELs of this composition have been demonstrated, but not yet as far out in wavelength as 1.55 μm.

Electrical Injection and Current Confinement

As shown in Fig. 28, light is emitted through a window hole in the top electrode. It is difficult to inject carriers through the Bragg reflector because the wide bandwidth layers provide potential wells that trap carriers; but this can be overcome with increased operating voltage. Sometimes graded layers are used in the DBR structure to reduce carrier trapping. Current confinement to a finite area was originally done by proton implantation or by etching mesas and then planarizing with polyimide. VCSELs of fairly large diameter (>10 μm) are straight-forward to make and are useful when low threshold and single-mode are not required. Recently a selective oxidation technique has been developed that enables a small oxide-defined current aperture. A high-aluminum fraction $Al_xGa_{1-x}As$ layer (~98%) is grown above the active layer and a mesa is etched to below that layer. Then a long, soaking, wet-oxidization process selectively creates a ring of native oxide that can stop carrier transport. The chemical reaction moves in from the side of the etched pillar and is stopped when the desired diameter is achieved. Such a resistive aperture confines current only where needed, and can double the maximum conversion efficiency to almost 60 percent.

Threshold voltages less than 3 V are common in diameters ~12 μm. The oxide-defined current channel increases the efficiency, but tends to cause multiple transverse modes due to relatively strong oxide-induced index guiding. This may introduce modal noise into fiber communication systems. Single-mode requirements force the diameter to be very small (below 4 to 5 μm) or for the design to incorporate additional features, as discussed in the following section.

Transverse injection eliminates the need for the current to travel through the DBR region, but typically requires even higher voltage. This approach has been proven useful when highly conductive layers are grown just above and below the active region. Because carriers have to travel farther with transverse injection, it is important that these layers have as high mobility as possible. This has been achieved by injecting carriers from both sides through *n*-type layers. Such a structure can still inject holes into the active layer if a buried tunnel junction is provided, as shown in Fig. 29. The tunnel junction consists of a single layer-pair of very thin highly doped n^{++} and p^{++} layers and must be located near the active layer so that its holes can be utilized. After the first As-based growth step, the tunnel junction is laterally structured by means of standard photolithography and chemical dry etching. It is then regrown with phosphorous-containing *n*-layers. The lateral areas surrounding the tunnel junction contain an *npn* electronic structure and do not conduct electricity. Only within the area of the tunnel junction are electrons from the *n*-type InP spacer converted into holes.

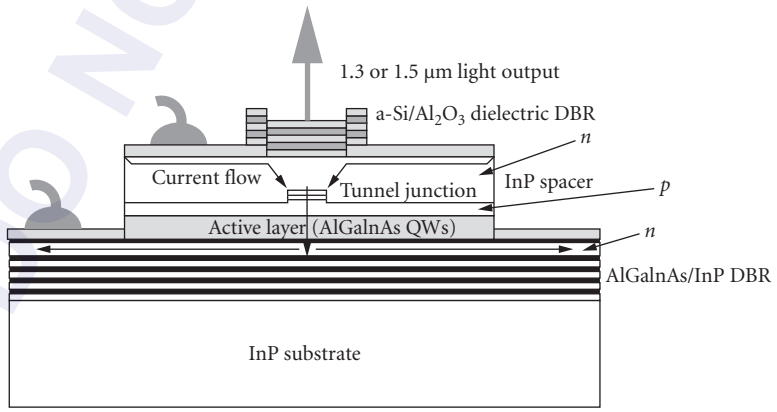

FIGURE 29 BHT geometry for single-mode VCSEL, showing flow of current. (*Adapted from Ref. 45.*)

Spatial Characteristics of Emitted Light

Single transverse mode operation remains a challenge for VCSELs, particularly at the larger diameters and higher current levels. When modulated, lateral spatial instabilities tend to set in and spatial hole burning causes transverse modes to jump. This can introduce considerable modal noise when coupling VCSEL light into fibers.

The two most common methods to control transverse modes are the same as used to control current spreading: ion implantation and an internal oxidized aperature: Ion implantation keeps the threshold relatively low, but thermal lensing coupled with weak index guiding is insufficient to prevent multilateral-mode operation due to spatial hole burning; also the implanted geometry does not provide inherent polarization discrimination. The current confining aluminum oxide aperture formed by selective oxidization acts as a spatial filter and encourages the laser to operate in low-order modes. Devices with small oxide apertures (2×2 to 4×4 μm^2) can operate in a single-mode. Devices with 3.5-μm diameters have achieved single-mode output powers on the order of 5 mW, but devices with larger apertures will rapidly operate in multiple transverse modes as the current is raised.[46]

VCSELs with small diameter are limited in the amount of power they can emit while remaining single-mode, and their efficiency falls off as the diameter becomes smaller. A variety of designs have been reported for larger-aperture VCSELs that emit single-mode. This section lists several approaches; some have become commercially available and others are presently at the research stage: (1) Ion implantation and oxide-defined spatial filters have been *combined* with some success at achieving single-mode. (2) Etched pillar mesas favor single-mode operation because they have sidewall scattering losses that are higher for higher-order modes. The requirement is that the mode selective losses must be large enough to overcome the effects of spatial hole burning.[47] (3) As with traditional lasers, an etched pillar mesa can be overgrown to create a buried heterostructure (BH), providing a real index guide that can be structured to be single-mode.[48] (4) A BH design can be combined with ion implantation and/or selectively oxidized apertures, for the greatest design flexibility. (5) Surface relief has been integrated on top of the cladding layer (before depositing a top dielectric mirror), physically structuring it so as to eliminate higher-order modes; the surface relief incorporates a quarter-wave ring structure that decreases the reflectivity for higher-order modes.[49] (6) The VCSEL can be surrounded with a second growth of *higher* refractive semiconductor material, which causes an *antiguide* that preferentially confines the lowest-order mode.[50] (7) A photonic crystal has been incorporated under the top dielectric mirror, which provides an effective graded index structure that favors maintaining a single-mode.[51]

All of these approaches can be used with current injection through the DBR mirrors, or with lateral injection, usually through an oxide aperture. A number of single-mode geometries use buried tunnel junctions (BTJ), which may be made with small enough area to create single-mode lasers without incorporating any other features.[45] Often higher powers are achieved by combining wider area BTJ along with some of the other approaches outlined above.

Light Out versus Current In

The VCSEL will, in general, have similar *L-I* performance to edge-emitting laser diodes, with some small differences. Because the acceptance angle for the mode is higher than in edge-emitting diodes, there will be more spontaneous emission, which will show up as a more graceful turn-on of light out versus voltage in. As previously mentioned, the operating voltage is 2 to 3 times that of edge-emitting lasers. Thus, Eq. (5) must be modified to take into account the operating voltage drop across the resistance R of the device. The operating power efficiency is

$$\eta_{\text{eff}} = \eta_D \frac{I_{\text{op}} - I_{\text{th}}}{I_{\text{th}}} \frac{V_g}{V_g + I_{\text{op}} R} \tag{50}$$

Small diameter single-mode VCSELs would typically have a 5-μm radius, a carrier injection efficiency of 80 to 90 percent, an internal optical absorption loss $\alpha_i L$ of 0.003, an optical scattering loss

of 0.001, and a net transmission through the front mirror of 0.005 to 0.0095. Carrier losses reducing the quantum efficiency are typically due to spontaneous emission in the wells, spontaneous emission in the barriers, Auger recombination, and carrier leakage.

Typical commercial VCSELs designed for compatibility with single-mode fiber incorporate an 8-μm proton implantation window and 10-μm-diameter window in the top contact. Such diodes may have threshold voltages of ~3 V and threshold currents of a few milliamperes. These lasers may emit up to ~2 mW maximum output power. Devices will operate in zero-order transverse spatial mode with gaussian near-field profile when operated with DC drive current less than about twice threshold. When there is more than one spatial mode, or both polarizations, there will usually be kinks in the *L-I* curve, as with multimode edge-emitting lasers.

Spectral Characteristics

Since the laser cavity is short, the longitudinal modes are much farther apart in wavelength than in a cleaved cavity laser, typically separated by 50 nm, so only one longitudinal mode will appear, and there is longitudinal mode purity. The problem is with *lateral* spatial modes, since at higher power levels the laser does not operate in a single spatial mode. Each spatial mode will have a slightly different wavelength, perhaps separated by 0.01 to 0.02 nm. Lasers that start out as single-mode and single frequency at threshold will often demonstrate frequency broadening at higher currents due to multiple modes, as shown in Fig. 30*a*.[52]

Even when the laser operates in a single spatial mode, it may have two orthogonal directions of polarization (discussed next), that will exhibit different frequencies, as shown in Fig. 30*b*.[53] Thus both single-mode and polarization stability are required to obtain a true single-mode.

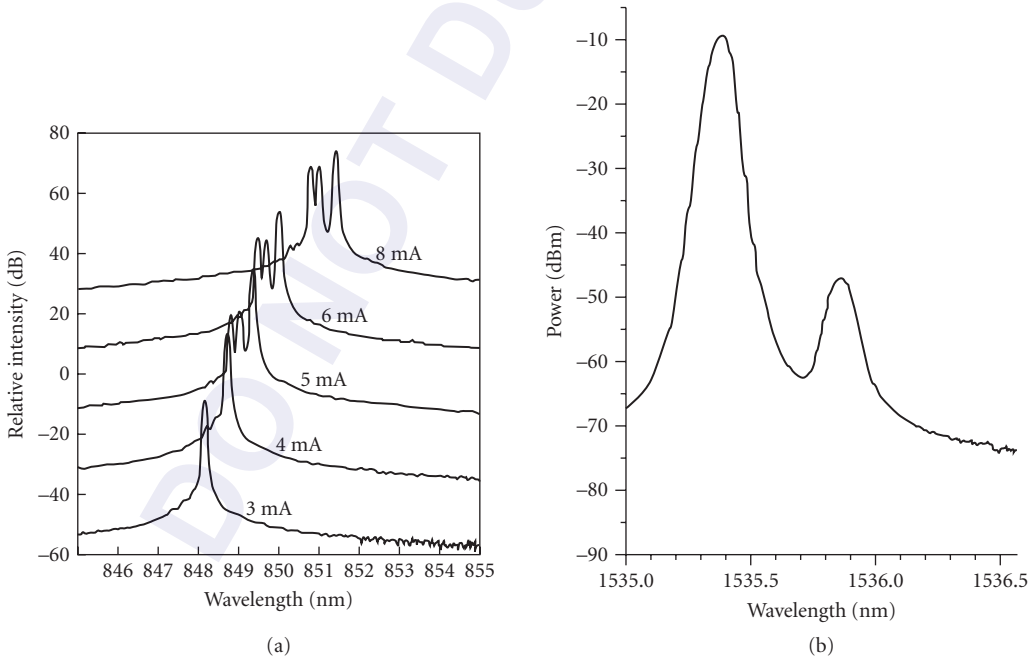

FIGURE 30 VCSEL spectra: (*a*) emission spectra recorded at different injection currents for BH-VCSELs of 10 μm diameter[52] and (*b*) different emission spectra due to different polarizations of a BJT single-mode VCSEL.[53]

When a VCSEL is modulated, lateral spatial instabilities may set in and spatial hole burning may cause transverse modes to jump. This can broaden the spectrum. In addition, external reflections can cause instabilities and increased relative intensity noise, just as in edge-emitting lasers.[54] For very short cavities, such as between the VCSEL and a butt-coupled fiber (with ~4 percent reflectivity), instabilities do not set in, but the output power can be affected by the additional mirror, which forms a Fabry-Perot cavity with the output mirror and can reduce or increase its effective reflectivity, depending on the round-trip phase difference. When the external reflection comes from ~1 cm away, bifurcations and chaos can be introduced with a feedback parameter $F > 10^{-4}$, where $F = C_e\sqrt{f_{\text{ext}}}$, with C_e and f_{ext} as defined in the discussion surrounding Eq. (31). For $R_o = 0.995$, $R_{\text{ext}} = 0.04$, the feedback parameter $F \sim 10^{-3}$, instabilities can be observed if reflections get back into the VCSEL.

Polarization

A VCSEL with a circular aperture has no preferred polarization state. The output tends to oscillate in linear but random polarization states, which may wander with time (and temperature) and may have slightly different emission wavelengths (Fig. 30*b*). Polarization-preserving VCSELs require breaking the symmetry by introducing anisotropy in the optical gain or loss. Some polarization selection may arise from an elliptical current aperture. The strongest polarization selectivity has come from growth on (311) GaAs substrates, which causes anisotropic gain.

Commercial VCSELs

The most readily available VCSELs are GaAs-based, emitting at 850-nm wavelength. Commercial specifications for these devices list typical multimode output powers from 1 to 2.4 mW and single-mode output powers from 0.5 to 2 mW, depending on design. Drive voltages vary from 1.8 to 3 V, with series resistance typically about 100 Ω. Spectral width for multimode lasers is about 0.1 nm, while for single-mode lasers it can be as narrow as 100 MHz. Beam divergence FWHM is typically 18° to 25° for multimode lasers and 8° to 12° for single-mode VCSELs, with between 20 to 30 dB sidemode suppression.[55]

Red VCSELs, emitting at 665 nm, are available from fewer suppliers, and have output powers of 1 mW, threshold currents between 0.6 and 2.5 mA, and operating voltages of 2.8 to 3.5 V. Their divergence angle is 14° to 20° and slope efficiency is 0.9 mW/mA, with sidemode suppression between 14 and 50 dB. Reported bandwidths are 3 to 3.5 GHz.[56]

Long-wavelength VCSELs have output powers between 0.7 and 1 mW, with threshold currents between 1.1 and 2.5 mA. Series resistance is 100 Ω, with operating voltage between 2 and 3 V. Single-mode spectral width is 30 MHz and modulation bandwidth is 3 GHz. Sidemode suppression is between 30 and 40 dB, with slope efficiency of 0.2 mW/mA and an angular divergence between 9° and 20°.[57]

13.11 LITHIUM NIOBATE MODULATORS

The most direct way to create a modulated optical signal for communication application is to directly modulate the current driving the laser diode. However, as discussed in Secs. 13.4 and 13.5, this may cause turn-on delay, relaxation oscillation, mode-hopping, and/or chirping of the optical wavelength. Therefore, an alternative often used is to operate the laser in a continuous manner and to place a modulator after the laser. This modulator turns the laser light off and on without impacting the laser itself. The modulator can be butt-coupled directly to the laser, located in the laser chip package and optically coupled by a microlens, or remotely attached by means of a fiber pigtail between the laser and modulator.

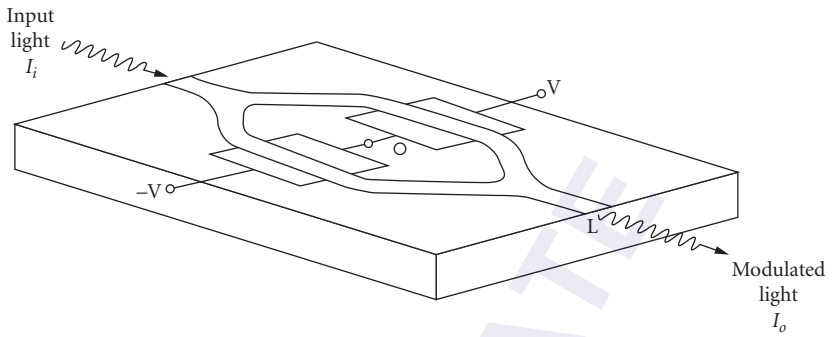

FIGURE 31 *Y*-branch interferometric modulator in the "push-pull" configuration. Center electrodes are grounded. Opposite polarity electrodes are placed on the outsides of the waveguides. Light is modulated by applying positive or negative voltage to the outer electrodes.

Lithium niobate modulators have become one of the main technologies used for high-speed modulation of continuous-wave (CW) diode lasers, particularly in applications (such as cable television) where extremely linear modulation is required, or where chirp is to be avoided at all costs. These modulators operate by the electro-optic effect, in which an applied electric field changes the refractive index. Integrated optic waveguide modulators are fabricated by diffusion into lithium niobate substrates. The end faces are polished and butt-coupled (or lens-coupled) to a single-mode fiber pigtail (or to the laser driver itself). This section describes the electro-optic effect in lithium niobate, its use as a phase modulator and an intensity modulator, considerations for high-speed operation, and the difficulties in achieving polarization independence.[58]

Most common is the *Y*-branch interferometric modulator shown in Fig. 31, discussed in a following subsection. The waveguides that are used for these modulators are fabricated in lithium niobate either by diffusing titanium into the substrate from a metallic titanium strip or by means of ion exchange. The waveguide pattern is obtained by photolithography. The standard thermal indiffusion process takes place in air at 1050°C over 10 hours. An 8-μm-wide, 50-nm thick strip of titanium creates a fiber-compatible single-mode at $\lambda = 1.3$ μm. The process introduces ~1.5 percent titanium at the surface, with a diffusion profile depth of ~4 μm. The result is a waveguide with increased extraordinary refractive index of 0.009 at the surface and an ordinary refractive index change of ~0.006. A typical modulator will incorporate aluminum electrodes 2 cm long, deposited on either side of the waveguides, with a gap of 10 μm.

In the case of ion exchange, the lithium niobate sample is immersed in a melt containing a large proton concentration (typically benzoic acid or pyrophosphoric acid at >170°C), with nonwaveguide areas protected from diffusion by masking; the lithium near the surface of the substrate is replaced by protons, which increases the refractive index. Ion-exchange alters only the extraordinary polarization; that is, only light polarized parallel to the *z* axis is waveguided. Thus, it is possible in lithium niobate to construct a polarization-independent modulator with titanium indiffusion, but not with proton-exchange. Nonetheless, ion exchange creates a much larger refractive index change (~0.12), which provides more flexibility in modulator design. Annealing after diffusion can reduce insertion loss and restore the degraded electro-optic effect. Interferometric modulators with moderate index changes ($\Delta n < 0.02$) are insensitive to aging at temperatures of 95°C or below. Using higher index change devices, or higher temperatures, may lead to some degradation with time. Tapered waveguides can be fabricated easily by ion exchange for high coupling efficiency.[59]

Electro-Optic Effect

The *electro-optic effect* is the change in refractive index that occurs in a noncentrosymmetric crystal in the presence of an applied electric field. The linear electro-optic effect is represented by a

third-rank tensor for the refractive index. However, using symmetry rules it is sufficient to define a reduced tensor r_{ij}, where $i = 1,\ldots, 6$ and $j = x, y, z$, denoted as 1, 2, 3. Then, the linear electro-optic effect is traditionally expressed as a linear change in the inverse refractive index tensor squared (see Chap. 7 in this volume):

$$\Delta\left(\frac{1}{n^2}\right)_i = \sum_j r_{ij} E_j \qquad j = x, y, z \tag{51}$$

where E_j is the component of the applied electric field in the jth direction. In isotropic materials, r_{ij} is a diagonal tensor. An applied electric field can introduce off-diagonal terms in r_{ij}, as well as change the lengths of the principle dielectric axes. The general case is treated in Chap. 13, Vol. II. In lithium niobate ($LiNbO_3$), the material of choice for electro-optic modulators, the equations are simplified because the only nonzero components and their magnitudes are[60]

$$r_{33} = 31 \times 10^{-12}\ \text{m/V} \qquad r_{13} = r_{23} = 8.6 \times 10^{-12}\ \text{m/V}$$

$$r_{51} = r_{42} = 28 \times 10^{-12}\ \text{m/V} \qquad r_{22} = -r_{12} = -r_{61} = 3.4 \times 10^{-12}\ \text{m/V}$$

The crystal orientation is usually chosen so as to obtain the largest electro-optic effect. This means that if the applied electric field is along z, then light polarized along z sees the largest field-induced change in refractive index. Since $\Delta(1/n^2)_3 = \Delta(1/n_z)^2 = r_{33}E_z$, performing the difference gives

$$\Delta n_z = -\frac{n_z^3}{2} r_{33} E_z \Gamma \tag{52}$$

A *filling factor* Γ (also called an *optical-electrical field overlap parameter*) has been included due to the fact that the applied field may not be uniform as it overlaps the waveguide, resulting in an effective field that is somewhat less than 100 percent of the maximum field.

In the general case for the applied electric field along z, the tensor remains diagonal and $\Delta(1/n^2)_1 = r_{13}E_z = \Delta(1/n^2)_2 = r_{23}E_z$, and $\Delta(1/n^2)_3 = r_{33}E_z$. This means that the index ellipsoid has not rotated, its axes have merely changed in length. Light polarized along any of these axes will see a pure phase modulation. Because r_{33} is largest, polarizing the light along z and providing the applied field along z will provide the largest phase modulation for a given field. Light polarized along either x or y will have the same index change, which might be a better direction if polarization-independent modulation is desired. However, this would require light to enter along z, which is the direction in which the field is applied, so it is not practical.

As another example, consider the applied electric field along y. In this case the nonzero terms are

$$\Delta\left(\frac{1}{n^2}\right)_1 = r_{12}E_y \qquad \Delta\left(\frac{1}{n^2}\right)_2 = r_{22}E_y = -r_{12}E_y \qquad \Delta\left(\frac{1}{n^2}\right)_4 = r_{42}E_y \tag{53}$$

There is now a yz cross-term, coming from r_{42}. Diagonalization of the perturbed tensor finds new principal axes, only slightly rotated about the z axis. Therefore, the principal refractive index changes are essentially along the x and y axes, with the same values as $\Delta(1/n^2)_1$ and $\Delta(1/n^2)_2$ in Eq. (53). If light enters along the z axis without a field applied, both polarizations (x and y) see an ordinary refractive index. With a field applied, both polarizations experience the same phase change (but opposite sign). In a later section titled "Polarization Independence," we describe an interferometric modulator that does not depend on the sign of the phase change. This modulator is polarization independent, using this crystal and applied-field orientation, at the expense of operating at somewhat higher voltages, because $r_{22} < r_{33}$.

Since lithium niobate is an insulator, the direction of the applied field in the material depends on how the electrodes are applied. Figure 32 shows a simple phase modulator. Electrodes that straddle the modulator provide an in-plane field as the field lines intersect the waveguide, as shown in Fig. 32*b*.

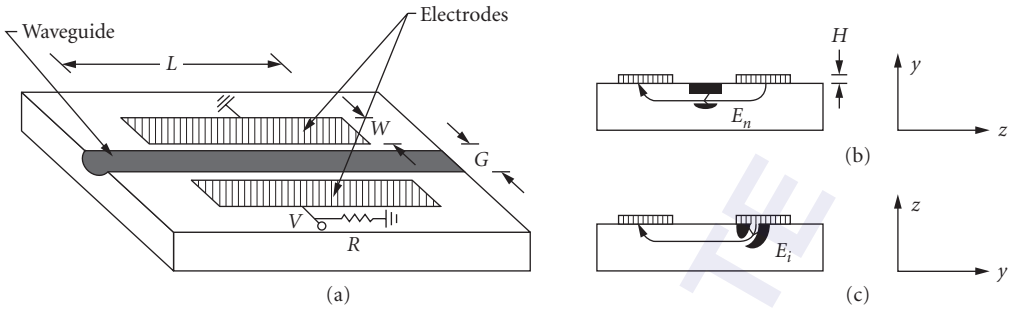

FIGURE 32 (*a*) Geometry for phase modulation in lithium niobate with electrodes straddling the channel waveguide. (*b*) End view of (*a*), showing how the field in the channel is parallel to the surface. (*c*) End view of a geometry placing one electrode over the channel, showing how the field in the channel is essentially normal to the surface.

This requires the modulator to be *y-cut* $LiNbO_3$ (the *y* axis is normal to the wafer plane), with the field lines along the *z* direction; *x-cut* $LiNbO_3$ will perform similarly. Figure 32*c* shows a modulator in *z-cut* $LiNbO_3$. In this case, the electrode is placed over the waveguide, with the electric field extending downward through the waveguide (along the *z* direction). The field lines will come up at a second, more distant electrode. In either case, the field may be fringing and nonuniform, which is why the filling factor Γ has been introduced.

Phase Modulation

Applying a field to one of the geometries shown in Fig. 32 results in pure *phase modulation*. The field is roughly *V/G*, where *G* is the gap between the two electrodes. For an electrode length *L*, the phase shift is

$$\Delta\phi = \Delta n_z kL = -\frac{n_o^3}{2} r_{33}\left(\frac{V}{G}\right)\Gamma\, kL \tag{54}$$

The refractive index for bulk $LiNbO_3$ is given by[61]

$$n_o = 2.195 + \frac{0.037}{[\lambda\,(\mu\text{m})]^2} \qquad \text{and} \qquad n_e = 2.122 + \frac{0.031}{[\lambda\,(\mu\text{m})]^2}$$

Inserting numbers for $\lambda = 1.55$ μm gives $n_o = 2.21$. When $G = 10$ μm and $V = 5$ V, a π phase shift is expected in a length $L \sim 1$ cm.

It can be seen from Eq. (54) that the electro-optic phase shift depends on the product of the length and voltage. Longer modulators can use smaller voltages to achieve a π phase shift. Shorter modulators require higher voltages. Thus, the figure of merit for phase modulators is typically the product of the voltage required to reach π times the length. The modulator just discussed has a 5-V· cm figure of merit.

The electro-optic phase shift has a few direct uses, such as providing a *frequency shifter* (since $\partial\phi/\partial t \propto \Delta v$). However, in communication systems this phase shift is generally used in an interferometric configuration to provide intensity modulation, discussed in the following section.

Y-Branch Interferometric (Mach-Zehnder) Modulator

The *interferometric modulator* is shown schematically in Fig. 31. This geometry allows waveguided light from the two branches to interfere, forming the basis of an intensity modulator. The amount of

interference is tunable by providing a relative phase shift on one arm with respect to the other. Light entering a single-mode waveguide is equally divided into the two branches at the *Y* junction, initially with zero relative phase difference. The guided light then enters the two arms of the waveguide interferometer, which are sufficiently separated that there is no coupling between them. If no voltage is applied to the electrodes, and the arms are exactly the same length, the two guided beams arrive at the second *Y* junction in phase and enter the output single-mode waveguide in phase. Except for small radiation losses, the output is equal in intensity to the input. However, if a π phase difference is introduced between the two beams via the electro-optic effect, the combined beam has a lateral amplitude profile of odd spatial symmetry. This is a second-order mode and is not supported in a single-mode waveguide. The light is thus forced to radiate into the substrate and is lost. In this way, the device operates as an electrically driven optical intensity on-off modulator. Assuming perfectly equal splitting and combining, the fraction of light transmitted is

$$\eta = \left[\cos\left(\frac{\Delta\phi}{2}\right)\right]^2 \tag{55}$$

where $\Delta\phi$ is the difference in phase experienced by the light in the different arms of the interferometer: $\Delta\phi = \Delta nkL$, where $k = 2\pi/\lambda$, Δn is the difference in refractive index between the two arms, and L is the path length of the field-induced refractive index difference. The voltage at which the transmission goes to zero ($\Delta\phi = \pi$) is usually called V_π. By operating in a push-pull manner, with the index change increasing in one arm and decreasing in the other, the index difference Δn is twice the index change in either arm. This halves the required voltage.

Note that the transmitted light is periodic in phase difference (and therefore voltage). The response depends only on the integrated phase shift and not on the details of its spatial evolution. Therefore, nonuniformities in the electro-optically induced index change that may occur along the interferometer arms do not affect the extinction ratio. This property has made the Mach Zehnder (MZ) modulator the device of choice in communication applications.

For analog applications, where linear modulation is required, the modulator is prebiased to the quarter-wave point (at voltage $V_b = \pi/2$), and the transmission efficiency becomes linear in $V - V_b$ (for moderate excursions):

$$\eta = \frac{1}{2}\left[1 + \sin\frac{\pi(V - V_b)}{2V_\pi}\right] \approx \frac{1}{2} + \frac{\pi}{2}\frac{(V - V_b)}{V_\pi} \tag{56}$$

The electro-optic effect depends on the polarization. For the electrode configuration shown here, the applied field is in the plane of the lithium niobate wafer, and the polarization of the light to be modulated must also be in that plane. This will be the case if a TE-polarized laser diode is butt-coupled (or lens-coupled) with the plane of its active region parallel to the plane of the lithium niobate wafer, and if the wafer is *Y*-cut. Polarization-independent modulation requires a different orientation, to be described later. First, however, we discuss the electrode requirements for high-speed modulation.

High-Speed Operation

The optimal electrode design depends on how the modulator is to be driven. Because the electrode is on the order of 1 cm long, the fastest devices require traveling-wave electrodes rather than lumped electrodes. Lower-speed modulators can use lumped electrodes, in which the modulator is driven as a capacitor terminated in a parallel resistor matched to the impedance of the source line. The modulation speed depends primarily on the *RC* time constant determined by the electrode capacitance and the terminating resistance. To a smaller extent, the speed also depends on the resistivity of the electrode itself. The capacitance per unit length is a critical design parameter. This depends on the material dielectric constant, the electrode gap G and the electrode width W. With

increasing *G,* the capacitance per unit length decreases and the bandwidth-length product increases essentially logarithmically. In $LiNbO_3$, when the electrode widths and gap are equal, the capacitance per unit length is 2.3 pF/cm and the bandwidth-length product is $\Delta f_{RC}L = 2.5$ GHz · cm. The trade-off is between large *G/W* to reduce capacitance and small *G/W* to reduce drive voltage and electrode resistance. The ultimate speed of lumped electrode devices is limited by the electric signal transit time, with a bandwidth-length product of 2.2 GHz · cm. The way to achieve higher speed modulation is to use traveling-wave electrodes.

The traveling-wave electrode is a miniature transmission line. Ideally, the impedance of this coplanar line is matched to the electrical drive line and is terminated in its characteristic impedance. In this case, the modulator bandwidth is determined by the difference in velocity between the optical and electrical signals (velocity mismatch or walk-off), and any electrical propagation loss. Because of competing requirements between a small gap to reduce drive voltage and a wide electrode width to reduce RF losses, as well as reflections at any impedance transition, subtle trade-offs must be considered in designing traveling-wave devices.

Lithium niobate MZ modulators operating out to 35 GHz at $\lambda = 1.55$ μm are commercially available, with $V_\pi = 10$ V, with <5 dB insertion loss and >20 dB extinction ratio.[62] To operate near quadrature, which is the linear modulation point, a bias voltage of ~4 V is required. Direct coupling from a laser or polarization-maintaining fiber is required, since these modulators operate on only one polarization.

Insertion Loss

Modulator insertion loss can be due to Fresnel reflection at the lithium niobate-air interfaces, which can be reduced by antireflection coatings or index matching (which only helps, but does not eliminate this loss, because of the very high refractive index of lithium niobate). The other cause of insertion loss is mode mismatch. To match the spatial profile of the fiber mode, a deep and buried waveguide must be diffused. Typically, the waveguide will be 9 μm wide and 5 μm deep. While the in-plane mode can be gaussian and can match well to the fiber mode, the out-of-plane mode is asymmetric, and its depth must be carefully optimized. In an optimized modulator, the coupling loss per face is about 0.35 dB and the propagation loss is about 0.3 dB/cm. This result includes a residual index-matched Fresnel loss of 0.12 dB.

Misalignment can also cause insertion loss. An offset of 2 μm typically increases the coupling loss by 0.25 dB. The angular misalignment must be maintained below 0.5° in order to keep the excess loss below 0.25 dB.[63]

Propagation loss comes about from absorption, metallic overlay, scattering from the volume or surface, bend loss, and excess loss in the *Y*-branches. Absorption loss at 1.3 and 1.55 μm wavelengths appears to be <0.1 dB/cm. Bend loss can be large, unless any curvature of guides is small. The attenuation coefficient in a bend has the form $\alpha = C_1 \exp(-C_2 R)$, where $C_1 = 15$ mm^{-1} and $C_2 = 0.4$ mm^{-1} in titanium indiffused lithium niobate, at wavelengths around 1.3 to 1.5 μm. This means that a 5-mm-long section of constant radius 20 mm will introduce only 0.1 dB of excess loss.[63]

A final source of loss in *Y*-branches is excess radiation introduced by sharp transitions at the *Y* junction.These junctions must be fabricated carefully to avoid such losses, since tolerances on waveguide roughness are critically small.

Polarization Independence

As previously shown, if the light is incident along the *z* axis and the field is along the *y* axis, then light polarized along *x* and *y* experience the same phase shift, but with opposite signs. This requires an *x*-cut crystal, with an in-plane field along *y*, which provides polarization-independent interferometric modulation at the sacrifice of somewhat higher half-wave voltage (e.g., 17 V).[64] Because of the difficulty of achieving exactly reproducible lengths in the two arms of the *Y*-branch interferometer, it was found useful to do a postfabrication phase correction using laser ablation.

Photorefractivity and Optical Damage

Lithium niobate exhibits *photorefractivity*, also called *optical damage*, when it is a nuisance. This phenomenon is a change in refractive index as a result of photoconduction originating in weak absorption by deep traps and a subsequent redistribution of charges within the lithium niobate. Because the photoconductive crystal is electro-optic, the change in electric field resulting from charge motion shows up as a change in refractive index, altering the phase shift as well as the waveguiding properties. While photorefractivity seriously limits the performance of lithium niobate modulators at shorter wavelengths (even at 850 nm),[65] it is not a serious concern at 1.3 μm and 1.55 μm.

However, partial screening by photocarriers may cause a drift in the required bias voltage of modulators, and systems designers may need to be sensitive to this.

Multimode Interferometric Mach-Zehnder Modulator

An alternative geometry has been developed for the waveguide Mach-Zehnder interferometer that replaces the *Y* branch by a multimode interferometric (MMI) power splitter, which is shown in Fig. 33. The MMI modulator works on the principle that there are distances at which light traveling down a step-index waveguide self-images. These self-imaging planes are analogous to Talbot planes for plane waves. The process of self-imaging is indicated in Fig. 33*a*.[66] It can be seen that if light is incident in a spatial distribution localized to only one-half of the guide, at a distance of 1/2 ($3L_\pi$) the power will be split equally into two spatial distributions. This enables a simple power splitter, as shown in Fig 33*b*.[66]

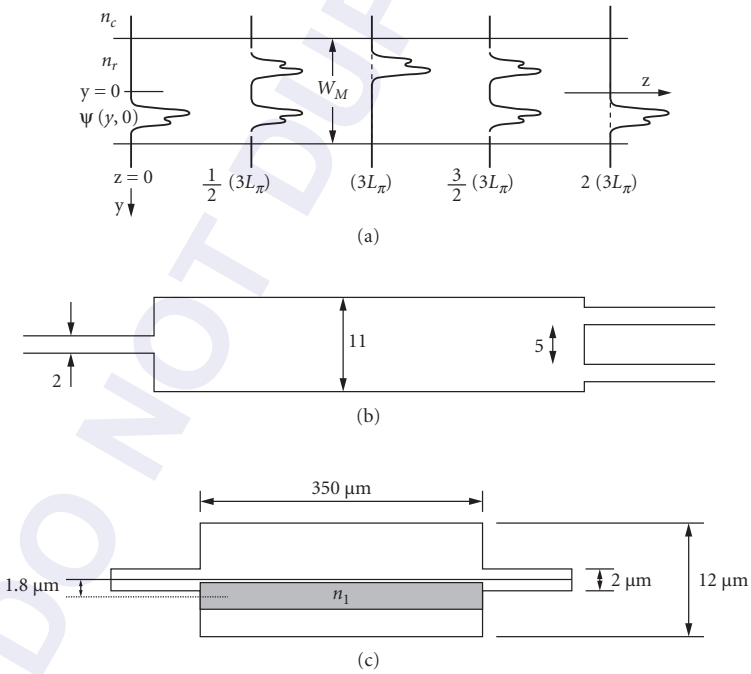

FIGURE 33 Multimode interferometric (MMI) devices as observed from above: (*a*) multimode waveguide showing the input field $\Psi(y,0)$, a mirrored single image at ($3L_\pi$), a direct single image at $2(3L_\pi)$, and two-fold images at 1/2 ($3L_\pi$) and 3/2 ($3L_\pi$);[66] (*b*) power splitter, achieved at 1/2 ($3L_\pi$) with typical dimensions as shown in micrometers;[66] and (*c*) interference modulator, achieved at ($3L_\pi$), with voltage applied by the darkened electrode; ground plane is under the substrate.[67]

In a step-index multimode guide, because the modes are equally spaced, the beat length L_π is given by

$$L_\pi = \pi/(\beta_o - \beta_1) \approx 4n_{co}W_e^2/3\lambda_o \tag{57}$$

where W_e is the effective width of the guide, including Goos-Hanschen shifts. For $W_e = 11$ μm, this gives $L_\pi \sim 0.5$ mm in semiconductors, so a power splitter could be less than a millimeter long.

Ultracompact modulators can be constructed by the method shown in Fig. 33*c*,[67] with an electrode applied to only part of the structure, which will nonuniformly change the phases and destroy the coherent mixing that self-images the light to the output waveguide. Different electrode structures and electro-optic media have been demonstrated, including prism electrodes in electro-optic polymers.[68]

Electro-Optic Polymer Modulators

For a number of years researchers have been working to make polymer modulators a reality. Electro-optic polymers contain nonlinear chromophores capable of providing large electro-optic effects at transmission wavelengths of 1.3 and 1.55 μm, with electro-optic coefficients of ~70 pm/V, with the potential of ~100 pm/V, which is 3 to 4 times greater than of lithium niobate. The technology typically involves spin coating of the polymer onto a silicon substrate, poling it, and applying electrodes. Electro-optic polymers are compatible with semiconductor fabrication methods and have low dielectric constants, so they can be easily velocity matched when applying traveling-wave electrodes for high-speed switching.

However, electro-optic polymers have had serious reliability issues. Gradual relaxation of the electro-optic coefficient is due to the slow misalignment of the chromophores, which form antiparallel pairs and effectively cancel out the electro-optic effect. This problem has been largely resolved using chemical anchoring schemes and/or poling in inert environments. There continues to be a problem with gradual changes in refractive index; however, some device designs are relatively robust to refractive index changes. The MMI is proposed to be such a structure, with simple design tolerance toward fluctuation of refractive indices.

For these modulators, highly active chromophores are dispersed at high concentrations in host polymers. A traditional commercially available chromophore is Disperse Red 1 (DR1), while much higher activity chromophores have been researched and are rapidly becoming commercially available. The polymer host is amorphous polycarbonate or polysulfone. The chromophore-doped polymer is dissolved in cyclohexanone (CHN) and tetrahydrofuran and then spin coated on the substrate. Cladding is typically spun on using commercially available acrylate. Relief structures, such as ridge waveguides, are plasma-etched into the films. After electrodes are deposited, the chromophore-doped polymer is made electro-optic by poling. In this process the sample is heated (e.g., at 130°C for 15 min) with a constant voltage applied (e.g., 600 V) between the bottom and the top electrodes. The temperature is dropped back to room temperature with the electric field still applied to ensure that the chromophores are oriented to achieve noncentrosymetric alignment.[69]

13.12 ELECTROABSORPTION MODULATORS

Semiconductors exhibit field-dependent absorption and refractive index. Such modulators can be integrated directly on the same chip as the laser, or placed external to the laser chip. External modulators may be butt-coupled to the laser, coupled by means of a microlens or by means of a fiber pigtail.

Electroabsorption

The electric field dependence of the absorption near the band edge of a semiconductor is called *electroabsorption*, and is particularly strong in quantum wells, where it is often called the *quantum-confined*

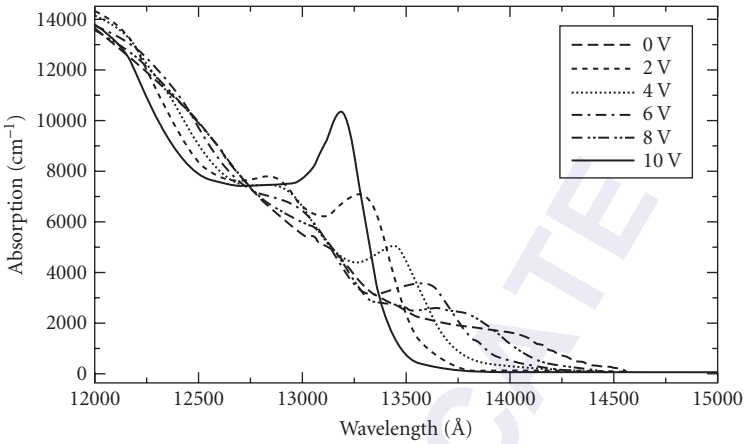

FIGURE 34 Spectrum of quantum-confined Stark effect (QCSE) in InAsP/InP-strained MQWs. The absorption changes with applied field.[70]

Stark Effect (QCSE) An example of the wavelength dependence of the QCSE is shown in Fig. 34. The absorption spectrum of QWs exhibits a peak at the *exciton resonance*: when a field is applied, the exciton resonance moves to longer wavelengths, becomes weaker, and broadens. This means that on the long-wavelength side, the absorption increases with field, as the exciton resonance moves to longer wavelengths. At wavelengths closer to the exciton resonance, the absorption will first increase with field, then plateau, and finally decrease, as the field continues to grow. At wavelengths shorter than the zero-field exciton resonance, the absorption will decrease with increasing field, as the resonance moves to longer wavelengths.

While electroabsorption in QWs is much larger than in bulk, due to the sharpness of the excitonic-enhanced absorption edge, the useful absorption change must be multiplied by the filling factor of the QW in the waveguide, which reduces its effective magnitude. Under some conditions, electroabsorption near the band edge in bulk semiconductors (typically called the *Franz-Keldysh effect*) may also be useful in electroabsorption modulators.

Waveguide Modulators

When light traverses a length of QW material, the transmission will be a function of applied voltage. An electroabsorption modulator consists of a length of waveguide containing QWs. The waveguide is necessary to confine the light to the QW region so that it does not diffract away. Thus, low-refractive-index layers must surround the layer containing the QWs. Discrete electroabsorption modulators are typically made by using geometries similar to those of edge-emitting lasers (Fig. 1), but without mirrors. They are cleaved, antireflection coated, and then butt-coupled to the laser chip. They are operated by a reverse bias, rather than the forward bias of a laser. Or the modulator can be integrated on the laser chip, with the electroabsorption modulation region following a DFB or DBR laser in the optical train, as shown in Fig. 35. This figure shows the simplest electroabsorption modulator, with the same MQW composition as the DFB laser. This ridge waveguide device has been demonstrated with a 3-dB bandwidth of 30 GHz. The on-off contrast ratio is 12.5 dB for a 3-V drive voltage in a 90-μm-long modulator.[71] The use of the same QWs is possible by setting the grating that determines the laser wavelength to well below the exciton resonance. Because of the inherently wide-gain spectrum exhibited by strained layer MQWs, this detuning is possible for the laser and still allows it to operate in the optimal wavelength region for the electroabsorption modulator.

Other integrated electroabsorption modulators use a QW composition in the electroabsorption region that is different from that of the laser medium. Techniques for integration are discussed later.

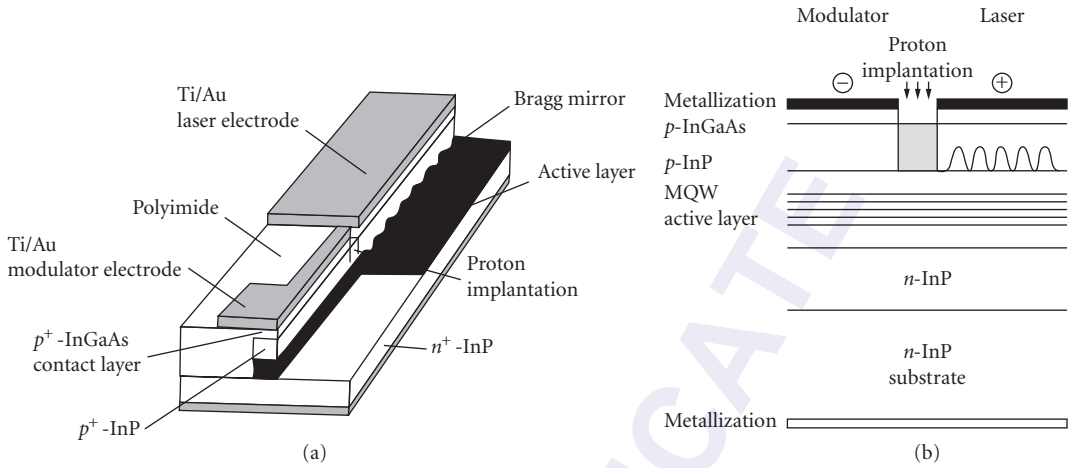

FIGURE 35 Electroabsorption modulator: (*a*) geometry for a channel electroabsorption modulator (foreground) integrated on the same chip with a DFB laser (background, under the Bragg mirror) and (*b*) side view, showing how the same MQW active layer can be used under forward bias with a grating to provide a DFB laser, and in a separate region under reverse bias for modulation, with the two regions electrically separated by proton implantation.[50]

Intensity Modulation by Electroabsorption

In an electroabsorption waveguide modulator of length L, where the absorption is a function of applied field E, the transmission is a function of field: $T(E) = \exp[-\alpha(E)L]$, where α is the absorption per unit length, averaging the QW absorption over the entire waveguide. (That is, α is the QW absorption multiplied by the filling factor of the QW in the waveguide.) Performance is usually characterized by two quantities: *insertion loss* (throughput at high transmission) and *contrast ratio* (ratio of high transmission to low transmission). Assume that the loss in the QW, initially at low value $\alpha\_$, increases by $\delta\alpha$. The *contrast ratio* is given by: $\text{CR} \equiv T_{\text{high}}/T_{\text{low}} = \exp(\delta\alpha L)$. The *insertion loss* is given by $A \equiv 1 - T_{\text{high}} = 1 - \exp(-\alpha\_ L) \approx \alpha\_ L$. A long path length L means a high contrast ratio but also a large insertion loss and large capacitance, which results in a slower speed. Choosing the most practical length for any given application requires trading off the contrast ratio against insertion loss and speed.

To keep a moderate insertion loss, waveguide lengths should be chosen so that $L \approx 1/\alpha\_$, which sets the contrast ratio as $\text{CR} = \exp(\delta\alpha/\alpha\_)$. The contrast ratio depends on the ratio of the change in absorption to the absorption in the low-loss state; this fact is used to design the QW composition and dimensions relative to the wavelength of operation. In general, the contrast ratio improves farther from the band edge, but the maximum absorption is smaller there, so the modulator must be longer, which increases its capacitance, decreases its speed, and increases its loss. Contrast ratios may reach 10/1 or more with <2 V applied for optimized electroabsorption modulators. In a waveguide, the contrast ratio does not depend on the filling factor of the QW in the waveguide, but the required length L does. Since high-speed modulators require small capacitance and small length, the filling factor should be as high as possible.

Waveguide modulators are used at wavelengths where the absorption is not too large, well below the band edge. In this wavelength region, electroabsorption at a fixed wavelength can be modeled by a pure quadratic dependence on field. Thus $\alpha(E) \approx \alpha_o + \alpha_2 E^2$, where α_2 will typically depend on the wavelength, the QW and barrier dimensions and composition, and the waveguide filling factor. Intimately connected with this change in absorption is a change in refractive index with a similar field dependence: $\delta n(E) \approx n_2 E^2$, where n_2 is also strongly dependent on wavelength. Both electroabsorption and electrorefraction are about an order of magnitude larger in QWs than in bulk material. Specific

numerical values depend on the detailed design, but typical values are on the order of $\alpha_o \sim 100\ \text{cm}^{-1}$, $\delta\alpha \sim 1000\ \text{cm}^{-1}$, $L \sim 200\ \mu\text{m}$ for 2 V applied across an *i* region 2.5-μm thick, for a field of ~10 kV/cm. This means $\alpha_2 \sim 2 \times 10^{-5}\ \text{cm/V}^2$. Also, $n_2 \sim 2 \times 10^{-11}\ \text{V}^{-2}$.

Applying a Field in a Semiconductor

The electric field is usually applied by reverse biasing a *pin* junction. The electric field is supported by the semiconductor depletion region that exists within a *pin* junction, or at a metal-semiconductor junction (Schottky barrier). Charge carrier depletion in the *n* and *p* regions may play a role in determining the electric field across thin intrinsic regions. Taking this into account while assuming an undoped *i* region, the electric field across the *i* region of an ideally abrupt *pin* junction, when the undoped layer d_i is sufficiently large, can be expressed as[72]

$$E = \frac{V_{\text{tot}}}{d_i}\left[1 - \frac{\varepsilon V_{\text{tot}}(1 + N_d/N_a)}{2eN_d d_i^2}\right] \tag{58}$$

where N_d is the (donor) doping density in the *n* region, N_a is the (acceptor) doping density in the *p* region, e is the elementary charge, ε is the dielectric constant, d_i is the thickness of the intrinsic region, and V_{tot} is the sum of the applied and built-in field (defined positive for reverse bias). This assumes the *n* and *p* regions are highly doped and the *i* region is undoped, so that most of the voltage is dropped across the *i* region. To lowest order, this is just the field across a capacitor of thickness d_i. For a typical applied voltage of 5 V and $d_i = 0.25\ \mu\text{m}$, with $N_a = 10^{18}\ \text{cm}^{-3}$ and $N_d = 10^{18}\ \text{cm}^{-3}$, $E = 2 \times 10^5\ \text{V/cm}$. How much this will change the absorption and refractive index depends on wavelength and, of course, material design.

Operating Characteristics

In addition to contrast ratio, insertion loss, and required voltage, performance of electroabsorption modulators depends on speed, chirp, polarization dependence, optical power-handling capabilities, and linearity. These factors all depend on the wavelength of operation, the materials, the presence of strain, the QW and waveguide geometry, and the device design. Extensive trade-offs must be made to achieve the best possible operation for a given application. Modulators will differ, depending on the laser and the proposed applications.

Chirp Because a change in refractive index usually occurs during any absorption change $\delta\alpha$, electroabsorption modulators, in general, exhibit *chirp* (frequency broadening due to the time-varying refractive index, also observed in modulated lasers), which can seriously limit their usefulness. As with semiconductor lasers, the figure of merit is $\beta = k_o \delta n/\delta\alpha$. Unlike lasers, however, there are particular wavelengths of sizable absorption change at which $\delta n = 0$. Studies have shown that these nulls in index change can be positioned where $\delta\alpha$ is large by using coupled quantum wells (CQWs).[74] These structures provide two, three, or more wells so closely spaced that the electron wave functions overlap between them. If desired, several sets of these CQWs may be used in a single waveguide, if they are separated by large enough barriers that they do not interact. Chirp-free design is an important aspect of electroabsorption modulators.

On the other hand, since the chirp can be controlled in electroabsorption modulators, there are conditions under which it is advantageous to provide a negative chirp to cancel out the positive chirp introduced by fibers. This allows 1.55-μm laser pulses to travel down normally dispersive fiber (with zero material dispersion at 1.3 μm) without the pulses unduly spreading.

Polarization Dependence In general, the QCSE is strongly polarization dependent, although there may be specific wavelengths at which TE and TM polarized light experience the same values of

electroabsorption (and/or electrorefraction). It turns out that polarization-independent modulation is more readily achieved by using strained QWs. In addition, the contrast ratio of electroabsorption change at long wavelengths can be improved by using strained QWs.

Optical Power Dependence During the process of electroabsorption, the modulators can absorb some of the incident light, creating electron-hole pairs. If these pairs remain in the QWs, at high optical powers they will introduce a free carrier plasma field that can screen the exciton resonance. This broadens the absorption spectrum and reduces the contrast ratio. In some cases, electroabsorption modulators operating at the band edge of bulk semiconductors (the *Franz-Keldysh effect*) may be able to operate with higher laser power. A common approach is to use shallow QWs, so that the electrons and holes may escape easily.

Even when the electron-hole pairs created by absorption escape the QWs, they will move across the junction to screen the applied field. This will tend to reduce the applied field, so the performance will depend on the magnitude of absorbed light. Photogenerated carriers must also be removed, or they will slow down the modulator's response time. Carriers may be removed by leakage currents in the electrodes or by recombination.

Built-in Bias Because *pin* junctions have built-in fields, even at zero applied voltage, electroabsorption modulators have a prebias. Some applications use a small forward bias to achieve even larger modulation depths. However, the large forward current resulting from the forward bias limits the usefulness of this approach. There are, at present, some research approaches to remove the internal fields using an internal strain-induced piezoelectric effect to offset the *pn* junction intrinsic field.

Commercial Discrete Electroabsorption Modulators Discrete electroabsorption modulators can be fast: 30 GHz or more. They can be designed either for low chirp (α can be < 0.5), or low polarization-dependent loss (< 0.5), but not both. Typically they may operate with voltages from −4 to +1 V with 20-dB extinction ratio.[75] They are limited in optical power to 20 mW and require temperature-stabilization with a thermoelectric cooler. Their greatest disadvantage, however, is their large insertion loss (typically 7.5 to 10 dB), because mode profiles from single-mode fibers do not match the electroabsorptive semiconductor waveguides.

One approach to reduce the insertion loss is to use the electroabsorption modulator in reflection (R-EAM). Devices have been reported with 4.5 dB typical insertion loss and 0.5 dB polarization dependent loss. These devices have 11 dB modulation depth with a voltage range from 0 to -3 V, and 14 GHz bandwidth. Other devices operate at 35 GHz with a 1 dB polarization dependent loss and 10 dB contrast ratio.[76]

Integrating the Modulator
